PAPERS

Percentile Performance Criteria For Limiting Average Markov Decision Processes	<i>J. A. Eilar, D. Krass, and K. W. Ross</i>	2
Design and Analysis of Fuzzy Identifiers of Nonlinear Dynamic Systems	<i>J. A. Wang</i>	11
Stochastic Approximation with Averaging and Feedback: Rapidly Convergent On-Line Algorithms	<i>H. T. Kushner and J. Yang</i>	24
Exponential Stabilization of Nonholonomic Chained Systems	<i>O. J. Sordalen and O. Egeland</i>	35
Global Total Least Squares Modeling of Multivariable Time Series	<i>B. Roorda and C. Heij</i>	50
Control of Chained Systems: Application to Path Following and Time Varying Point Stabilization of Mobile Robots	<i>C. Samson</i>	64

TECHNICAL NOTES AND CORRESPONDENCE

Input-Output Robust Tracking Control Design for Flexible Joint Robots	<i>Z. Qu</i>	78
The Use of Symbolic Computation in Nonlinear Control: Is It Viable?	<i>B. de laet</i>	84
Note on Decentralized Adaptive Controller Design	<i>J. Lyou</i>	89
Characterization of Zeros in Two-Frequency Scale Systems	<i>H. M. Oloomi and M. F. Sawan</i>	92
Semi-Global Stabilizability of Linear Null Controllable Systems with Input Nonlinearities	<i>A. R. Tecl</i>	96
Stability and Exponential Stability of an Adaptive Control Scheme for Plants of any Relative Degree	<i>G. Bartolini, A. Ferrara, and A. A. Stotsky</i>	100
Preservation of Reachability and Observability under Sampling with a First Order Hold	<i>T. Hagiwara</i>	104
On Robust Asymptotic Tracking: Perturbations on Coprime Factors and Parameterization of All Solutions	<i>G. O. Cornea and M. A. da Silva</i>	107
A Version of Hautus' Test for Tandem Connection of Linear Systems	<i>A. Bacciotti and G. Beccati</i>	111
Poisson LQR Design for Asynchronous Multirate Controllers	<i>R. P. Tecland</i>	115
On Solving Diophantine Equations by Real Matrix Manipulation	<i>M. Yamada, P. C. Zuo, and Y. Funahashi</i>	118
Nonlinear Versus Linear Control in the Absolute Stabilizability of Uncertain Systems with Structured Uncertainty	<i>A. A. Savkin and I. R. Petersen</i>	122

(Continued on back cover)

The Control Systems Society is an organization within the framework of the IEEE of members with professional interest in automatic control. All members of the IEEE are eligible for membership in the Society and will receive the TRANSACTIONS upon payment of the annual Society membership fee of \$15.00. For further information write to the address below. Member copies of Transactions/Journals are for personal use only.

INFORMATION FOR AUTHORS

In the IEEE TRANSACTIONS ON AUTOMATIC CONTROL the IEEE Control Systems Society publishes high-quality papers on the theory, design, and application of control systems. The TRANSACTIONS is published monthly.

Two types of contributions are regularly considered:

- 1) *Papers*—Presentation of significant research, development, or application of control concepts.
- 2) *Technical Notes and Correspondence*—Brief technical notes, comments on published areas or established control topics, corrections to papers and notes published in the TRANSACTIONS.

In addition, special papers (tutorials, surveys, and perspectives on the theory and applications of control systems topics) are solicited. Authors are urged to contact one of the Associate Editors at Large before submitting such papers.

Submission of a manuscript signifies that it has been neither copyrighted, published, nor submitted or accepted for publication elsewhere.

Submitted manuscripts must be typewritten in English. All submitted manuscripts should be as concise as possible. Technical Notes and Correspondence are normally limited to 12 double-spaced, typed pages. Papers of length exceeding 40 double-spaced, typed pages are strongly discouraged. The Editor reserves the right to refuse to consider such papers.

A. Process for Submission of Manuscript

- 1) *Papers*—Send seven copies of the paper together with two copies of a transmittal letter enclosed in one package to the Editor in Chief. These will be subject to a full review procedure, and a decision on whether or not to accept the paper will be made by members of the Transactions Editorial Board.
- 2) *Technical Notes and Correspondence*—Technical Notes and Correspondence should be sent to the Editor for Technical Notes and Correspondence; five copies are required. Decisions are made on the basis of a simplified review procedure.
- 3) Original illustrations should not be sent until requested, but authors should be ready to submit these immediately upon acceptance for publication.
- 4) Authors of accepted Papers are requested to supply their biographies (100 words or less) and photographs. For style, see biographies in this issue.
- 5) Enclose two copies of your letter of transmittal. Do not send letters of transmittal under separate cover. Give your preferred address for correspondence. Inform the Editor in Chief or Editor for Technical Notes and Correspondence of any change of address.
- 6) Authors of accepted manuscripts will be required to provide the final version of their manuscript on a computer diskette along with the hard copy.

B. Copyright

It is the policy of the IEEE to own the copyright to the technical contribution it publishes on behalf of the interests of the IEEE, its authors, and their employers, and to facilitate the appropriate reuse of this material by others. To comply with the U.S. Copyright Law, authors are required to sign an IEEE copyright form before publication. This form, a copy of which appears in the January 1995 issue of this journal, returns to authors and their employers full rights to reuse their material for their own purposes. Authors must submit a signed copy of this form with their manuscripts.

C. Style for Manuscript

- 1) First page must contain: a) Title of paper (without symbols); b) Author(s) and affiliation(s); c) Abstract (not exceeding 300 words for Papers or 75 words for Technical Notes and Correspondence, and without equations, references, or footnotes); d) Complete mailing address, telephone number, and if available, electronic mail (email) address and facsimile (fax) number of each author; e) Preferred address for correspondence and return of proofs; and f) Footnotes (if desired) containing acknowledgment of financial or other support.
- 2) If possible, please prepare copies using two sides of each page. Authors should be aware, however, that after acceptance of a manuscript, a one-sided copy must be provided for IEEE production purposes.
- 3) Provide an Introduction that includes a statement of the purpose and contribution of the paper.
- 4) If appropriate, indicate advantages, limitations, and possible applications in a Conclusion section.
- 5) References should be numbered and appear in a separate bibliography at the end of the paper. Use numerals in square brackets to cite references, e.g., [15]. References should be complete and in IEEE style (see examples in this issue).

D. Style for Illustrations

- 1) It is in the author's interest to submit professional quality illustrations. Drafting or art service cannot be provided by the IEEE.
- 2) Original drawings should be in black ink on white background. Maximum size is restricted to 21.6 by 27.9 cm. Glossy prints of illustrations are also acceptable.
- 3) All lettering should be large enough to permit legible reduction of the figure to column width, sometimes as small as one quarter of the original size. Typed lettering is usually not acceptable on figures.
- 4) Lightly pencil each figure number on the back of each original illustration. Captions should not appear on figures.
- 5) Provide a separate sheet listing all figure captions in proper style for the typesetter, e.g., Fig. 5. The error variance for the optimal filter.
- 6) Contributors' photographs should measure between 1.6 cm and 9.5 cm across the widest part of the head. The overall size of the photographic paper used can be anything from passport size to 27.9 cm.

E. Mandatory Overlength Page Charges

A mandatory page charge is imposed on all papers exceeding eight TRANSACTIONS pages (about 28 double-spaced, typed pages) in length, including illustrations. The charge is \$125 per page for each page over the first eight and is a prerequisite for publication. Details are provided at the time of acceptance; authors are, however, urged to keep this in mind when submitting and revising their papers.

F. Page Charges

After a manuscript has been accepted for publication, the author's company or institution will be approached with a request to pay a charge of \$110 per page to cover part of the cost of publication. Payment of page charges for this IEEE TRANSACTIONS, like journals of other professional societies, is not a necessary prerequisite for publication. The author will receive 100 free reprints (without covers) only if the page charge is honored. Detailed instructions will accompany the proofs.

IEEE

TRANSACTIONS ON

AUTOMATIC CONTROL

A PUBLICATION OF THE IEEE CONTROL SYSTEMS SOCIETY

FEBRUARY 1995

VOLUME 40

NUMBER 2

IETAC (ISSN 0018-9286)

Canning the Issue 197

Editorial — The 1994 George S. Axelby Outstanding Paper Award 199

PAPERS

Adaptive Control of Plants with Unknown Hystereses	<i>G. Tao and P. V. Kokotović</i>	200
Robust Stability Under a Class of Nonlinear Parametric Perturbations	<i>M. Fu, S. Dasgupta, and V. Blondel</i>	213
Discrete Time Observers for Singularly Perturbed Continuous Time Systems	<i>K. R. Shouse and D. G. Taylor</i>	224
Adaptive Back-Pressure Congestion Control Based on Local Information	<i>L. Tassiulas</i>	236
Stability of Queueing Networks and Scheduling Policies	<i>P. R. Kumar and S. P. Meyn</i>	251
Second-Order Properties of Families of Discrete Event Systems	<i>R. Rajan and R. Agrawal</i>	261

TECHNICAL NOTES AND CORRESPONDENCE

Regional Pole Placement of Multivariable Systems Under Control Structure Constraints	<i>S. S. Keerthi and M. S. Phatak</i>	272
Continuous Robust Control Design for Nonlinear Uncertain Systems Without <i>a Priori</i> Knowledge of Control Direction	<i>I. Kaloust and Z. Qu</i>	276
On the Ordering of Optimal Hedging Points in a Class of Manufacturing Flow Control Models	<i>G. Liberopoulos and J.-Q. Hu</i>	282
Recursive Identification Method for MISO Wiener-Hammerstein Model	<i>M. Boutayeb and M. Darouach</i>	287
Production Rate Control for Failure-Prone Production Systems With No Backlog Permitted	<i>J. Q. Hu</i>	291
Relative Stability of a Linear Time-Varying Process with First-Order Nonlinear Time-Varying Feedback	<i>J. S. Anas</i>	296
Properties of Optimal Weighted Sensitivity Designs	<i>K. E. Lenz</i>	298
A Periodic Fixed-Structure Approach to Multirate Control	<i>W. M. Haddad and V. Kapila</i>	301
Pursuing a Maneuvering Target Which Uses a Random Process for Its Control	<i>V. E. Beneš, K. L. Helmes, and R. W. Rishel</i>	307
A Subspace Fitting Method for Identification of Linear State-Space Models	<i>A. Swindlehurst, R. Roy, B. Ottersten, and T. Kailath</i>	311
Consistency of Modified LS Estimation Method for Identifying 2-D Noncausal SAR Model Parameters	<i>P. Y. Zhao and J. Litva</i>	316
A Robust Hybrid Stabilization Strategy for Equilibria	<i>J. Guckenheimer</i>	321
Adaptive Control of Systems with Unknown Output Backlash	<i>G. Tao and P. V. Kokotović</i>	326

(Continued on back cover)

The Control Systems Society is an organization within the framework of the IEEE of members with professional interest in automatic control. All members of the IEEE are eligible for membership in the Society and will receive the TRANSACTIONS upon payment of the annual Society membership fee of \$15.00. For further information write to the address below. Member copies of Transactions/Journals are for personal use only.

INFORMATION FOR AUTHORS

In the IEEE TRANSACTIONS ON AUTOMATIC CONTROL the IEEE Control Systems Society publishes high quality papers on the theory design and application of control systems. The TRANSACTIONS is published monthly.

Two types of contributions are regularly considered:

1) *Papers* - Presentation of significant research, development, or application of control concepts.

2) *Technical Notes and Correspondence* - Brief technical notes, comments on published areas or established control topics, corrections to papers and notes published in the TRANSACTIONS.

In addition, special papers (tutorials, surveys, and perspectives on the theory and applications of control systems topics) are solicited. Authors are urged to contact one of the Associate Editors at Large before submitting such papers.

Submission of a manuscript signifies that it has been neither copyrighted, published, nor submitted or accepted for publication elsewhere.

Submitted manuscripts must be typewritten in English. All submitted manuscripts should be as concise as possible. Technical Notes and Correspondence are normally limited to 12 double spaced typed pages. Papers of length exceeding 40 double spaced typed pages are strongly discouraged. The Editor reserves the right to refuse to consider such papers.

A. Process for Submission of Manuscript

- 1) *Papers* - Send seven copies of the paper together with two copies of a transmittal letter enclosed in one package to the Editor in Chief. These will be subject to a full review procedure, and a decision on whether or not to accept the paper will be made by members of the Transactions Editorial Board.
- 2) *Technical Notes and Correspondence* - Technical Notes and Correspondence should be sent to the Editor for Technical Notes and Correspondence. Five copies are required. Decisions are made on the basis of a simplified review procedure.
- 3) Original illustrations should not be sent until requested, but authors should be ready to submit these immediately upon acceptance for publication.
- 4) Authors of accepted Papers are requested to supply their biographies (100 words or less) and photographs. For style, see biographies in this issue.
- 5) Enclose two copies of your letter of transmittal. Do not send letters of transmittal under separate cover. Give your preferred address for correspondence. Inform the Editor-in-Chief or Editor for Technical Notes and Correspondence of any change of address.
- 6) Authors of accepted manuscripts will be required to provide the final version of their manuscript on a computer diskette along with the hard copy.

B. Copyright

It is the policy of the IEEE to own the copyright to the technical contribution it publishes on behalf of the interests of the IEEE, its authors, and their employers, and to facilitate the appropriate reuse of this material by others. To comply with the U.S. Copyright Law, authors are required to sign an IEEE copyright form before publication. This form, a copy of which appears in the January 1995 issue of this journal, returns to authors and their employers full rights to reuse their material for their own purposes. Authors must submit a signed copy of this form with their manuscripts.

C. Style for Manuscript

- 1) First page must contain: a) Title of paper (without symbols); b) Author(s) and affiliation(s); c) Abstract (not exceeding 300 words for Papers or 75 words for Technical Notes and Correspondence, and without equations, references, or footnotes); d) Complete mailing address (telephone number and, if available, electronic mail (email) address and facsimile (fax) number of each author); e) Preferred address for correspondence and return of proofs; and f) Footnotes (if desired) containing acknowledgment of financial or other support.
- 2) If possible, please prepare copies using two sides of each page. Authors should be aware, however, that after acceptance of a manuscript, a one-sided copy must be provided for IEEE production purposes.
- 3) Provide an Introduction that includes a statement of the purpose and contribution of the paper.
- 4) If appropriate, indicate advantages, limitations, and possible applications in a Conclusion section.
- 5) References should be numbered and appear in a separate bibliography at the end of the paper. Use numerals in square brackets to cite references, e.g., [15]. References should be complete and in IEEE style (see examples in this issue).

D. Style for Illustrations

- 1) It is in the author's interest to submit professional quality illustrations. Drafting or art service cannot be provided by the IEEE.
- 2) Original drawings should be in black ink on white background. Maximum size is restricted to 21.6 by 27.9 cm. Glossy prints of illustrations are also acceptable.
- 3) All lettering should be large enough to permit legible reduction of the figure to column width, sometimes as small as one quarter of the original size. Typed lettering is usually not acceptable on figures.
- 4) Lightly pencil each figure number on the back of each original illustration. Captions should not appear on figures.
- 5) Provide a separate sheet listing all figure captions in proper style for the typesetter, e.g., Fig. 5. The error variance for the optimal filter.
- 6) Contributors' photographs should measure between 1.6 cm and 9.5 cm across the widest part of the head. The overall size of the photographic paper used can be anything from passport size to 27.9 cm.

E. Mandatory Overlength Page Charges

A mandatory page charge is imposed on all papers exceeding eight TRANSACTIONS pages (about 28 double-spaced typed pages) in length, including illustrations. The charge is \$125 per page for each page over the first eight and is a prerequisite for publication. Details are provided at the time of acceptance; authors are, however, urged to keep this in mind when submitting and revising their papers.

F. Page Charges

After a manuscript has been accepted for publication, the author's company or institution will be approached with a request to pay a charge of \$110 per page to cover part of the cost of publication. Payment of page charges for this IEEE TRANSACTIONS-like journals of other professional societies is not a necessary prerequisite for publication. The author will receive 100 free reprints (without covers) only if the page charge is honored. Detailed instructions will accompany the proofs.

PAPERS

Observer Design for Nonlinear Systems with Discrete-Time Measurements	<i>P. E. Moraal and J. W. Grizzle</i>	395
A Probabilistic Approach to Multivariable Robust Filtering and Open-Loop Control	<i>K. Öhrn, A. Ahlén, and M. Sternad</i>	405
A New Model for Control of Systems with Friction	<i>C. Canudas de Wit, H. Olsson, K. J. Åström, and P. Lischinsky</i>	419
Adaptive Nonlinear Design with Controller-Identifier Separation and Swapping	<i>M. Kistić and P. V. Kokotović</i>	426
Approximate Decoupling and Asymptotic Tracking for MIMO Systems	<i>D. N. Godbole, and S. S. Sastry</i>	441
A Generalized Orthonormal Basis for Linear Dynamical Systems	<i>P. S. C. Heuberger, P. M. J. Van den Hof, and O. H. Bosgra</i>	451
H_∞ Control via Measurement Feedback for General Nonlinear Systems	<i>A. Isidori and W. Kang</i>	466

TECHNICAL NOTES AND CORRESPONDENCE

Perturbation Bounds for Root-Clustering of Linear Systems in a Specified Second Order Subregion	<i>W. Bakker, J. S. Luo, and A. Johnson</i>	473
Comments on "Strictly Positive Real Transfer Functions Revisited"	<i>H. J. Marquez and C. J. Damaren</i>	478
On Interval Polynomials with No Zeros in the Unit Disc	<i>V. Blondel</i>	479
The Logical Control of an Elevator	<i>D. N. Dyck and P. E. Caines</i>	480
Robust Stability Criteria for Dynamical Systems Including Delayed Perturbations	<i>H. Wu and K. Mizukami</i>	487
An Efficient Method for Unconstrained Optimization Problems of Nonlinear Large Mesh-Interconnected Systems	<i>S.-Y. Lin and C.-H. Lin</i>	490
On the Possible Divergence of the Projection Algorithm	<i>E. Lefeber and J. W. Polderman</i>	495
A Comment on the Method of the Closest Unstable Equilibrium Point in Nonlinear Stability Analysis	<i>E. Noldus and M. Loccupier</i>	497
Boundaries of Conditional Quadratic Forms—A Comment on "Stabilization via Static Output Feedback"	<i>D. Cheng and C. F. Martin</i>	500

(Continued on back cover)

The Control Systems Society is an organization, within the framework of the IEEE, of members with professional interest in automatic control. All members of the IEEE are eligible for membership in the Society and will receive the *TRANSACTIONS* upon payment of the annual Society membership fee of \$15.00. For further information, write to the address below. *Member copies of Transactions/Journals are for personal use only.*

IEEE TRANSACTIONS ON AUTOMATIC CONTROL is published monthly by The Institute of Electrical and Electronics Engineers, Inc. Responsibility for the contents rests upon the authors and not upon IEEE, the Society/Council or its members. IEEE Corporate Office: 345 East 47th Street, New York, NY 10017-2394. IEEE Operations Center: 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331. NJ Telephone: 908-981-0060. Price/Publication Information: Individual copies: IEEE Members \$10.00 (first copy only), nonmembers \$20.00 per copy. (Note: Add \$4.00 postage and handling charge to any order from \$1.00 to \$50.00, including prepaid orders.) Member and nonmember subscription prices available on request. Available in microfiche and microfilm. Copyright and Reprint Permissions: Abstracting is permitted with credit to the source. Libraries are permitted to photocopy for private use of patrons, provided the per-copy fee indicated at the bottom of the first page is paid through the Copyright Clearance Center, 29 Congress Street, Salem, MA 01970. For all other copying, reprint, or republication permission, write to Copyrights and Permissions Department, IEEE Publications Administration, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331. Copyright ©1995 by The Institute of Electrical and Electronics Engineers, Inc. All rights reserved. Second class postage paid at New York, NY and at additional mailing offices. Postmaster: Send address changes to IEEE TRANSACTIONS ON AUTOMATIC CONTROL, IEEE, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331. Printed in U.S.A.

INFORMATION FOR AUTHORS

In the IEEE TRANSACTIONS ON AUTOMATIC CONTROL, the IEEE Control Systems Society publishes high-quality papers on the theory, design, and application of control systems. The TRANSACTIONS is published monthly.

Two types of contributions are regularly considered:

- 1) *Papers*—Presentation of significant research, development, or application of control concepts.
- 2) *Technical Notes and Correspondence*—Brief technical notes, comments on published areas or established control topics, corrections to papers and notes published in the TRANSACTIONS

In addition, special papers (tutorials, surveys, and perspectives on the theory and applications of control systems topics) are solicited. Authors are urged to contact one of the Associate Editors at large before submitting such papers.

Submission of a manuscript signifies that it has been neither copyrighted, published, nor submitted or accepted for publication elsewhere.

Submitted manuscripts must be typewritten in *English*. All submitted manuscripts should be as concise as possible. Technical Notes and Correspondence are normally limited to 12 double-spaced, typed pages. Papers of length exceeding 40 double-spaced, typed pages are strongly discouraged. The Editor reserves the right to refuse to consider such papers.

A. Process for Submission of Manuscript

- 1) *Papers*. Send seven copies of the paper together with two copies of a transmittal letter enclosed in one package to the Editor-in-Chief. These will be subject to a full review procedure, and a decision on whether or not to accept the paper will be made by members of the Transactions Editorial Board.
- 2) *Technical Notes and Correspondence*: Technical Notes and Correspondence should be sent to the Editor for Technical Notes and Correspondence; five copies are required. Decisions are made on the basis of a simplified review procedure.
- 3) Original illustrations should not be sent until requested, but authors should be ready to submit these immediately upon acceptance for publication.
- 4) Authors of accepted Papers are requested to supply their biographies (100 words or less) and photographs. For style, see biographies in this issue.
- 5) Enclose two copies of your letter of transmittal. Do not send letters of transmittal under separate cover. Give your preferred address for correspondence. Inform the Editor-in-Chief or Editor for Technical Notes and Correspondence of any change of address.
- 6) Authors of accepted manuscripts will be required to provide the final version of their manuscript on a computer diskette along with the hard copy.

B. Copyright

It is the policy of the IEEE to own the copyright to the technical contribution it publishes on behalf of the interests of the IEEE, its authors and their employers, and to facilitate the appropriate reuse of this material by others. To comply with the U.S. Copyright Law, authors are required to sign an IEEE copyright form before publication. This form, a copy of which appears in the January 1995 issue of this journal, returns to authors and their employers full rights to reuse their material for their own purposes. Authors must submit a signed copy of this form with their manuscripts.

C. Style for Manuscript

- 1) First page must contain: a) Title of paper (without symbols), b) Author(s) and affiliation(s), c) Abstract (not exceeding 300 words for Papers or 75 words for Technical Notes and Correspondence, and without equations, references, or footnotes), d) Complete mailing address, telephone number, and, if available, electronic mail (email) address and facsimile (fax) number of each author, e) Preferred address for correspondence and return of proofs, and f) Footnotes (if desired) containing acknowledgment of financial or other support.
- 2) If possible, please prepare copies using two sides of each page. Authors should be aware, however, that after acceptance of a manuscript, a one-sided copy must be provided for IEEE production purposes.
- 3) Provide an Introduction that includes a statement of the purpose and contribution of the paper.
- 4) If appropriate, indicate advantages, limitations, and possible applications in a Conclusion section.
- 5) References should be numbered and appear in a separate bibliography at the end of the paper. Use numerals in square brackets to cite references, e.g., [15]. References should be complete and in IEEE style (see examples in this issue).

D. Style for Illustrations

- 1) It is in the author's interest to submit professional quality illustrations. Drafting or art service cannot be provided by the IEEE.
- 2) Original drawings should be in black ink on white background. Maximum size is restricted to 21.6 by 27.9 cm. Glossy prints of illustrations are also acceptable.
- 3) All lettering should be large enough to permit legible reduction of the figure to column width, sometimes as small as one quarter of the original size. Typed lettering is usually not acceptable on figures.
- 4) Lightly pencil each figure number on the back of each original illustration. Captions should not appear on figures.
- 5) Provide a separate sheet listing all figure captions, in proper style for the typesetter, e.g., "Fig. 5. The error variance for the optimal filter."
- 6) Contributors' photographs should measure between 1.6 cm and 9.5 cm across the widest part of the head. The overall size of the photographic paper used can be anything from passport size to 27.9 cm.

E. Mandatory Overlength Page Charges

A mandatory page charge is imposed on all papers exceeding eight TRANSACTIONS pages (about 28 double-spaced, typed pages) in length, including illustrations. The charge is \$125 per page for each page over the first eight and is a prerequisite for publication. Details are provided at the time of acceptance; authors are, however, urged to keep this in mind when submitting and revising their papers.

F. Page Charges

After a manuscript has been accepted for publication, the author's company or institution will be approached with a request to pay a charge of \$110 per page to cover part of the cost of publication. Payment of page charges for this IEEE TRANSACTIONS, like journals of other professional societies, is not a necessary prerequisite for publication. The author will receive 100 free reprints (without covers) only if the page charge is honored. Detailed instructions will accompany the proofs.

INFORMATION FOR AUTHORS

In the IEEE TRANSACTIONS ON AUTOMATIC CONTROL, the IEEE Control Systems Society publishes high-quality papers on the theory, design, and application of control systems. The TRANSACTIONS is published monthly.

Two types of contributions are regularly considered:

1) *Papers*—Presentation of significant research, development, or application of control concepts.

2) *Technical Notes and Correspondence*—Brief technical notes, comments on published areas or established control topics, corrections to papers, and notes published in the TRANSACTIONS.

In addition, special papers (tutorials, surveys, and perspectives on the theory and applications of control systems topics) are solicited. Authors are urged to contact one of the Associate Editors at Large before submitting such papers.

Submission of a manuscript signifies that it has been neither copyrighted, published, nor submitted or accepted for publication elsewhere.

Submitted manuscripts must be typewritten in English. All submitted manuscripts should be as concise as possible. Technical Notes and Correspondence are normally limited to 12 double-spaced, typed pages. Papers of length exceeding 40 double-spaced, typed pages are strongly discouraged. The Editor reserves the right to refuse to consider such papers.

A. Process for Submission of Manuscript

- 1) *Papers*: Send seven copies of the paper together with two copies of a transmittal letter enclosed in one package to the Editor-in-Chief. These will be subject to a full review procedure, and a decision on whether or not to accept the paper will be made by members of the Transactions Editorial Board.
- 2) *Technical Notes and Correspondence*: Technical Notes and Correspondence should be sent to the Editor for Technical Notes and Correspondence; five copies are required. Decisions are made on the basis of a simplified review procedure.
- 3) Original illustrations should not be sent until requested, but authors should be ready to submit these immediately upon acceptance for publication.
- 4) Authors of accepted Papers are requested to supply their biographies (100 words or less) and photographs. For style, see biographies in this issue.
- 5) Enclose two copies of the letter of transmittal. Do not send letters of transmittal under separate cover. Give the authors preferred address for correspondence. Inform the Editor-in-Chief or Editor for Technical Notes and Correspondence of any change of address.
- 6) Authors of accepted manuscripts will be required to provide the final version of their manuscript on a computer disk in ASCII text file, along with two paper copies, or a final version can be emailed to "t-ac@ieee.org."

B. Copyright

It is the policy of the IEEE to own the copyright to the technical contributions it publishes. To comply with IEEE copyright policy, authors are required to sign an IEEE Copyright Transfer Form before publication in either the print or electronic medium. The form is provided upon approval of their manuscript. Authors must submit a signed copy of this form with their manuscripts.

C. Style for Manuscript

- 1) First page must contain: a) Title of paper (without symbols), b) Author(s) and affiliation(s), c) Abstract (not exceeding 300 words for Papers or 75 words for Technical Notes and Correspondence, and without equations, references, or footnotes), d) Complete mailing address, telephone number, and, if available, electronic mail (email) address and facsimile (fax) number of each author, e) Preferred address for correspondence and return of proofs, and f) Footnotes (if desired) containing acknowledgment of financial or other support.
- 2) Provide an Introduction that includes a statement of the purpose and contribution of the paper.
- 3) If appropriate, indicate advantages, limitations, and possible applications in a Conclusion section.
- 4) References should be numbered and appear in a separate bibliography at the end of the paper. Use numerals in square brackets to cite references, e.g., [15]. References should be complete and in IEEE style (see examples in this issue).

D. Style for Illustrations

Illustrations should be kept to a minimum. Figures and photos should be original proofs and not xeroxes. Photos must be glossy prints with no screens. Laser prints are not acceptable in place of photos or where gray-scale graphics are involved. All line drawings and photos should be in black and white unless specifically requested. Letters should be large enough to be readily legible when the drawing is reduced to a one-column width as much as 4:1 reduction from the original. Materials should be no larger than 22 x 28 cm (8 1/2 x 11"). Do not incorporate electronic graphics into the paper. List captions on a separate sheet of paper, not on the illustrations.

E. Mandatory Overlength Page Charges

A mandatory page charge is imposed on all papers exceeding eight TRANSACTIONS pages (about 28 double-spaced, typed pages) in length, including illustrations. The charge is \$125 per page for each page over the first eight and is a prerequisite for publication. Details are provided at the time of acceptance; authors are, however, urged to keep this in mind when submitting and revising their papers.

F. Page Charges

After a manuscript has been accepted for publication, the author's company or institution will be approached with a request to pay a charge of \$110 per page to cover part of the cost of publication. Payment of page charges for this IEEE TRANSACTIONS, like journals of other professional societies, is not a necessary prerequisite for publication. The author will receive 100 free reprints (without covers) only if the page charge is honored. Detailed instructions will accompany the proofs.

Percentile Performance Criteria for Limiting Average Markov Decision Processes, Filar, Krass, and Ross.

This paper addresses the question of whether a policy can be found that achieves a specified value (target) of the long-run limiting average reward at a specified probability level (percentile) for a Markov Decision Process (MDP). This is motivated from the fact that an optimal policy for an infinite horizon MDP with a limiting average reward criterion is insensitive to the probability distribution function of the long-run average reward. Therefore, it is possible that an optimal policy might carry an unacceptably high probability of low values of the long-run average reward. For a problem with a single objective, a complete classification of both the maximal achievable target levels and of their corresponding percentiles is presented. Also, in the case of a communicating MDP, it is shown that every target level can be achieved with only two possible values: zero or one. The approach is constructive and thus furnishes an algorithm for computing a deterministic policy for any feasible target level and percentile pair. Problems with multiple objectives and/or constraints are also studied. These are considered in detail for communicating MDP's with constructive solutions obtained for most cases.

Design and Analysis of Fuzzy Identifiers of Nonlinear Dynamic Systems, Wang.

This paper develops identification algorithms based on "fuzzy" IF-THEN rules for nonlinear dynamic systems. These rules can be either collected from human experts or generated from sensory measurements. Two fuzzy identifiers are developed based upon different rules structures. Both algorithms are shown to be globally stable in the sense that all variables are uniformly bounded and, under mild conditions, the associated prediction errors converge to zero. The algorithms are applied to identify the chaotic glycolytic oscillator.

Stochastic Approximation with Averaging and Feedback: Rapidly Convergent "On Line" Algorithms, Kushner and Yang.

This paper is concerned with the problem of stochastic approximation with averaging of the type considered by Poyak and Juditsky. The authors point out that while the averaging approach has many advantages, choosing the appropriate slowly time-varying gain can

be a nuisance. The authors propose a new stochastic approximation model with constant gain and a feedback term. The rate of convergence of the approximation sequence and the averages are analyzed. This result can be applied to fixed parameter estimation problems. The feedback approach is further extended to time-varying parameter cases. The authors conclude the paper with a simulation study of the proposed algorithms.

Exponential Stabilization of Nonholonomic Chained Systems, Sordalen and Egeland.

This paper analyzes the stabilization of two-input driftless nonholonomic systems in chained form. It is shown how to achieve global asymptotic stability with exponential convergence about any reference configuration by using a nonsmooth time-varying feedback control law. The notion of K-exponential stability is used. Simulation results are given in addition to theoretical analysis.

Global Total Least Squares Modeling of Multivariable Time Series, Roorda and Heij.

This paper concerns the problem of modeling discrete-time multivariate time series by a finite dimensional linear system. The paper differs from other papers on identification in its viewpoint: Model error is defined as the minimal adjustment of the data required to make the time series obey the system equations so that no distinction need be made between system inputs and outputs. The goal of finding an ideal realization can thus be formulated as a total least squares problem. An iterative algorithm is devised to obtain an optimal model, and several numerical simulations are presented as illustrations.

Control of Chained Systems. Application to Path Following and Time-Varying Point Stabilization of Mobile Robots, Samson.

This paper studies the control of a class of nonholonomic kinematic systems. Such systems are nonholonomic in that they are subject to nonintegrable constraints, and they are kinematic in that the controls are velocity controls. The class of systems studied here—systems in chained form—has proven to be particularly amenable to analysis. Here it is shown that systems in chained form may be put into a convenient skew-symmetric chained form, and some open-loop and closed-loop control problems are solved, including global point stabilization by time-varying feedback.

Percentile Performance Criteria For Limiting Average Markov Decision Processes

Jerzy A. Filar, Dmitry Krass, and Keith W. Ross, *Senior Member, IEEE*

Abstract—In this paper we address the following basic feasibility problem for infinite-horizon Markov decision processes (MDP's): can a policy be found that achieves a specified value (target) of the long-run limiting average reward at a specified probability level (percentile)? Related optimization problems of maximizing the target for a specified percentile and vice versa are also considered. We present a complete (and discrete) classification of both the maximal achievable target levels and of their corresponding percentiles. We also provide an algorithm for computing a deterministic policy corresponding to any feasible target-percentile pair.

Next we consider similar problems for an MDP with multiple rewards and/or constraints. This case presents some difficulties and leads to several open problems. An LP-based formulation provides constructive solutions for most cases.

I. INTRODUCTION AND DEFINITIONS

INFINITE horizon Markov decision processes (MDP's, for short) have been extensively studied since the 1950's. One of the most commonly considered versions is the so-called "limiting average reward" model. In this model the decision-maker aims to maximize the expected value of the limit-average ("long-run average") of an infinite stream of single-stage rewards. There are now a number of good algorithms for computing optimal deterministic policies in the limiting average MDP's (e.g., see [4], [6], [11]).

It should be noted, however, that an optimal policy in the above "classical" sense is insensitive to the probability distribution function of the long-run average reward. That is, it is possible that an optimal policy, while yielding an acceptably high expected long-run average reward, carries with it unacceptably high probability of low values of that same random variable. This "risk insensitivity" is inherent in the formulation of the classical objective criterion as that of maximizing the expected value of a random variable, and it is not necessarily undesirable. Nonetheless, in this paper we adopt the point of view that there are many natural situations where the decision-maker is interested in finding a policy that will achieve a sufficiently high long-run average reward, that is, a target level with a sufficiently high probability, that is, a percentile. The key conceptual difference between this paper

and the classical problem is that our controller is not searching for an optimal policy but rather for a policy that is "good enough," knowing that such a policy will typically fail to exist if the target level and the percentile are set too high. Conceptually, our approach is somewhat analogous to that often adopted by statisticians in testing of hypotheses where it is desirable (but usually not possible!) to simultaneously minimize both the "type 1" and the "type 2" errors. See Bouakiz [5] for a review of similar approaches in economics and operations research literature and White [16] for a review of various approaches to risk-sensitivity in MDP's.

We start out by considering a problem with a single objective. It will be seen (Section IV below) that for our target level-percentile problem it is possible to present a complete (and discrete) classification of both the maximal achievable target levels and of their corresponding percentiles (see Theorem 4.3 and its corollaries). The case of a communicating MDP is particularly interesting as here every target level can be achieved with only two possible values: zero or one (see Theorem 4.1 and its corollary). In all cases our approach is constructive in the sense that we can supply an algorithm for computing a deterministic policy for any feasible target level and percentile pair.

In Section V we turn our attention to problems with multiple objectives and/or constraints. The connection of this to the problem with sample path constraint of [13] and [14] is discussed. In Section VI, we show how the techniques developed in Section IV extend directly to these problems, provided that the problems can be solved for a communicating MDP (see Theorem 6.3). The multiobjective/constrained problems are considered in detail for communicating MDP's, with constructive solutions obtained for most cases (see Theorems 6.1 and 6.2). Conclusions and some open problems are presented in Section VII.

Our analysis is made possible by the recently developed decomposition and sample path theory due to Ross and Varadarajan [14]. The logical development of the results is along the lines of Filar [8]. The latter paper, to the best of our knowledge, introduced the percentile objective criterion in the context of a limiting average Markov control problem, but substituted the long-run expected frequencies in place of actual percentile probabilities since the decomposition and sample path theory of [14] was not known at that time (the unusual way of evaluating risk in [8] was also pointed out in [16]). Some earlier related work appeared in Mitten [12], Sobel [15], and Henig [10]. In the remainder of this section we shall introduce the notation of the limiting average Markov decision process.

Manuscript received January 22, 1992; revised April 12, 1993. This work was supported in part by the AFOSR and the NSF Grants ECS-8704954 and NCR-8707620.

IEEE Log Number 9406094.

A finite MDP, Γ , is observed at discrete-time points $n = 1, 2, \dots$. The state space is denoted by $S = \{1, 2, \dots, |S|\}$. With each state $i \in S$ we associate a finite action set $A(i)$. At any time point n , the system is in one of the states, and an action has to be chosen by the decision-maker. If the system is in state i and the action $a \in A(i)$ is chosen, then an immediate reward $r(i, a)$ is earned and the process moves to a state $j \in S$ with transition probability p_{iaj} , where $p_{iaj} \geq 0$ and $\sum_{j \in S} p_{iaj} = 1$.

A decision rule u^n at time n is a function which assigns a probability to the event that action a is taken at time n . In general u^n may depend on all realized states up to and including time n . A policy (or a control) u is a sequence of decision rules: $u = (u^1, u^2, \dots, u^n, \dots)$. A policy is stationary if each u^n depends only on the current state at time n , and $u^1 = u^2 = \dots = u^n = \dots$. A pure (or deterministic) policy is a stationary policy with nonrandomized decision rules. A stationary policy f induces a Markov chain $P(f)$ with the transitions $P(f)_{ij} = \sum_{a \in A(i)} p_{iaj} f_{ia}$ for $i, j \in S$, where f_{ia} is the probability (under f) that action a is chosen whenever state i is visited. If $P(f)$ consists of a single recurrent class of states, then f is called an irreducible policy. If $P(f)$ contains some transient states in addition to a single recurrent class, then f is called a unichain policy. MDP Γ is called unichain if every stationary policy in Γ is unichain.

Let X_n and A_n be the random variables that denote the state at time n and the action chosen at time n , and define the limiting average reward as the random variable

$$R := \lim_{N \rightarrow \infty} \inf \frac{1}{N} \sum_{n=1}^N r(X_n, A_n).$$

It should now be clear that once a policy u and an initial state $X_1 = s_1$ are fixed, the expectation $\phi(u, s_1) := E_u[R | X_1 = s_1]$ of R is well defined and will, from now on, be referred to as the expected average reward due to a policy u . The classical limiting average reward problem is to find an optimal policy u^* such that for all policies u

$$\phi(u^*, s_1) \geq \phi(u, s_1) \quad \text{for all } s_1 \in S. \quad (1.1)$$

It is well known (e.g., see [4]) that there always exists a pure optimal policy u^* .

II. PROBLEMS RELATING TO PERCENTILE OBJECTIVE CRITERIA

We shall say that any pair (τ, α) such that $\tau \in \mathbb{R}$ and $\alpha \in [0, 1]$ constitutes a target level-percentile pair. We shall address the following problems.

Problem 1: Fix $s_1 \in S$. Given $(\tau, \alpha) \in \mathbb{R} \times [0, 1]$ does there exist a policy u such that

$$P_u(R \geq \tau | X_1 = s_1) \geq \alpha? \quad (2.1)$$

If (2.1) holds for some policy u , then we shall say that u achieves the target level τ at percentile α , and τ will be called α -achievable.

Problem 2: Given $\alpha \in [0, 1]$ find

$$\tau_\alpha := \sup \{ \tau \mid \tau \text{ is } \alpha\text{-achievable} \}. \quad (2.2)$$

Problem 3: Given $\tau \in \mathbb{R}$ find

$$\alpha_\tau := \sup \{ \alpha \in [0, 1] \mid \exists \text{ a policy } u \text{ s.t. (2.1) holds} \}. \quad (2.3)$$

Remark 2.1: It should be clear that in many situations the natural goal of maximizing the target level will be in direct conflict with the goal of maximizing the percentile value. This is because τ_α is a nonincreasing function of α , while α_τ is a nonincreasing function of τ .

III. PRELIMINARIES

We shall develop our results within the framework of the decomposition and sample path theory due to Ross and Varadarajan [14] (for a related decomposition, see [2]). This decomposition approach has also proved instrumental in solving other limiting average MDP problems with nonstandard criteria (see [14] and [3]). In this section we collect some results from [14] that will be needed for the proofs in the subsequent sections.

In [14] it is shown that the state space S has a unique partition C_1, C_2, \dots, C_K, T , whose properties are summarized below.

Theorem 3.1 (Proposition 2 of [14]): For any policy u , we have

$$\sum_{k=1}^K P_u(\Phi_k | X_1 = s_1) = 1$$

where

$$\Phi_k := \{X_n \in C_k \text{ almost always}\}$$

(where "almost always" means that $X_n \notin C_k$ finitely often).

The sets C_1, \dots, C_K and T are referred to as strongly communicating classes and the set of transient states, respectively. For a given strongly communicating class C_k , denote by $\Gamma(k)$ the MDP restricted to C_k . Thus, the state space of $\Gamma(k)$ is C_k and the action space $A_k(i)$, $i \in C_k$, is given by

$$A_k(i) = \{a \in A(i) : p_{iaj} = 0 \quad \forall j \notin C_k\}.$$

From [14] we know that $A_k(i)$ is nonempty for all $i \in C_k$ and that $\Gamma(k)$ is a communicating MDP. Recall that a communicating MDP is such that for any pair of states $i, j \in S$, there is a pure policy under which j is accessible from i . Now consider the following linear program $LP(k)$

$$\begin{aligned} \max \quad & \sum_{i \in C_k} \sum_{a \in A_k(i)} r(i, a) x_{ia} \\ \text{s.t.} \quad & \sum_{i \in C_k} \sum_{a \in A_k(i)} (\delta_{ij} - p_{iaj}) x_{ia} = 0 \quad j \in C_k \\ & \sum_{i \in C_k} \sum_{a \in A_k(i)} x_{ia} = 1 \\ & x_{ia} \geq 0, \quad i \in C_k, \quad a \in A_k(i). \end{aligned}$$

Let v_k denote the optimal objective function value of $LP(k)$. We can now state the following result.

Theorem 3.2 (Lemma 4 [14]): For all policies u , all initial states $s_1 \in S$, and all $k = 1, \dots, K$, we have

$$P_u(R \leq v_k \mid \Phi_k, X_1 = s_1) = 1$$

whenever $P_u(\Phi_k, X_1 = s_1) > 0$.

IV. BASIC RESULTS FOR THE SINGLE REWARD CASE

We shall first solve Problems 1–3 for the case of Γ being a communicating MDP. In this case, there is one strongly communicating class C_1 , and T is empty; thus, $S = C_1$.

Consider then $LP(1)$ and to simplify notation denote $v := v_1$. Also let $\{x_{ia}^*\}$ be an optimal basic feasible solution of $LP(1)$ and g^* be a stationary optimal policy constructed from $\{x_{ia}^*\}$ (e.g., see [11], [9], or [13]). Then g^* satisfies

$$\phi(g^*, s_1) = v, \quad s_1 \in S \quad (4.1)$$

where v is the maximal objective function value in $LP(1)$. Moreover, the Markov chain $P(g^*)$ associated with the policy g^* has at most one recurrent class plus (a perhaps empty) set of transient states.

Theorem 4.1: In a communicating MDP Γ there exists a policy that achieves the target level τ with percentile α if and only if $\tau \leq v$. If $\tau \leq v$, then the pure policy g^* achieves the target level τ with percentile α , for any $\alpha \in [0, 1]$.

Note: This result (at least for the unichain case) seems to be well known in the “folklore” of MDP’s. A proof for the communicating case can be found in Asriev and Rotar’ [1] (who establish this result for a much more general stochastic dynamic control model). Since our proof is quite simple, we present it here for completeness.

Proof: Since g^* gives rise to a Markov chain with one recurrent class, we have

$$P_{g^*}(R = \phi(g^*, s_1) \mid X_1 = s_1) = 1$$

(e.g., see [13, Proposition 1 (iii)]). Combining this with (4.1) gives

$$P_{g^*}(R = v \mid X_1 = s_1) = 1. \quad (4.2)$$

From Theorem 3.2, we have

$$P_u(R \leq v \mid X_1 = s_1) = 1. \quad (4.3)$$

The result then follows from (4.2) and (4.3).

As a direct consequence of Theorem 4.1 we have the following corollary.

Corollary 4.1: In a communicating MDP Γ , $\tau_\alpha = v$ for all $\alpha \in (0, 1]$, moreover

$$\alpha_\tau = \begin{cases} 1 & \text{if } \tau \leq v \\ 0 & \text{if } \tau > v. \end{cases}$$

Problems 1–3 have now been solved for the communicating MDP’s. We return to the general case, where we have strongly communicating classes C_1, \dots, C_K and the set T of transient states. Denote by g_k^* the pure policy of Theorem 4.1 associated with $\Gamma(k)$, the MDP restricted to C_k .

Corollary 4.2: For a fixed $k \in \{1, \dots, K\}$, let g be a pure policy that coincides with g_k^* on C_k and is defined arbitrarily elsewhere. Then

$$P_g(R = v_k \mid \Phi_k, X_1 = s_1) = 1$$

if $P_g(\Phi_k, X_1 = s_1) > 0$.

Proof: Note that the definition of Φ_k implies that C_k must be reached in finite time (P_g – a.s.). Thus, the result follows easily from the proof of Theorem 4.1.

Next, we shall consider a fixed target level τ and associate with it an index set $I_\tau = \{k: 1 \leq k \leq K, v_k \geq \tau\}$, and an auxiliary “0-1 MDP” Γ_τ , whose states, actions, and transition probabilities are the same as Γ , but with rewards defined by

$$r^\tau(i, a) := \begin{cases} 1 & \text{if } i \in C_k \text{ and } k \in I_\tau \\ 0 & \text{otherwise.} \end{cases}$$

It is easy to see that for an arbitrary policy u , the expected average reward in Γ_τ is given by

$$\begin{aligned} \phi^\tau(u, s_1) &= E_u \left[\lim_{N \rightarrow \infty} \inf \frac{1}{N} \sum_{n=1}^N 1(X_n \in C_k) \mid X_1 = s_1 \right] \\ &= \sum_{k \in I_\tau} P_u(\Phi_k \mid X_1 = s_1) \end{aligned} \quad (4.4)$$

where $1(\cdot)$ is the indicator function. Note that the last equality above follows from Theorem 3.1 and the definition of Φ_k , since P_u -a.s. after some finite time t we must have $X_n \in C_k$ for all $n \geq t$ and some $k \in \{1, \dots, K\}$.

Theorem 4.2: Let g^* be an optimal pure policy in Γ_τ which coincides with g_k^* on C_k for $k \in I_\tau$.¹ There exists a policy u satisfying

$$P_u(R \geq \tau \mid X_1 = s_1) \geq \alpha \quad (4.5)$$

where α is the percentile, if and only if $\phi^\tau(g^*, s_1) \geq \alpha$. Further, if the target τ can be achieved at percentile α , then it can be achieved by the pure policy g^* .

Proof: From Theorem 3.1 we have that for any policy u

$$P_u(R \geq \tau \mid X_1 = s_1) = \sum_{k=1}^K P_u(R \geq \tau \mid \Phi_k, X_1 = s_1) P_u(\Phi_k \mid X_1 = s_1). \quad (4.6)$$

From Theorem 3.2 we have

$$P_u(R \geq \tau \mid \Phi_k, X_1 = s_1) = 0 \quad k \notin I_\tau. \quad (4.7)$$

From Corollary 4.2

$$\begin{aligned} 1 &= P_{g^*}(R \geq \tau \mid \Phi_k, X_1 = s_1) \\ &\geq P_u(R \geq \tau \mid \Phi_k, X_1 = s_1) \quad k \notin I_\tau \end{aligned} \quad (4.8)$$

¹ Note that there is no loss of generality here, because g_k^* ensures that once the process enters C_k it remains there forever. Thus it yields the maximal reward of one for every state $i \in C_k$, $k \in I_\tau$.

where the inequality follows from the optimality of g_k^* for $\Gamma(k)$. Combining (4.6)–(4.8) gives

$$\begin{aligned} P_u(R \geq \tau \mid X_1 = s_1) &\leq P_{g^*}(R \geq \tau \mid X_1 = s_1) \\ &= \sum_{k \in I_\tau} P_{g^*}(\Phi_k \mid X_1 = s_1) \\ &= \phi^\tau(g^*, s_1) \end{aligned}$$

from which the result follows.

It is important to note that Theorem 4.2 provides a constructive answer to Problem 1 of Section II concerning α -achievability of the target level τ . We shall now address the problem of determining τ_α —the maximal achievable percentile for the fixed level τ . Towards this goal we assume without loss of generality that the strongly communicating classes C_1, \dots, C_K are ordered so that

$$v_1 \geq v_2 \geq \dots \geq v_K. \quad (4.9)$$

Recall the definition of the MDT Γ_{v_k} (here v_k is the target level). To simplify the notation, we will refer to Γ_{v_k} as Γ_k and to the corresponding expected average reward as ϕ^k instead of ϕ^{v_k} .

Theorem 4.3: Let g_k^* be an optimal pure policy for MDP Γ_k chosen as in Theorem 4.2. We have for $\alpha \in (0, 1]$ that

$$\tau_\alpha = \tau^* := \max \{v_k \mid \phi^k(g_k^*, s_1) \geq \alpha, \quad k = 1, \dots, K\}. \quad (4.10)$$

Proof: Let l be the largest index that achieves the maximum in (4.10), l is well defined since $\phi^K(g_K^*, s_1) = 1$. Since $\tau^* = v_l$, we have $I_{\tau^*} = \{1, 2, \dots, l\}$. Thus, from Theorem 4.2, we know that

$$P_{g^*}(R \geq \tau^* \mid X_1 = s_1) \geq \alpha. \quad (4.11)$$

Hence, τ^* is α -achievable, implying that $\tau_\alpha \geq \tau^*$. If strict inequality were possible in the preceding statement, then there would exist a $\tau' > \tau^*$ and a policy u such that

$$P_u(R \geq \tau' \mid X_1 = s_1) \geq \alpha. \quad (4.12)$$

Now let

$$m := \max \{k : v_k \geq \tau'\}$$

noting that if $v_k < \tau'$ for all $k = 1, \dots, K$, then the left side of (4.12) equals zero contradicting the hypothesis $\alpha > 0$. By the definition of m we have

$$v_m \geq \tau' > \tau^*. \quad (4.13)$$

Applying Theorem 3.1, Theorem 4.1 and optimality g_m^* to (4.12) yields

$$\begin{aligned} \alpha &\leq \sum_{k=1}^K P_u(R \geq \tau' \mid \Phi_k, X_1 = s_1) P_u(\Phi_k \mid X_1 = s_1) \\ &= \sum_{k=1}^m P_u(R \geq \tau' \mid \Phi_k, X_1 = s_1) P_u(\Phi_k \mid X_1 = s_1) \\ &\leq \sum_{k=1}^m P_u(\Phi_k \mid X_1 = s_1) \\ &= \phi^m(u, s_1) \leq \phi^m(g_m^*, s_1). \end{aligned} \quad (4.14)$$

But, by the definition of τ^* , (4.14) implies $\tau^* \geq v_m$, which contradicts (4.13).

Corollary 4.3: The maximal α -achievable target level, τ_α , is a monotone nonincreasing step-function of α , defined on the interval $(0, 1]$.

Proof: Choose g_k^* as in Theorem 4.3. Let $\alpha_k := \phi^k(g_k^*, s_1)$ for $k = 1, \dots, K$, so that $0 \leq \alpha_1 \leq \alpha_2 \leq \dots \leq \alpha_K = 1$. If we define $\tau_0 := v_1$, then by Theorem 4.3, $\tau_\alpha = \tau_0$ for all $\alpha \in (0, \alpha_1]$. Similarly, $\tau_\alpha = \tau_k$, a constant for all $\alpha \in (\alpha_k, \alpha_{k+1}]$, where $\tau_k \geq \tau_{k+1}$ for each $k = 1, \dots, K-1$.

Corollary 4.4: Choose g_k^* as in Theorem 4.3. The maximum percentile α_τ for a given target level τ , is a monotone nonincreasing step function of τ defined in the interval $[v_K, v_1]$. In particular for $\tau \in (v_{k+1}, v_k]$ we have

$$\alpha_\tau = \phi^k(g_k^*, s_1)$$

for each $k = 1, \dots, K-1$.

Proof: This follows easily from the monotonicity of $\phi^k(g_k^*, s_1)$ in the index k .

Remark 4.1: Corollaries 4.3 and 4.4 demonstrate the strength of the percentile objective criteria. Namely, the decomposition of states into C_1, \dots, C_K and T , and the subsequent computation of policies g_k^* together with “breakpoints” τ_k , and v_k for τ_α and α_τ , respectively, allows for a flexible and practical evaluation of gain-risk trade-offs in an average reward MDP.

In view of Corollaries 4.3 and 4.4 the only “reasonable” choices of α and τ are of the special form (τ, α) with $\tau = \tau_\alpha$ and $\alpha = \alpha_\tau$; these correspond to Pareto-optimal solutions.

The preceding results are summarized in the following algorithm, which (for a fixed initial state s_1) finds all target-level-percentile pairs of the indicated “special form”

- Step 1:** Apply the algorithm of [14] to find the decomposition C_1, \dots, C_K, T .
- Step 2:** For each $k \in \{1, \dots, K\}$, find the value v_k of $\Gamma(k)$. Order the strongly communicating classes so that $v_1 \geq \dots \geq v_K$.
- Step 3:** For each $k \in \{1, \dots, K\}$, form the MDP Γ_k and find the optimal policy g_k^* . Let $\alpha_k = \phi^k(g_k^*, s_1)$.
- Step 4:** Let $J = \{(v_k, \alpha_k) \mid k = 1, \dots, K\}$. If $(\tau_1, \alpha), (\tau_2, \alpha) \in J$ and $\tau_1 > \tau_2$, then eliminate (τ_2, α) from J . Continue until no further eliminations are possible.
- Step 5:** We have constructed the set $J = \{(\tau, \alpha) = (\tau_\alpha, \alpha_\tau) \mid \tau \in \mathbb{R}, \alpha \in (0, 1]\}$.

Note that Step 2 is not hard computationally, since very efficient algorithms are known for communicating MDP's. In Step 3 one should use the aggregated MDP method of [14], where each strongly communicating class is replaced by one state. In addition to computational efficiency, this method will automatically yield a deterministic optimal policy satisfying the conditions of Theorem 4.2. Also, since when k is incremented by one, only one immediate reward changes in the aggregated problem (the rest of the data stay the same), perhaps a parametric solution method can be used (e.g. by using LP algorithms for solving the aggregated problem). Further computational efficiency can be gained by quitting

Step 3 as soon as $\alpha_k = 1$ for some k (since all subsequent α_k 's are automatically equal to one). Note also that steps 1 and 2 need not be repeated for different starting states. Finally, we note that before starting the algorithm, one should check whether MDP Γ is communicating (easily verifiable conditions can be found in [9]). If so, the complete characterization is immediately available from Corollary 4.1.

V. PROBLEMS WITH MULTIPLE REWARDS AND CONSTRAINTS—FORMULATIONS

A natural extension of the percentile objective criteria is to the case where each action carries multiple immediate rewards, i.e., each immediate reward is actually a vector of some fixed length L .

$$r(i, a) \in \mathbb{R}^L \text{ for } i \in S, a \in A(i).$$

The definition of the limiting average reward in Section I leads to a vector R of random variables.

At this point two approaches can be taken. Under the first approach, a separate target level-percentile pair would be specified for each of the L components of $R = (R_1, \dots, R_L)$. This leads to the following multi-objective version of Problem 1 (of Section II).

Problem 4: Fix $s_1 \in S$. Given a pair of vectors $(\tau, \alpha) \in \mathbb{R}^L \times [0, 1]^L$, does there exist a policy u such that

$$P_u(R_l \geq \tau_l \mid X_1 = s_1) \geq \alpha_l \text{ for } l = 1, \dots, L?$$

This problem appears to present serious difficulties and is presently unsolved. Below we present an example showing that stationary policies do not suffice for this case, thus indicating that it is unlikely that a simple extension of the results and methods developed in Section IV will work in this case.

Example 5.1: Consider the following MDP with $L = 2$

$$\begin{aligned} r(1, 1) &= (1, 0), & p_{111} &= 1, & r(1, 2) &= (0, 0), & p_{122} &= 1 \\ r(2, 1) &= (0, 1), & p_{212} &= 1. \end{aligned}$$

Thus action 1 is absorbing in both states, and action 2 in state 1 results in immediate rewards of $(0, 0)$ and transition to state 2 with probability one.

Suppose the initial state is one and that the target level-percentile pairs are $(\frac{1}{2}, \frac{1}{2})$ for each component of the reward vector. Note that for any stationary policy f

$$\begin{aligned} P_f(R_1 = 1 \mid X_1 = 1) &= 1, \\ P_f(R_2 = 0 \mid X_1 = 1) &= 1, \text{ if } f_{11} = 1 \end{aligned}$$

and

$$\begin{aligned} P_f(R_1 = 0 \mid X_1 = 1) &= 1, \\ P_f(R_2 = 1 \mid X_1 = 1) &= 1, \text{ if } f_{11} < 1. \end{aligned}$$

Therefore, no stationary policy suffices.

Let g be the deterministic policy that takes action 1 in each state, and let u^1 be the decision rule that takes actions 1 and 2 with probabilities $1/2$ each in state 1. Define the nonstationary

policy u to be $u = (u^1, g)$ (i.e., u uses the decision rule u^1 at time 1 and follows g thereafter). It is easy to see that

$$P_u\left(R_1 \geq \frac{1}{2} \mid X_1 = 1\right) = \frac{1}{2}, \quad P_u\left(R_2 \geq \frac{1}{2} \mid X_1 = 1\right) = \frac{1}{2}$$

and thus u achieves both the specified target-levels at the corresponding percentiles. In fact the same conclusions apply for any $\tau_1, \tau_2 \in (0, 1)$.

Under the second approach to a problem with multiple rewards, a separate target level is specified for each component of R , and all target levels are required to be achieved simultaneously at a single percentile level α .

Problem 5: Fix $s_1 \in S$. Given a vector $\tau \in \mathbb{R}^L$ and $\alpha \in [0, 1]$, does there exist a policy u such that

$$P_u(R_l \geq \tau_l, l = 1, \dots, L \mid X_1 = s_1) \geq \alpha? \quad (5.1)$$

Intuitively, the difference between the two approaches is that in Problem 4, the requirements are placed on the marginal distributions of the components of R , while in Problem 5 the requirement is placed on the joint distribution of R . Henceforth, we will refer to these two approaches as the "marginal-probability" and the "joint-probability" formulations, respectively. While the marginal-probability formulation provides for more modeling flexibility, the advantage of the joint-probability formulation is that it leads to more tractable problems: most of the results obtained for Problem 1 will be extended to Problem 5.

We note that an extension to multiple rewards is especially important, since some of the components of $r(i, a)$ can be regarded as negatives of the costs. In this case, the corresponding components of R and τ can be regarded as constraints which must be satisfied at the specified percentile level (either singly in Problem 4 or jointly in Problem 5). This can be seen as a generalization of the "sample path constraint" of Ross and Varadarajan [13] and [14] (which in our notation corresponds to $\alpha = 1$ and $L = 1$).

VI. BASIC RESULTS FOR THE MULTIPLE REWARDS CASE

In this section we consider Problem 5 for the case of communicating MDP's. We employ the linear-programming-based techniques developed in [6], [11], and [13] and introduced in Section III above. It should be noted that the problem considered in this section is related to the problem of finding optimal policies in average-reward communicating MDP's with state-action frequency constraints. It is well known (see e.g., [7, example 9.3]) that stationary policies may not be optimal in this case. For a problem with one inequality constraint, [13] shows that an ϵ -optimal stationary policy can always be found (the policy is generally not deterministic). This result is related to Theorem 6.2.

In the sequel, all vector inequalities and equalities are defined componentwise, that is $R \geq \tau$ means $R_l \geq \tau_l$, $l = 1, \dots, L$.

We first state some preliminary definitions and results. Consider the following polyhedral set

$$\Delta = \left\{ \begin{array}{l} \sum_{a \in A(i)} x_{ia} = \sum_{j \in S} \sum_{a \in A(j)} p_{ja} x_{ja}, \quad i \in S \\ \sum_{i \in S} \sum_{a \in A(i)} x_{ia} = 1 \\ x_{ia} \geq 0, \quad i \in S, a \in A(i) \end{array} \right. \quad (6.1)$$

(this is simply the feasible region of $LP(k)$ of Section III). For $\mathbf{x} = (x_{ia}) \in \Delta$, define a stationary policy

$$f(\mathbf{x})_{ia} = \begin{cases} \frac{x_{ia}}{\sum_{a \in A(i)} x_{ia}} & \text{if } i \in S, \sum_{a \in A(i)} x_{ia} > 0, \\ & a \in A(i) \\ \frac{1}{|A(i)|} & \text{if } i \in S, \sum_{a \in A(i)} x_{ia} = 0. \end{cases} \quad (6.2)$$

Define the following random variable (whenever it exists), representing long-term average state-action frequencies

$$Z_{ia} = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T 1[X_t = i, A_t = a]. \quad (6.3)$$

We will need the following well-known results, the proofs of which can be found in [11] and [13].

Lemma 6.1: Let Γ be an arbitrary MDP.

i) If f is a stationary policy then P_f -almost surely, Z is well-defined, $Z \in \Delta$, and

$$R = \sum_{i \in S} \sum_{a \in A(i)} r(i, a) Z_{ia}.$$

ii) If f is a stationary policy and f is unichain, then

$$Z_{ia} = \pi(f)_i f_{ia} \quad P_f - \text{a.s.}$$

where $\pi(f)$ is the unique stationary probability vector of $P(f)$.

iii) If $\mathbf{x} \in \Delta$ and $f(\mathbf{x})$ is unichain, then

$$Z = \mathbf{x} P_{f(\mathbf{x})} - \text{a.s.}$$

iv) If Γ is a communicating MDP and $\mathbf{x} \in \Delta$, $\mathbf{x} > 0$, then $f(\mathbf{x})$ is an irreducible stationary policy.

Let τ be a given target vector and α a given percentile level.

We now define the following linear program LP

max b

Subject to

$$\begin{array}{l} \sum_{a \in A(i)} x_{ia} = \sum_{j \in S} \sum_{a \in A(j)} p_{ja} x_{ja} \quad i \in S \\ \sum_{i \in S} \sum_{a \in A(i)} x_{ia} = 1 \\ \sum_{i \in S} \sum_{a \in A(i)} r(i, a) x_{ia} \geq \tau_l \quad l = 1, \dots, L \\ x_{ia} \geq b, \quad i \in S, a \in A(i) \\ b \geq 0. \end{array}$$

Note that the feasible region of LP is contained in $\Delta \times \mathbf{R}$.

Theorem 6.1: Let Γ be a communicating MDP.

i) If LP is infeasible, then for any policy u

$$P_u(R \geq \tau \mid X_1 = s_1) = 0.$$

ii) Suppose LP is feasible. Let (\mathbf{x}^*, b^*) be an optimal solution and $f^* = f(\mathbf{x}^*)$. If $b^* > 0$, or f^* is unichain, then

$$P_{f^*}(R \geq \tau \mid X_1 = s_1) = 1.$$

Proof:

- i) The proof is analogous to the proof of Proposition 2 in [14].
- ii) If $b^* > 0$ then f^* is irreducible by Lemma 6.1-iv) and thus, by Lemma 6.1-iii), $\mathbf{x}^* = Z P_{f^*}$ -a.s. It now follows by Lemma 6.1-i) and the feasibility of \mathbf{x}^* that

$$R \geq \tau P_{f^*} - \text{a.s.}$$

This result is a counterpart of Theorem 4.1 for the single-objective case. When conditions in part ii) of Theorem 6.1 hold, it provides a solution to Problem 5 for any $\alpha \in [0, 1]$, and if the condition in part i) holds then Problem 5 has no solutions for any α . Unlike Theorem 4.1, however, the current result does not provide a complete characterization of solutions. If the optimal value b^* of LP is equal to zero and $f(\mathbf{x}^*)$ is not unichain, then it is not currently known whether Problem 5 has any solutions or any solutions in stationary policies. The following example shows that it is possible to have a situation where no feasible stationary policies exist when $b^* = 0$.

Example 6.1: Consider the following MDP Γ with $L = 2$

$$\begin{array}{cc} i = 1 & i = 2 \\ \begin{array}{l} r(1, 1) = (1, 0), \quad p_{111} = 1 \\ r(1, 2) = (0, 0), \quad p_{122} = 1 \end{array} & \begin{array}{l} r(2, 1) = (0, 1), \quad p_{212} = 1 \\ r(2, 2) = (0, 0), \quad p_{221} = 1 \end{array} \end{array}$$

where $s_1 = 1$, $\tau = (1/2, 1/2)$ and $\alpha > 0$. Then LP is feasible with $b^* = 0$ and

$$\mathbf{x}^* = (x_{11}, x_{12}, x_{21}, x_{22})^T = (1/2, 0, 1/2, 0)^T.$$

Thus $f(\mathbf{x}^*)$ is not unichain, and in fact it is easy to see that for any stationary policy f , $P_f(R \geq \tau) = 0$. It is not known whether there exists some nonstationary policy u such that $P_u(R \geq \tau) > 0$.

It might be reasonable to suppose that when $b^* = 0$, the presence of feasible stationary policies might be detected by checking whether $f(\mathbf{x}^*)$ is unichain for any optimal basic feasible solution \mathbf{x}^* of LP (this would cover Example 6.1 where there is only one optimal basic feasible solution). The following example, however, shows that it is possible that $b^* = 0$, $f(\mathbf{x}^*)$ is not unichain for any optimal basic feasible solution, and yet, feasible stationary policies exist for any $\alpha > 0$.

Example 6.2: Consider the following MDP Γ with $L = 3$

$$\begin{array}{cc} i = 1 & i = 2 \\ \begin{array}{l} r(1, 1) = (1, 0, 0), \quad p_{111} = 1 \\ r(1, 2) = (0, 0, 0), \quad p_{122} = 1 \\ r(1, 3) = (-1, 0, 0), \quad p_{131} = 1 \end{array} & \begin{array}{l} r(2, 1) = (0, 1, 0), \quad p_{211} = 1 \\ r(2, 2) = (0, 1, 0), \quad p_{223} = 1 \\ r(2, 3) = (0, 1, 0), \quad p_{232} = 1 \end{array} \\ i = 3 & \\ \begin{array}{l} r(3, 1) = (0, 0, 1), \quad p_{313} = 1 \\ r(3, 2) = (0, 0, 0), \quad p_{322} = 1 \end{array} & \end{array}$$

and let $s_1 = 1$. Take some $\alpha > 0$ and $\tau = (1/4, 1/4, 1/4)$. It is not hard to verify that the resulting LP has the optimal value $b^* = 0$ with only two optimal basic feasible solutions

$$\begin{aligned} \mathbf{x}^1 &= (x_{11}, x_{12}, x_{13}, x_{21}, x_{22}, x_{31}, x_{32})^T \\ &= (1/4, 1/4, 0, 1/4, 0, 1/4, 0)^T \end{aligned}$$

and

$$\mathbf{x}^2 = (1/4, 0, 0, 0, 1/4, 1/4, 1/4)^T.$$

Neither $f(\mathbf{x}^1)$ nor $f(\mathbf{x}^2)$ is unichain and, in fact, the probability of achieving τ is zero for both of these policies. If we take the feasible point

$$\mathbf{x}^* = \frac{1}{2}\mathbf{x}^1 + \frac{1}{2}\mathbf{x}^2 = (1/4, 1/8, 0, 1/8, 1/8, 1/4, 1/8)^T$$

then $f(\mathbf{x}^*)$ is unichain and $P_f(\mathbf{x}^*)(R \geq \tau \mid X_1 = s_1) = 1$

We will call a target vector τ for which LP is feasible and has optimal value $b^* = 0$ an indeterminate target vector.

We note that this case does not arise in the case of unichain MDP's (since one of the two conditions of Theorem 6.1 must be met), and we have the following corollary.

Corollary 6.1: Suppose Γ is a unichain MDP. Then either LP is infeasible, in which case Problem 5 has no solutions for any $\alpha > 0$, or LP is feasible with an optimal solution (b^*, \mathbf{x}^*) , in which case for $f = f(\mathbf{x}^*)$, $P_f(R \geq \tau \mid X_1 = s_1) = 1$.

In the remainder of this section we show that the difficulties associated with indeterminate target vectors can always be avoided by a slight relaxation of the target vector and that indeterminate target vectors are sufficiently "rare" in the set of all possible target vectors. We will need the following result.

Lemma 6.2: Suppose Γ is a communicating MDP. Take $\mathbf{x} \in \Delta$. Then for any $\epsilon > 0$ and $s_1 \in S$, there exists an irreducible stationary policy f such that

$$P_f(\|\mathbf{Z} - \mathbf{x}\| \leq \epsilon \mid X_1 = s_1) = 1$$

(where $\|\cdot\|$ is an arbitrary vector norm).

Proof: If $\mathbf{x} > 0$, then $f = f(\mathbf{x})$ is irreducible by Lemma 6.1-iv), and it follows by Lemma 6.1-iii) that $\mathbf{Z} = \mathbf{x}$ P_f -a.s.

Now suppose that $x_{ia} = 0$ for some $i \in S$, $a \in A(i)$. Let g be a completely randomized (stationary) policy (i.e., $g_{ia} = \frac{1}{|A(i)|}$ for any $i \in S$, $a \in A(i)$). Since Γ is a communicating MDP, g must be irreducible. By Lemma 6.1-ii), $\mathbf{Z} = \mathbf{x}(g)$ P_g -almost surely, where $\mathbf{x}(g)_{ia} = \pi(g)_{ia}$ for $i \in S$, $a \in A(i)$. By Lemma 6.1-i), $\mathbf{x}(g) > 0$ and $\mathbf{x}(g) \in \Delta$. Let

$$\mathbf{x}(\lambda) = \lambda \mathbf{x} + (1 - \lambda)\mathbf{x}(g) \text{ for } \lambda \in (0, 1).$$

Clearly, $\mathbf{x}(\lambda) \in \Delta$ and $\mathbf{x}(\lambda) > 0$ for any $\lambda < 1$. It follows by continuity of $\mathbf{x}(\lambda)$ with respect to λ that we can choose $\lambda^* \in (0, 1)$ so that

$$\|\mathbf{x}(\lambda^*) - \mathbf{x}\| \leq \epsilon. \quad (6.4)$$

Let $f = f(\mathbf{x}(\lambda^*))$. By Lemma 6.1-iv), f must be irreducible. It follows by Lemma 6.1-iii) that $\mathbf{Z} = \mathbf{x}(\lambda^*)$ P_f -a.s. The result now follows immediately from (6.4).

We are now ready to prove the following result.

Theorem 6.2: Suppose Γ is a communicating MDP and τ is an indeterminate target vector. Let δ be an arbitrary vector with positive components and choose $\epsilon > 0$. Then there exists

an irreducible stationary policy f such that

$$P_f(R \geq \tau - \epsilon \delta \mid X_1 = s_1) = 1.$$

Proof: Let (b^*, \mathbf{x}^*) be an optimal solution of LP with target vector τ . By assumption, $b^* = 0$. By Lemma 6.2, for any $\gamma > 0$, there exists an irreducible stationary policy f such that $\|\mathbf{x}' - \mathbf{x}^*\| \leq \gamma$, where $\mathbf{x}' = \mathbf{Z}$ is a constant P_f -almost surely. Choose γ small enough so that

$$\sum_{i \in S} \sum_{a \in A(i)} x'_{ia} \tau(i, a) \geq \tau - \epsilon \delta \quad P_f \text{ a.s.} \quad (6.5)$$

(this can always be done since the left-hand side of (6.5) is a continuous function of \mathbf{x}' and $\sum_{i \in S} \sum_{a \in A(i)} x'_{ia} \tau(i, a) \geq \delta$).

Since f is irreducible, by Lemma 6.1-ii), P_f -almost surely $\mathbf{x}' > 0$, i.e., $\mathbf{x}' \geq b' > 0$ for some $b' \in \mathbb{R}$. It follows from (6.5) that (b', \mathbf{x}') is feasible in LP with the target vector $\tau - \epsilon \delta$ and consequently, the optimal value for this LP is positive. The result now follows from Theorem 6.1-ii).

Thus, any strict relaxation of an indeterminate target vector produces a target vector for which Problem 5 can be solved by an irreducible policy for any percentile level α . Geometrically, the situation is as follows: let $T = \{\tau \mid LP \text{ is feasible}\}$. T must be a closed set. Let

$TS = \{\tau \mid \text{Problem 5 has a solution in unichain policies}$

for any percentile $\alpha \in [0, 1]\}$,

$TF = \{\tau \mid LP \text{ has optimal value } b^* > 0\}$.

$TI = \{\tau \mid \tau \text{ is an indeterminate target vector}\}$.

Then $TS \cup TI = T$, $TF \subset TS$, and $TI \subset \text{boundary}\{T\}$. Note also that the intersection of TS and TI need not be empty, as shown by Example 6.2. We illustrate the relationships between these sets in the context of Example 6.1, where

$$T = \{\tau_1 \leq 1, \tau_2 \leq 0\} \cup \{\tau_1 \leq 0, \tau_2 \leq 1\} \\ \cup \{\tau_1 + \tau_2 \leq 1, \tau_1 > 0, \tau_2 > 0\}$$

(represented by the shaded region on Fig. 1)

$$TS = T \setminus \{\tau_1 + \tau_2 = 1, \tau_1 > 0, \tau_2 > 0\},$$

$$TI = \{\tau_1 = 1, \tau_2 \leq 0\} \cup \{\tau_1 \leq 0, \tau_2 = 1\} \\ \cup \{\tau_1 + \tau_2 = 1, \tau_1 > 0, \tau_2 > 0\}$$

(the boundary of T), and

$$TF = T \setminus TI.$$

Remark 6.1: In summary, our results for the communicating case with multiple rewards closely parallel the corresponding results for the single reward: for "most" target vectors, either Problem 5 has no solution or else it is solvable by irreducible policies for any percentile level. The differences from the single reward case lie in the fact that the feasible stationary policies might have to be randomized (for single reward deterministic policies sufficed), and in our inability to

Fig. 1. The set of possible target vectors for Example 6.1.

handle (completely) the indeterminate target vector case. If the modeler has some flexibility in setting the target vector, the indeterminate case can always be avoided. In some cases, however, such flexibility might not exist. Therefore, we consider the further study of the indeterminate case to be important. Specifically, the following questions should be addressed:

- 1) Must nonstationary feasible policies exist when τ is indeterminate? In particular, do such policies exist in Example 6.1?
- 2) Can the indeterminate target vectors for which Problem 5 has a solution in unichain policies (i.e., $\tau \in TI \cap TS$) be characterized? It would be particularly interesting to find a computationally simple characterization or show that one does not exist.

We now turn our attention to the general (multichain) MDPs. Surprisingly, the extension of our communicating MDP results to this case can be done quite easily by employing the decomposition and sample path theory.

As in Section IV above, let C_1, \dots, C_K, T be the strongly communicating classes and the set of transient states of Γ , and let $\Gamma(k)$ be the MDP restricted to C_k . Define the index set

$$J_\tau = \{k \mid 1 \leq k \leq K, \text{ The optimal value of } LP \text{ for } \Gamma(k) \text{ is positive}\}.$$

For $k \in J_\tau$, let f_k^* be the stationary policy of Theorem 6.1-ii) associated with the MDP $\Gamma(k)$. Following Section IV, define MDP Γ_τ whose states, actions, and the transition law are the same as Γ , but with the rewards defined by

$$r^\tau(i, a) := \begin{cases} 1 & \text{if } i \in C_k, a \in A(i) \text{ and } k \in J_\tau \\ 0 & \text{otherwise.} \end{cases} \quad (6.6)$$

Theorem 6.3: Assume the target vector τ is not an indeterminate target vector for any $\Gamma(k)$, $k = \{1, \dots, K\}$. Let f^* be an optimal stationary policy in Γ_τ which coincides with f_k^* on C_k for $k \in J_\tau$.² There exists a policy u satisfying

$$P_u(R \geq \tau \mid X_1 = s_1) \geq \alpha \quad (6.7)$$

if and only if $\phi^\tau(f^*, s_1) \geq \alpha$. Further, if the target vector τ can be achieved at percentile α , then it can be achieved by the stationary policy f^* .

Proof: Exactly the same as in Theorem 4.2.

This result provides a constructive answer to Problem 5, provided τ satisfies the assumption of Theorem 6.3.

²See the footnote in Theorem 4.2.

Remark 6.2: Similarly to Problem 3 of Section II, define

$$\alpha_\tau = \sup \{\alpha \in [0, 1] \mid \exists \text{ a policy } u \text{ s.t. (5.1) holds}\}.$$

It is clear from the proof of Theorem 4.2 that $\alpha_\tau = \phi^\tau(f^*, s_1)$ and the policy f^* constructed above achieves τ at percentile α_τ .

VII. PROBLEMS FOR FURTHER RESEARCH

In the preceding sections we have outlined several problems for further research. For the multiple reward case, a satisfactory treatment of the marginal-probability formulation described in Section V would be very useful. Open problems connected with the indeterminate target vector case were discussed in Remark 6.1.

Another important open problem associated with the percentile objective criterion is the satisfactory treatment of the discounted case. Analysis of a similar problem for this case can be found in Bouakiz [5]; however, no algorithmic results were obtained. Problems 1–3 of Section II appear to be much harder in this case, mainly because no equivalent of the decomposition theory is known (or perhaps, possible) for discounted MDP's.

Design and Analysis of Fuzzy Identifiers of Nonlinear Dynamic Systems

Li-Xin Wang, *Member, IEEE*

Abstract—In this paper, we use fuzzy systems as identifiers for nonlinear dynamic systems. We provide a theoretical justification for the fuzzy identifiers by proving that they are capable of following the output of a general nonlinear dynamic system to arbitrary accuracy in any finite time interval. The fuzzy identifiers are constructed from a set of adaptable fuzzy IF-THEN rules and can combine both numerical information (in the form of input-output pairs obtained by exciting the system with an input signal and measuring the corresponding outputs) and linguistic information (in the form of IF-THEN rules about the behavior of the system in terms of vague and fuzzy words) into their designs in a uniform fashion. We develop two fuzzy identifiers. The first one is designed through the following four steps: 1) define some fuzzy sets in the state space $U \subset R^n$ of the system; these fuzzy sets do not change; 2) construct fuzzy rule bases of the fuzzy identifier which comprise rules whose IF parts constitute all the possible combinations of the fuzzy sets defined in 1); 3) design the fuzzy systems in the fuzzy identifier based on the fuzzy rule bases of 2); and 4) develop an adaptive law for the free parameters in the fuzzy identifier. The second fuzzy identifier is designed in a similar way as the first one except that: a) the parameters characterizing the fuzzy sets in the state space change during the adaptation procedure; and b) the fuzzy systems and the adaptive law are different. We prove that: 1) both fuzzy identifiers are globally stable in the sense that all variables in the fuzzy identifiers are uniformly bounded, and 2) under some conditions the identification errors of both fuzzy identifiers converge to zero asymptotically. Finally, we simulate the fuzzy identifiers for identifying the chaotic glycolytic oscillator, and the results show that: 1) the fuzzy identifiers can approximate the chaotic system at a reasonable speed and accuracy without using any linguistic information, and 2) by incorporating some fuzzy linguistic IF-THEN rules about the behavior of the system into the fuzzy identifiers, the speed and accuracy of the fuzzy identifiers are greatly improved.

I. INTRODUCTION

EXISTING identification schemes determine a model for a system based on the input-output pairs which are collected by exciting the system with an input signal and measuring the corresponding outputs [8], [20]. For many complex systems, however, an important portion of information comes from another source: human experts, who are very familiar with the systems and can provide linguistic descriptions about the behavior of the system in terms of vague and fuzzy words. For example, although we may not know the exact mathematical model of a car, we can describe the behavior of

the car as follow: "IF apply 'more' force to the accelerator of the car, THEN the speed of the car will 'increase'," where the 'more' and 'increase' are characterized by fuzzy membership functions. Although these linguistic descriptions are not precise, they provide important information about the system. In fact, for many industrial process control problems, a human operator can determine a set of successful control rules based only on the linguistic descriptions about the processes [5], [11], [13], [17], [38]. Unfortunately, existing identification schemes ignore this important source of information and cannot incorporate the linguistic descriptions directly into the identifiers. The goal of this paper is to develop identifiers of nonlinear systems which combine both linguistic descriptions and input-output pairs in a uniform fashion into their designs.

Fuzzy systems are powerful tools for achieving this goal because, on one hand, fuzzy systems are constructed from fuzzy IF-THEN rules so that linguistic descriptions can be naturally incorporated into the fuzzy identifiers; on the other hand, adaptive laws can be developed (as shown in this paper) to adjust the free parameters of the fuzzy identifiers to make them match the input-output pairs. Specifically, the initial identifiers are constructed from linguistic information, and the parameters are then adjusted on-line based on input-output pairs. In this way, the fuzzy identifiers combine both linguistic and numerical information into their designs.

The idea of fuzzy systems was introduced by Zadeh [41] very early in the literature of fuzzy sets. Research on fuzzy systems has been developed in two main directions. The first studies fuzzy systems in the same conceptual framework as classical systems and has given birth to a body of abstract results concerning the stability [4], [14], reachability [6], [25], observability [6], [25], etc., of fuzzy systems. The second direction is the linguistic approach to fuzzy systems [22], [30], [43], [44], in which a fuzzy system is constructed from a collection of fuzzy rules (propositions) and a fuzzy inference engine which uses techniques in approximate reasoning [1], [45]. This approach was used to synthesize fuzzy logic controllers [18], [19], [22] which has been successfully applied to a wide variety of practical problems during the past decade [5], [11], [13], [17], [30], [40]. We adapt this second approach to fuzzy systems in this paper.

The basic configuration of a fuzzy system is shown in Fig. 1. There are four components in a fuzzy system:

1) Fuzzy rule base which comprises fuzzy rules describing how the fuzzy system performs; it is the heart of the whole system in the sense that other three components are used to interpret and combine these rules to form the final system.

Manuscript received February 6, 1992; revised January 11, 1994 and April 30, 1994. Recommended by Associate Editor, S. P. Meyn.

IEEE Log Number 9406095.

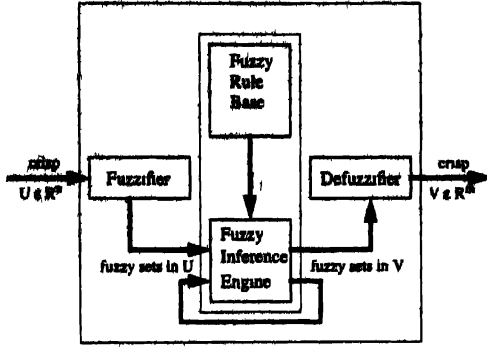

Fig. 1. Basic configuration of fuzzy systems.

2) Fuzzy inference engine which uses techniques in approximate reasoning to determine a mapping from the fuzzy sets in the input space $U \subset R^n$ to the fuzzy sets in the output space $V \subset R^m$.

3) Fuzzifier which maps crisp points in the input space into fuzzy sets in the input space.

4) Defuzzifier which maps fuzzy sets in the output space into crisp points in the output space. Depending upon whether there are fuzzifier and defuzzifier, we have two classes of fuzzy systems. The first class of fuzzy systems comprise only the fuzzy rule base and fuzzy inference engine and therefore operate in a pure fuzzy environment, i.e., inputs and outputs to these fuzzy systems are fuzzy variables. If there is a feedback (as shown in Fig. 1 by the dashed arrow line), we have the so-called fuzzy dynamic systems [4], [14], [32], [33]. The second class of fuzzy systems comprise all the four components and perform mappings from crisp $U \subset R^n$ to crisp $V \subset R^m$. In the literature, these second-class fuzzy systems are called fuzzy logic controllers [18], [19], because their most successful applications have been to control problems. In this paper, we use these second-class fuzzy systems as identifiers for nonlinear dynamic systems. Also, we consider only static fuzzy systems.

In Section II, we present a detailed description for each component of the fuzzy system and show the universal approximation properties of the fuzzy systems to nonlinear static and dynamic systems. In Sections III and IV, we develop two identifiers of nonlinear systems based on the fuzzy system models and study their stability and convergence properties. In Section V, we simulate the two fuzzy identifiers for a chaotic system and show how identification performance is improved by incorporating linguistic descriptions about the system into the fuzzy identifiers. Section VI concludes the paper.

II. DESCRIPTION AND ANALYSIS OF FUZZY SYSTEMS

Fig. 1 shows the basic configuration of the fuzzy systems considered in this paper. The fuzzy system performs a mapping from crisp $U \subset R^n$ to crisp $V \subset R^m$. We assume that $U = U_1 \times \cdots \times U_n$ and $V = V_1 \times \cdots \times V_m$, where $U_i, V_j \subset R$, $i = 1, 2, \dots, n$, and $j = 1, 2, \dots, m$. We first briefly review some basic concepts in fuzzy sets and systems theory which are useful in describing the fuzzy systems and then present a detailed description for each component of the fuzzy system.

A fuzzy set [42] F of a universe of discourse U is characterized by a membership function $\mu_F: U \rightarrow [0, 1]$ which associates with each element u of U a number $\mu_F(u)$ in the interval $[0, 1]$ which represents the grade of membership of u in F . The label F of a fuzzy set is often some linguistic term like "small," "large," etc.. A linguistic variable [44] is a variable whose values are words in a natural or artificial language, and these words are labels of fuzzy sets. A fuzzy IF-THEN rule [44] is an expression of the form "IF A THEN B ," where A and B are statements about what values the linguistic variables take on. A triangular norm ' \star ' is defined as a mapping from $[0, 1] \times [0, 1]$ to $[0, 1]$, and the most commonly used triangular norms are [18]

$$\begin{aligned} \min[x, y] & \quad \text{intersection} \\ x \star y &= xy \quad \text{algebraic product} \\ \max[0, x + y - 1] & \quad \text{bounded product} \end{aligned} \quad (1)$$

where $x, y \in [0, 1]$. A triangular conorm ' $\dot{+}$ ' is a mapping from $[0, 1] \times [0, 1]$ to $[0, 1]$, and the most commonly used triangular conorms are [18]

$$\begin{aligned} \max[x, y] & \quad \text{union} \\ x + y &= x + y - xy \quad \text{algebraic sum} \\ \min[1, x + y] & \quad \text{bounded sum.} \end{aligned} \quad (2)$$

Let F_1, \dots, F_n be fuzzy sets in X_1, \dots, X_n , respectively; the cartesian product of F_1, \dots, F_n , denoted by $F_1 \times \cdots \times F_n$, is a fuzzy set in the product space $X = X_1 \times \cdots \times X_n$ with membership function

$$\mu_{F_1 \times \cdots \times F_n}(x_1, \dots, x_n) = \mu_{F_1}(x_1) \star \cdots \star \mu_{F_n}(x_n). \quad (3)$$

Let R and S be fuzzy sets in $X \times W$ and $W \times Y$, respectively; the supstar composition of R and S , denoted by $R \circ S$, is a fuzzy set in $X \times Y$ with membership function

$$\mu_{R \circ S}(x, y) = \sup_{w \in W} [\mu_R(x, w) \star \mu_S(w, y)]. \quad (4)$$

Let A and B be fuzzy sets in X and Y , respectively; the fuzzy implication $A \rightarrow B$, or 'IF A THEN B ', is defined as a fuzzy set in $X \times Y$ with membership function

$$\mu_{A \rightarrow B}(x, y) = \mu_A(x) \star \mu_B(y). \quad (5)$$

Operations other than \star may be used in (5) to define the fuzzy implication (see [18]).

A fuzzy rule base R is a collection of fuzzy IF-THEN rules

$$R = [R^1, R^2, \dots, R^M] \quad (6)$$

with

$$\begin{aligned} R^l: & \text{ IF } (x_1 \text{ is } F_1^l \text{ and } \cdots \text{ and } x_p \text{ is } F_p^l); \\ & \text{ THEN } (y_1 \text{ is } G_1^l, \dots, y_q \text{ is } G_q^l) \end{aligned} \quad (7)$$

where $\underline{x} = (x_1, \dots, x_n)^T$ and $\underline{y} = (y_1, \dots, y_m)^T$ are the input and output vectors to the fuzzy system, respectively, F_i^l and G_j^l are labels of fuzzy sets in U_i and V_j , respectively, $1 \leq p \leq n$, $1 \leq q \leq m$, and $l = 1, 2, \dots, M$. It is clear that R^l of (7) can be decomposed into a collection of q rules

$$R^l = [R_1^l, \dots, R_q^l] \quad (8)$$

where

$$R_j^l: \text{IF } (x_1 \text{ is } F_1^l \text{ and } \dots \text{ and } x_p \text{ is } F_p^l); \\ \text{THEN } (y_j \text{ is } G_j^l) \quad (9)$$

$j = 1, 2, \dots, q.$

A fuzzy inference engine uses the rules in the fuzzy rule base to determine a mapping from fuzzy sets in U to fuzzy sets in V based on fuzzy logic operations. In the fuzzy inference engine, the IF part of R_j^l defines a cartesian product of F_1^l, \dots, F_p^l , and the R_j^l itself is viewed as a fuzzy implication $F_1^l \times \dots \times F_p^l \rightarrow G_j^l$. Let A be an arbitrary fuzzy set in U , then each R_j^l of (9) determines a fuzzy set $A \circ R_j^l$ in V_j based on the supstar composition

$$\mu_{A \circ R_j^l}(y_j) = \sup_{\underline{x} \in U} [\mu_A(\underline{x}) \star \mu_{F_1^l \times \dots \times F_p^l \rightarrow G_j^l}(\underline{x}, y_j)] \\ = \sup_{\underline{x} \in U} [\mu_A(\underline{x}) \star \mu_{F_1^l}(x_1) \star \dots \star \mu_{F_p^l}(x_p) \star \mu_{G_j^l}(y_j)] \quad (10)$$

where $y_j \in V_j$. The final fuzzy set $A \circ R_j$ ($R_j = [R_j^1, \dots, R_j^M]$) in V_j determined by the fuzzy inference engine is obtained by combining (10) for $l = 1, 2, \dots, M$ using the triangular conorm $\dot{+}$

$$\mu_{A \circ R_j}(y_j) = \mu_{A \circ R_j^1}(y_j) \dot{+} \dots \dot{+} \mu_{A \circ R_j^M}(y_j). \quad (11)$$

In summary, the fuzzy inference engine determines a mapping from fuzzy set A in U to fuzzy set $A \circ R$ in V by¹

$$\mu_{A \circ R}(\underline{y}) = (\mu_{A \circ R_1}(y_1), \dots, \mu_{A \circ R_m}(y_m))^T. \quad (12)$$

A fuzzifier maps a crisp point $\underline{x} = (x_1, \dots, x_n)^T \in U$ into a fuzzy set $A_x = [A_{x_1}, \dots, A_{x_n}]$ in $U = U_1 \times \dots \times U_n$, where A_{x_i} is a fuzzy set in U_i . If A_{x_i} is a fuzzy singleton with support x_i , i.e., $\mu_{A_{x_i}}(x'_i) = 1$ for $x'_i = x_i$ and $\mu_{A_{x_i}}(x'_i) = 0$ for all other $x'_i \in U_i$, then we call this a singleton fuzzifier. There are other types of fuzzifiers; see [34].

A defuzzifier maps a fuzzy set in V to a crisp point in V . The defuzzifier is needed because for most practical applications; a fuzzy system is required to give a crisp output, no matter whether it is used as a controller, a decision maker, etc.. Because the output of the fuzzy inference engine is a fuzzy set $A \circ R$ in V , the defuzzifier maps $A \circ R$ into a crisp point $\underline{y} \in V$. In the literature, the most commonly used defuzzifier is the following center average defuzzifier

$$y_j = \frac{\sum_{l=1}^M \bar{y}_j^l (\mu_{A \circ R_j^l}(\bar{y}_j^l))}{\sum_{l=1}^M (\mu_{A \circ R_j^l}(\bar{y}_j^l))} \quad (13)$$

where \bar{y}_j^l is the point in V_j at which $\mu_{G_j^l}(y_j)$ achieves its maximum value, $\mu_{A \circ R_j^l}(y_j)$ is given by (10), and $j = 1, 2, \dots, m$.

We propose a modified center average defuzzifier, defined as

$$y_j = \frac{\sum_{l=1}^M \bar{y}_j^l (\mu_{A \circ R_j^l}(\bar{y}_j^l) / \sigma_j^{l2})}{\sum_{l=1}^M (\mu_{A \circ R_j^l}(\bar{y}_j^l) / \sigma_j^{l2})} \quad (14)$$

where σ_j^{l2} is a parameter characterizing the shape of $\mu_{G_j^l}(y_j)$ such that the narrower the shape of $\mu_{G_j^l}(y_j)$, the smaller is σ_j^{l2} ;

¹ We assume that each y_j for $1 \leq j \leq m$ appears at least once in the R^l of (7), therefore $\mu_{A \circ R}(\underline{y})$ is an m -dimensional vector.

Fig. 2. Some subclasses of fuzzy systems.

for example, if $\mu_{G_j^l}(y_j) = \exp[-((y_j - \bar{y}_j^l)/\sigma_j^{l2})^2]$, then σ_j^{l2} is such a parameter. The modified center average defuzzifier is justified as follow. Common sense indicates that the sharper the shape of $\mu_{G_j^l}(y_j)$ is, the stronger is our belief that the output y_j should be nearer to $\bar{y}_j^l = \text{argsup}_{y_j \in V_j} (\mu_{G_j^l}(y_j))$ [according to the rule R_j^l of (9)]. The standard center average defuzzifier, (13), is a weighted average of the \bar{y}_j^l 's, and the weight $\mu_{A \circ R_j^l}(\bar{y}_j^l)$ determined by (10) do not take the shape of $\mu_{G_j^l}(y_j)$ into consideration. This is clearly not satisfactory based on our common sense. An obvious improvement is the modified center average defuzzifier (14).

Note that if we use the center average or modified center average defuzzifiers, we do not need to calculate the $\mu_{A \circ R_j}(y_j)$ of (11); we only need to calculate the $\mu_{A \circ R_j^l}(y_j)$ of (10) in the fuzzy inference engine.

We see that the fuzzy systems of Fig. 1 comprise a very rich class of static systems mapping from $U \subset R^n$ to $V \subset R^m$, because within each block there are many different choices, and many combinations of these choices can result in useful subclasses of fuzzy systems. If we view all the fuzzy systems as a set of functions, then each combination of these choices corresponds to a subset of the fuzzy systems, as shown for some examples in Fig. 2. We now show the specific functional forms of two subclasses of fuzzy systems which will be used later as basic building blocks of nonlinear system identifiers.

Definition 1: The set of fuzzy systems with singleton fuzzifier, center average defuzzifier, and product inference is all functions $f = (f_1, \dots, f_m)^T$ from U to V of the following form

$$f_j(\underline{x}) = \frac{\sum_{l=1}^M \bar{y}_j^l \left(\prod_{i=1}^p \mu_{F_i^l}(x_i) \right) \mu_{G_j^l}(\bar{y}_j^l)}{\sum_{l=1}^M \left(\prod_{i=1}^p \mu_{F_i^l}(x_i) \right) \mu_{G_j^l}(\bar{y}_j^l)} \quad (15)$$

where $\underline{x} = (x_1, \dots, x_n)^T \in U$, $1 \leq p \leq n$, and \bar{y}_j^l is the point at which $\mu_{G_j^l}(y_j)$ achieves its maximum value. Usually, $\mu_{G_j^l}(\bar{y}_j^l) = 1$. (15) is obtained by substituting (10) into (13),

replacing \star with the algebraic product in (1), and using the fact that if A is a fuzzy singleton with support \underline{x} (i.e., $\mu_A(\underline{x}) = 1$ and $\mu_A(\underline{x}') = 0$ for all $\underline{x}' \neq \underline{x}$), then $\mu_{A \circ R_j^i}(\underline{y}_j) = \sup_{\underline{x}' \in U} [\mu_A(\underline{x}') \star \mu_{F_1^i}(\underline{x}_1') \star \cdots \star \mu_{F_p^i}(\underline{x}_p') \star \mu_{G_j^i}(\underline{y}_j)] = \mu_{F_1^i}(\underline{x}_1) \star \cdots \star \mu_{F_p^i}(\underline{x}_p) \star \mu_{G_j^i}(\underline{y}_j)$.

Definition 2: The set of fuzzy systems with singleton fuzzifier, modified center average defuzzifier, product inference, and Gaussian membership function is all functions $f = (f_1, \dots, f_m)^T$ from U to V of the following form

$$f_j(\underline{x}) = \frac{\sum_{i=1}^M \bar{y}_j^i \left[\prod_{l=1}^p a_l^i \exp \left(-\frac{1}{2} \left(\frac{x_l - \bar{x}_l^i}{\sigma_l^i} \right)^2 \right) \right]}{\sum_{i=1}^M \left[\prod_{l=1}^p a_l^i \exp \left(-\frac{1}{2} \left(\frac{x_l - \bar{x}_l^i}{\sigma_l^i} \right)^2 \right) \right]} \bigg/ (\delta_j^i)^2 \quad (16)$$

which is obtained by taking $\mu_{F_l^i}(x_l) = a_l^i \exp(-(1/2)((x_l - \bar{x}_l^i)/\sigma_l^i)^2)$, $\mu_{G_j^i}(\underline{y}_j) = \exp(-(1/2)((\underline{y}_j - \bar{\underline{y}}_j^i)/\delta_j^i)^2)$, using the modified center average defuzzifier (14) with $\mu_{A \circ R_j^i}(\bar{\underline{y}}_j^i)$ given by (10) and $\star =$ algebraic product, and noticing that $\mu_A(\underline{x}) = 1$ and $\mu_A(\underline{x}') = 0$ for all $\underline{x}' \neq \underline{x}$, where $0 < a_l^i \leq 1$, $\sigma_l^i > 0$, $\delta_j^i > 0$, $\bar{x}_l^i \in U_l$, and $\bar{y}_j^i \in V_j$ are parameters.

The following theorem was proven in [34].

Theorem 1. Let Y be the set of fuzzy systems in Definition 2, and assume that U is compact. Then, for any real continuous function $g(\underline{x}) = (g_1(\underline{x}), \dots, g_m(\underline{x}))^T$ from U to V and arbitrary $\epsilon > 0$, there exist $f = (f_1(\underline{x}), \dots, f_m(\underline{x}))^T \in Y$ such that

$$\sup_{\underline{x} \in U} |f_j(\underline{x}) - g_j(\underline{x})| < \epsilon \quad (17)$$

for all $j = 1, 2, \dots, m$.

Next, we study the capability of using the fuzzy systems in Definition 2 to approximate dynamic systems over a finite time interval. Consider the dynamic system

$$\dot{\underline{x}} = A\underline{x} + g(\underline{x}, \underline{u}) \quad (18)$$

$$\underline{y} = h(\underline{x}, \underline{u}) \quad (19)$$

where $\underline{u} \in U$ is the input, $\underline{y} \in V$ is the output, $\underline{x} \in W \subset R^r$ is the state, A is a known Hurwitz matrix, and g, h are unknown continuous functions. We make the following assumption.

Assumption 2.1 For any \underline{u} in compact U and any finite initial condition $\underline{x}(0) = \underline{x}^0$, the solution $\underline{x}(t)$ of (18) satisfies $|\underline{x}(t) - \underline{x}^0| \leq b$ for some positive constant b and all $t \in [0, T]$, where T is an arbitrary positive constant.

Define K to be the set

$$K = \{(\underline{x}, \underline{u}) \in R^{r+n} : |\underline{x} - \underline{x}^0| \leq b + \epsilon, \underline{u} \in U\} \quad (20)$$

where $\epsilon > 0$ is an arbitrary constant, and \underline{x}^0 is any finite initial condition. Because U is compact and $|\underline{x}| \leq |\underline{x}^0| + b + \epsilon < \infty$, K is compact. Assumption 2.1 assures that for $\underline{u} \in U$ and finite \underline{x}^0 , (18) generates $(\underline{x}(t), \underline{u}(t)) \in K$ for $t \in [0, T]$. Let $\hat{g}(\underline{x}, \underline{u}|\Theta_g) = (\hat{g}_1(\underline{x}, \underline{u}|\Theta_g), \dots, \hat{g}_m(\underline{x}, \underline{u}|\Theta_g))^T$ and $\hat{h}(\underline{x}, \underline{u}|\Theta_h) = (\hat{h}_1(\underline{x}, \underline{u}|\Theta_h), \dots, \hat{h}_m(\underline{x}, \underline{u}|\Theta_h))^T$ be the fuzzy systems in Definition 2, where Θ_g, Θ_h are collections of the parameters $a_l^i, \bar{x}_l^i, \sigma_l^i$, and \bar{y}_j^i . Define Θ_g^* and Θ_h^* be such that

$$\sup_{\underline{x}, \underline{u} \in K} |\hat{g}(\underline{x}, \underline{u}|\Theta_g^*) - g(\underline{x}, \underline{u})| < \epsilon_g \quad (21)$$

$$\sup_{\underline{x}, \underline{u} \in K} |\hat{h}(\underline{x}, \underline{u}|\Theta_h^*) - h(\underline{x}, \underline{u})| < \epsilon_h \quad (22)$$

for some arbitrary $\epsilon_g > 0$ and $\epsilon_h > 0$. Theorem 1 assures the existence of the Θ_g^* and Θ_h^* . We now show that by replacing g and h in (18) and (19) with the \hat{g} and \hat{h} , we obtain a dynamic system whose output can approximate the output of (18) and (19) to arbitrary accuracy over any finite interval of time.

Theorem 2: Consider the dynamic system

$$\dot{\underline{x}} = A\underline{x} + \hat{g}(\underline{x}, \underline{u}|\Theta_g^*) \quad (23)$$

$$\underline{y} = \hat{h}(\underline{x}, \underline{u}|\Theta_h^*) \quad (24)$$

where $\underline{x}(0) = \underline{x}^0 = \underline{x}^0$, $\underline{u} \in U$, \hat{g} and \hat{h} are the fuzzy systems in Definition 2, and the parameters Θ_g^* and Θ_h^* are defined in (21) and (22). Then, for any $\epsilon > 0$, finite $T > 0$, and properly chosen ϵ_g and ϵ_h , we have that

$$\sup_{t \in [0, T]} |\underline{y}(t) - \underline{y}(t)| < \epsilon. \quad (25)$$

Proof of this theorem is given in Appendix A.

III. THE FIRST FUZZY IDENTIFIER

Consider the identification of the nonlinear system

$$\dot{\underline{x}} = f(\underline{x}) + g(\underline{x})u \quad (26)$$

where f and g are unknown functions from $U = U_1 \times \cdots \times U_n$ to $V = V_1 \times \cdots \times V_n$, $U_l, V_l \subset R$, $l = 1, 2, \dots, n$, and the input $u \in R$ and the state $\underline{x} \in R^n$ are assumed to be bounded and available for measurement. Our purpose is to develop an identification model where the f and g are replaced by fuzzy systems $\hat{f}(\underline{x}|\Theta_f)$ and $\hat{g}(\underline{x}|\Theta_g)$ and an adaptive law for updating the parameter matrices² Θ_f and Θ_g such that the identification model converges to the real system (26). First, we rewrite (26) as

$$\dot{\underline{x}} = \hat{f}(\underline{x}|\Theta_f^*) + \hat{g}(\underline{x}|\Theta_g^*)u + \underline{w} \quad (27)$$

where

$$\underline{w} \equiv [f(\underline{x}) - \hat{f}(\underline{x}|\Theta_f^*)] + [g(\underline{x}) - \hat{g}(\underline{x}|\Theta_g^*)]u, \quad (28)$$

$$\Theta_f^* \equiv \arg\min_{\Theta_f \in \Omega_f} [\sup_{\underline{x} \in U} |f(\underline{x}) - \hat{f}(\underline{x}|\Theta_f)|], \quad (29)$$

$$\Theta_g^* \equiv \arg\min_{\Theta_g \in \Omega_g} [\sup_{\underline{x} \in U} |g(\underline{x}) - \hat{g}(\underline{x}|\Theta_g)|] \quad (30)$$

and Ω_f and Ω_g are bounded feasible sets of Θ_f and Θ_g , respectively. We assume that $\Omega_f \equiv [\Theta: \text{tr}(\Theta\Theta^T) \leq M_f]$ and $\Omega_g \equiv [\Theta: \text{tr}(\Theta\Theta^T) \leq M_g]$, where M_f and M_g are given constants. Because of Theorem 1 and the boundedness of $u, |\underline{w}|$ can be arbitrarily small; therefore, without loss of generality we assume that $w_0 \equiv \sup_{t \geq 0} |\underline{w}(t)|$ is finite. We use the following serial-parallel identification model [24]

$$\dot{\underline{x}} = -\alpha \underline{x} + \alpha \underline{x} + \hat{f}(\underline{x}|\Theta_f) + \hat{g}(\underline{x}|\Theta_g)u \quad (31)$$

where α is a given positive scalar. The whole identification scheme is shown in Fig. 3. The goals of identification are the following.

²In the first fuzzy identifier we collect the parameters of the fuzzy systems into matrices, in the second fuzzy identifier we collect the parameters of the fuzzy systems into vectors

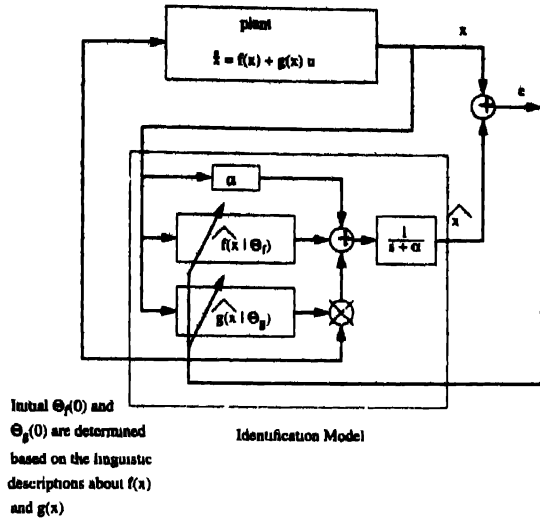

Fig. 3 Identification model using fuzzy systems.

Identification Goals: Specify the fuzzy systems $\hat{f}(\underline{x}|\Theta_f)$ and $\hat{g}(\underline{x}|\Theta_g)$, and develop an adaptive law for the parameters Θ_f and Θ_g such that:

- a) all signals involved in the identification model must be uniformly bounded, i.e., it must be guaranteed that $\hat{\underline{x}} \in L_\infty$, $\text{tr}(\Theta_f \Theta_f^T) \leq M_f$, and $\text{tr}(\Theta_g \Theta_g^T) \leq M_g$ (the input u and the system state \underline{x} are uniformly bounded by assumption), and
- b) the error $\underline{e} \equiv \underline{x} - \hat{\underline{x}}$ should be as small as possible.

To emphasize the point that our fuzzy identifiers can make use of linguistic descriptions about the unknown system (26), we make the following assumption.

Assumption 3.1: There are the following linguistic descriptions about the unknown functions $f(\underline{x})$ and $g(\underline{x})$

$$R_f^r: \text{IF } x_1 \text{ is } A_1^r \text{ and } \dots \text{ and } x_n \text{ is } A_n^r, \\ \text{THEN } f_1(\underline{x}) \text{ is } C_1^r, \dots, f_n(\underline{x}) \text{ is } C_n^r \quad (32)$$

and

$$R_g^s: \text{IF } x_1 \text{ is } B_1^s \text{ and } \dots \text{ and } x_n \text{ is } B_n^s, \\ \text{THEN } g_1(\underline{x}) \text{ is } D_1^s, \dots, g_n(\underline{x}) \text{ is } D_n^s \quad (33)$$

respectively, where A_i^r and B_i^s are fuzzy sets in U_i , C_i^r and D_i^s are fuzzy sets in V_i which achieve membership value one at some point, $r = 1, 2, \dots, N_f$, and $s = 1, 2, \dots, N_g$. We allow $N_f = N_g = 0$ which means that there are no linguistic descriptions about f and g .

Design of the First Fuzzy Identifier

Step 1: Define m_i fuzzy sets F_i^{j1} in U_i , such that for any $x_i \in U_i$, there exists at least one $\mu_{F_i^{j1}}(x_i) \neq 0$, where $i = 1, 2, \dots, n$, and $j_i = 1, 2, \dots, m_i$. We require that these F_i^{j1} 's include the A_i^r 's and B_i^s 's in (32) and (33). These fuzzy sets are fixed and will not change during the adaptation procedure of Step 4.

Step 2: Construct the fuzzy rules base of fuzzy system $\hat{f}(\underline{x}|\Theta_f)$ which consists of the following $\prod_{i=1}^n m_i$ rules

$$R^l: \text{IF } x_1 \text{ is } F_1^{j1} \text{ and } \dots \text{ and } x_n \text{ is } F_n^{jn}, \\ \text{THEN } \hat{f}_1(\underline{x}) \text{ is } G_1^l, \dots, \hat{f}_n(\underline{x}) \text{ is } G_n^l \quad (34)$$

where F_i^{j1} are defined in Step 1, G_i^l are fuzzy sets in V_i with $\mu_{G_i^l}(\theta_{if}^l) = 1$ for some parameter $\theta_{if}^l \in V_i$, $\Theta_f = (\theta_{1f}, \dots, \theta_{nf})^T$, $\theta_{if} = (\theta_{if}^1, \theta_{if}^2, \dots, \theta_{if}^{\prod_{i=1}^n m_i})^T$, $j_i = 1, 2, \dots, m_i$, $i = 1, 2, \dots, n$, and $l = 1, 2, \dots, \prod_{i=1}^n m_i$ with each l corresponds to a combination of (j_1, \dots, j_n) . Because the fuzzy rule base consists of all the possible rules concerning the fuzzy sets F_i^{j1} of Step 1 which include the A_i^r 's, it includes the linguistic descriptions in (32).

The initial parameters $\theta_{if}^l(0)$ are chosen as follow: if the IF part of G_i^l in (34) agrees with an IF part in (32), choose $\theta_{if}^l(0) = \text{argsup}_{y_i \in V_i} [\mu_{C_i^r}(y_i)]$; otherwise, choose $\theta_{if}^l(0)$ arbitrarily in V_i . Therefore, we incorporate the linguistic descriptions into the fuzzy identifier by constructing the initial fuzzy identifier based on these descriptions.

The fuzzy rule base and initial parameters of $\hat{g}(\underline{x}|\Theta_g)$ are determined in exactly the same way as $\hat{f}(\underline{x}|\Theta_f)$; we omit the details.

Step 3: Choose $\hat{f}(\underline{x}|\Theta_f) = (\hat{f}_1(\underline{x}|\theta_{1f}), \dots, \hat{f}_n(\underline{x}|\theta_{nf}))^T$ and $\hat{g}(\underline{x}|\Theta_g) = (\hat{g}_1(\underline{x}|\theta_{1g}), \dots, \hat{g}_n(\underline{x}|\theta_{ng}))^T$ to be fuzzy systems with singleton fuzzifier, center average defuzzifier, and product inference (Definition 1) based on the fuzzy rule bases constructed in Step 2

$$\hat{f}_i(\underline{x}|\theta_{if}) = \frac{\sum_{j_1=1}^{m_1} \dots \sum_{j_n=1}^{m_n} \theta_{if}^l [\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)]}{\sum_{j_1=1}^{m_1} \dots \sum_{j_n=1}^{m_n} [\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)]} \quad (35)$$

$$\hat{g}_i(\underline{x}|\theta_{ig}) = \frac{\sum_{j_1=1}^{m_1} \dots \sum_{j_n=1}^{m_n} \theta_{ig}^l [\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)]}{\sum_{j_1=1}^{m_1} \dots \sum_{j_n=1}^{m_n} [\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)]} \quad (36)$$

where $i = 1, 2, \dots, n$, and $l = 1, 2, \dots, \prod_{i=1}^n m_i$ with each l corresponds to a combination of (j_1, \dots, j_n) . Because of the way we define the fuzzy sets F_i^{j1} in Step 1, the denominators of (35) and (36) are nonzero for all $\underline{x} \in U$. Defining the fuzzy basis function [39]

$$p^l(\underline{x}) = \frac{\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)}{\sum_{j_1=1}^{m_1} \dots \sum_{j_n=1}^{m_n} [\mu_{F_1^{j_1}}(x_1) \dots \mu_{F_n^{j_n}}(x_n)]} \quad (37)$$

[l is defined as in (35) and (36)], collecting them into an $\prod_{i=1}^n m_i \times 1$ vector $\underline{p}(\underline{x})$, and collecting the θ_{if}^l and θ_{ig}^l into $\prod_{i=1}^n m_i \times 1$ vectors $\underline{\theta}_{if}$ and $\underline{\theta}_{ig}$ in the same order as $\underline{p}(\underline{x})$, we can rewrite (35) and (36) as

$$\hat{f}_i(\underline{x}|\theta_{if}) = \underline{\theta}_{if}^T \underline{p}(\underline{x}) \quad (38)$$

and

$$\hat{g}_i(\underline{x}|\theta_{ig}) = \underline{\theta}_{ig}^T \underline{p}(\underline{x}) \quad (39)$$

respectively. Recall that $\Theta_f \equiv (\theta_{1f}, \dots, \theta_{nf})^T$ and $\Theta_g \equiv (\theta_{1g}, \dots, \theta_{ng})^T$ and substitute (38) and (39) into (31); the fuzzy identifier becomes

$$\dot{\hat{\underline{x}}} = -\alpha \hat{\underline{x}} + \alpha \underline{x} + \Theta_f \underline{p}(\underline{x}) + \Theta_g \underline{p}(\underline{x}) u. \quad (40)$$

Step 4: Update the parameter matrices Θ_f and Θ_g using the following adaptive law

$$\dot{\Theta}_f = \begin{cases} \gamma_1 \underline{e} p^T(\underline{x}) & \text{if } (\text{tr}(\Theta_f \Theta_f^T) < M_f) \\ \text{or } (\text{tr}(\Theta_f \Theta_f^T) = M_f \text{ and } \underline{e}^T \Theta_f p(\underline{x}) \leq 0) \\ P[\gamma_1 \underline{e} p^T(\underline{x})] & \text{if } (\text{tr}(\Theta_f \Theta_f^T) = M_f \text{ and } \underline{e}^T \Theta_f p(\underline{x}) > 0), \end{cases} \quad (41)$$

$$\dot{\Theta}_g = \begin{cases} \gamma_2 \underline{e} p^T(\underline{x}) u & \text{if } (\text{tr}(\Theta_g \Theta_g^T) < M_g) \\ \text{or } (\text{tr}(\Theta_g \Theta_g^T) = M_g \text{ and } \underline{e}^T \Theta_g p(\underline{x}) u \leq 0) \\ P[\gamma_2 \underline{e} p^T(\underline{x}) u] & \text{if } (\text{tr}(\Theta_g \Theta_g^T) = M_g \text{ and } \underline{e}^T \Theta_g p(\underline{x}) u > 0) \end{cases} \quad (42)$$

where γ_1 and γ_2 are positive constants, $P[*]$ is the projection operator [7] defined as

$$P[\gamma_1 \underline{e} p^T(\underline{x})] \equiv \gamma_1 \underline{e} p^T(\underline{x}) - \gamma_1 \frac{\underline{e}^T \Theta_f p(\underline{x})}{\text{tr}(\Theta_f \Theta_f^T)} \Theta_f, \quad (43)$$

$$P[\gamma_2 \underline{e} p^T(\underline{x}) u] \equiv \gamma_2 \underline{e} p^T(\underline{x}) u - \gamma_2 \frac{\underline{e}^T \Theta_g p(\underline{x}) u}{\text{tr}(\Theta_g \Theta_g^T)} \Theta_g \quad (44)$$

$\underline{e} = \underline{x} - \hat{x}$, and the initial $\Theta_f(0)$ and $\Theta_g(0)$ are determined in Step 2.

Properties of the above fuzzy identifier are summarized in the following theorem.

Theorem 3: The fuzzy identifier (40) with the adaptive law (41) and (42) guarantees the following properties:

- a) $\text{tr}(\Theta_f \Theta_f^T) \leq M_f$, $\text{tr}(\Theta_g \Theta_g^T) \leq M_g$, and $\underline{\hat{x}} \in L_\infty$;
- b) there exist constants k_1 and k_2 such that

$$\int_0^t |\underline{e}(\tau)|^2 d\tau \leq k_1 + k_2 \int_0^t |\underline{w}(\tau)|^2 d\tau \quad (45)$$

for any $t \geq 0$, where $\underline{w}(\tau)$ is defined by (28); and

- c) if $\underline{w} \in L_2$, then $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$.

Proof of this theorem is given in Appendix A.

Remark 3.1: From c) of Theorem 3 we see that to have $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$, we require that \underline{w} is squared integrable. From the definition of \underline{w} (28)–(30), we see that \underline{w} is the sum of the minimum approximation errors of \hat{f} and \hat{g} to f and g over the entire state space U . From Theorem 1, this minimum approximation error should be small if we properly choose the fuzzy systems \hat{f} and \hat{g} .

Remark 3.2: From Step 2 we see that the linguistic descriptions (32) and (33) about the unknown functions $f(\underline{x})$ and $g(\underline{x})$ are used to construct the initial fuzzy identifier. If these descriptions provide good pictures of $f(\underline{x})$ and $g(\underline{x})$, we can expect that the adaptation procedure will converge fast, because the initial identifier constructed from good descriptions should be close to the true system. If no linguistic descriptions are available, the fuzzy identifier becomes a regular nonlinear identifier, similar to the radial basis function [3], [27] and neural network [28] identifiers.

Remark 3.3: In this fuzzy identifier, we fix the fuzzy sets in U and consider fuzzy systems whose IF parts are concerned only with these fuzzy sets. An advantage of doing so is that the fuzzy systems in the fuzzy identifier are linear in the parameter, therefore: 1) we were able to use a relatively simpler adaptive law to update the parameters, and 2) convergence of the

adaptation procedure is expected to be faster because we are not concerned with complicated nonlinear search problems. A disadvantage is that we have to consider all the possible combinations of the fuzzy sets in U , because these fuzzy sets cannot change so that we should have rules to cover every region of U , where by 'cover' we mean that for each $\underline{x} \in U$ there should exist at least one rule in the fuzzy rule bases of \hat{f} and \hat{g} whose 'strength' $(\mu_{F_1^1}(x_1) \cdots \mu_{F_n^1}(x_n))$ is not very small. Therefore, if the dimension n of a problem is large, then we have to choose the m_i 's relatively small so that the computational requirements of the fuzzy identifier do not exceed the capability of computing sources available. Clearly, the bigger the m_i 's, the more the rules, and therefore the smaller the minimum approximation error \underline{w} , which in turn means the smaller the identification error \underline{e} [see (45)]. In practical applications of this fuzzy identifier, we have to find a compromise between complexity and accuracy.

IV. THE SECOND FUZZY IDENTIFIER

As discussed in Remark 3.3, the fuzzy identifier in Section III may require a large number of rules for higher dimensional systems. An obvious way to overcome this rule explosion problem is to allow the fuzzy sets in U also to change during the adaptation procedure so that in principle any rule can cover any region of U ; therefore, we only need a small number of rules. This is the basic idea of the fuzzy identifier in this section. The price paid for this additional freedom is that the fuzzy identifier becomes nonlinear in the parameter, so that we have to use a more complicated adaptive law.

We consider the identification of the same system (26) and use the same serial-parallel model (31) (Fig. 3). The identification goals remain the same as in Section III, and we still consider Assumption 3.1. The design of the second fuzzy identifier, however, is quite different from the first one.

Design of the Second Fuzzy Identifier

Step 1. Define $2N$ fuzzy sets F_i^l and G_i^l in each U_i of U and $2N$ fuzzy sets E_i^l and H_i^l in each V_i of V with the following membership functions

$$\mu_{F_i^l}(x_i) = \exp \left[-\frac{1}{2} \frac{(x_i - \bar{x}_{if}^l)^2}{(\sigma_{if}^l)^2 + \epsilon} \right] \quad (46)$$

$$\mu_{G_i^l}(x_i) = \exp \left[-\frac{1}{2} \frac{(x_i - \bar{x}_{ig}^l)^2}{(\sigma_{ig}^l)^2 + \epsilon} \right] \quad (47)$$

$$\mu_{E_i^l}(y_i) = \exp \left[-\frac{1}{2} \frac{(y_i - \bar{y}_{ie}^l)^2}{(\sigma_{ie}^l)^2 + \epsilon} \right] \quad (48)$$

$$\mu_{H_i^l}(y_i) = \exp \left[-\frac{1}{2} \frac{(y_i - \bar{y}_{ih}^l)^2}{(\sigma_{ih}^l)^2 + \epsilon} \right] \quad (49)$$

where $\epsilon > 0$ is a small constant, $l = 1, 2, \dots, N$ (in general, $N \ll \prod_{i=1}^n m_i$), $x_i \in U_i$, $y_i \in V_i$, $i = 1, 2, \dots, n$, and \bar{x}_{if}^l , σ_{if}^l , \bar{x}_{ig}^l , σ_{ig}^l , \bar{y}_{ie}^l , σ_{ie}^l , \bar{y}_{ih}^l , and σ_{ih}^l are free parameters which will be updated in the adaptation procedure of Step 4. The purpose of adding the small $\epsilon > 0$ to the fuzzy membership functions (46)–(49) is that even if the σ 's = 0, the fuzzy membership functions are still well defined. This modification

will make the adaptive law simpler because we do not require the σ 's $\neq 0$. For this fuzzy identifier, we assume that the membership functions of A_i^r , B_i^s , C_i^r , and D_i^s in (32) and (33) are in the form of (46)–(49), respectively, and that $N \geq N_f$ and $N \geq N_g$.

Step 2: Construct the fuzzy rule bases of \hat{f} and \hat{g} as

$$R_f^l: \text{IF } x_1 \text{ is } F_1^l \text{ and } \dots \text{ and } x_n \text{ is } F_n^l, \\ \text{THEN } \hat{f}_1(\underline{x}) \text{ is } E_1^l, \dots, \hat{f}_n(\underline{x}) \text{ is } E_n^l \quad (50)$$

and

$$R_g^l: \text{IF } x_1 \text{ is } G_1^l \text{ and } \dots \text{ and } x_n \text{ is } G_n^l, \\ \text{THEN } \hat{g}_1(\underline{x}) \text{ is } H_1^l, \dots, \hat{g}_n(\underline{x}) \text{ is } H_n^l \quad (51)$$

respectively, where F_i^l , E_i^l , G_i^l , and H_i^l are defined in Step 1, and $l = 1, 2, \dots, N$. Choose $\hat{f}(\underline{x}|\underline{\theta}_f) = (\hat{f}_1(\underline{x}|\underline{\theta}_f), \dots, \hat{f}_n(\underline{x}|\underline{\theta}_f))^T$ and $\hat{g}(\underline{x}|\underline{\theta}_g) = (\hat{g}_1(\underline{x}|\underline{\theta}_g), \dots, \hat{g}_n(\underline{x}|\underline{\theta}_g))^T$ to be fuzzy systems with singleton fuzzifier, modified center average defuzzifier, product inference, and Gaussian membership function (Definition 2) based on the fuzzy rule bases of (50) and (51), respectively

$$\hat{f}_i(\underline{x}|\underline{\theta}_f) = \frac{\sum_{l=1}^N \bar{y}_{ie}^l \left[\prod_{j=1}^n \exp \left(-\frac{1}{2} \frac{(x_j - \bar{x}_{j,f}^l)^2}{(\sigma_{j,f}^l)^2 + \epsilon} \right) \right]}{\sum_{l=1}^N \left[\prod_{j=1}^n \exp \left(-\frac{1}{2} \frac{(x_j - \bar{x}_{j,f}^l)^2}{(\sigma_{j,f}^l)^2 + \epsilon} \right) \right]} \frac{[(\sigma_{ie}^l)^2 + \epsilon]}{[(\sigma_{ie}^l)^2 + \epsilon]}, \quad (52)$$

$$\hat{g}_i(\underline{x}|\underline{\theta}_g) = \frac{\sum_{l=1}^N \bar{y}_{ih}^l \left[\prod_{j=1}^n \exp \left(-\frac{1}{2} \frac{(x_j - \bar{x}_{j,g}^l)^2}{(\sigma_{j,g}^l)^2 + \epsilon} \right) \right]}{\sum_{l=1}^N \left[\prod_{j=1}^n \exp \left(-\frac{1}{2} \frac{(x_j - \bar{x}_{j,g}^l)^2}{(\sigma_{j,g}^l)^2 + \epsilon} \right) \right]} \frac{[(\sigma_{ih}^l)^2 + \epsilon]}{[(\sigma_{ih}^l)^2 + \epsilon]}, \quad (53)$$

where $\underline{\theta}_f$ and $\underline{\theta}_g$ are $4nN \times 1$ vectors which are collections of the free parameters. Specifically, $\underline{\theta}_f \equiv (\bar{y}_{1e}^1, \dots, \bar{y}_{1e}^N, \dots, \bar{y}_{ne}^1, \dots, \bar{y}_{ne}^N; \sigma_{1e}^1, \dots, \sigma_{1e}^N, \dots, \sigma_{ne}^1, \dots, \sigma_{ne}^N; \bar{x}_{1f}^1, \dots, \bar{x}_{1f}^N, \dots, \bar{x}_{nf}^1, \dots, \bar{x}_{nf}^N; \sigma_{1f}^1, \dots, \sigma_{1f}^N, \dots, \sigma_{nf}^1, \dots, \sigma_{nf}^N)$, and $\underline{\theta}_g$ is defined in exactly the same way as $\underline{\theta}_f$ with the subscript "e" replaced by "h" and "f" replaced by "g". Different from the first fuzzy identifier where we collected the free parameters into matrices Θ_f and Θ_g , we collect the free parameters into vectors $\underline{\theta}_f$ and $\underline{\theta}_g$ in this second fuzzy identifier. We still use the serial-parallel identification model (31), with $\hat{f}(\underline{x}|\Theta_f)$ and $\hat{g}(\underline{x}|\Theta_g)$ replaced by the $\hat{f}(\underline{x}|\underline{\theta}_f)$ and $\hat{g}(\underline{x}|\underline{\theta}_g)$ of (52) and (53), respectively.

Step 3: Compute the gradient matrices $(\partial \hat{f}(\underline{x}|\underline{\theta}_f)/\partial \underline{\theta}_f) = ((\partial \hat{f}_1(\underline{x}|\underline{\theta}_f)/\partial \underline{\theta}_f), \dots, (\partial \hat{f}_n(\underline{x}|\underline{\theta}_f)/\partial \underline{\theta}_f))$ and $(\partial \hat{g}(\underline{x}|\underline{\theta}_g)/\partial \underline{\theta}_g) = ((\partial \hat{g}_1(\underline{x}|\underline{\theta}_g)/\partial \underline{\theta}_g), \dots, (\partial \hat{g}_n(\underline{x}|\underline{\theta}_g)/\partial \underline{\theta}_g))$ using the following back-propagation algorithm which is derived in Appendix B

$$\frac{\partial \hat{f}_i}{\partial \sigma_{ie}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{-2z^l \sigma_{ie}^l}{((\sigma_{ie}^l)^2 + \epsilon)}, \quad (54)$$

$$\frac{\partial \hat{f}_i}{\partial \bar{x}_{j,f}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{1}{(\sigma_{ie}^l)^2 + \epsilon} z^l \frac{x_j - \bar{x}_{j,f}^l}{(\sigma_{j,f}^l)^2 + \epsilon}, \quad (55)$$

$$\frac{\partial \hat{f}_i}{\partial \sigma_{j,f}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{1}{(\sigma_{ie}^l)^2 + \epsilon} z^l \frac{2(x_j - \bar{x}_{j,f}^l)^2 \sigma_{j,f}^l}{((\sigma_{j,f}^l)^2 + \epsilon)^2}, \quad (56)$$

$$\frac{\partial \hat{f}_i}{\partial \sigma_{j,f}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{1}{(\sigma_{ie}^l)^2 + \epsilon} z^l \frac{2(x_j - \bar{x}_{j,f}^l)^2 \sigma_{j,f}^l}{((\sigma_{j,f}^l)^2 + \epsilon)^2}, \quad (57)$$

where

$$z^l \equiv \prod_{j=1}^n \exp \left(-\frac{1}{2} \frac{(x_j - \bar{x}_{j,f}^l)^2}{(\sigma_{j,f}^l)^2 + \epsilon} \right), \quad (58)$$

$$b_i \equiv \sum_{l=1}^N z^l / ((\sigma_{ie}^l)^2 + \epsilon) \quad (59)$$

$l = 1, 2, \dots, N$, and $i, j = 1, 2, \dots, n$; and $(\partial \hat{g}_i/\partial \bar{y}_{ih}^l)$, $(\partial \hat{g}_i/\partial \sigma_{ih}^l)$, $(\partial \hat{g}_i/\partial \bar{x}_{j,g}^l)$, and $(\partial \hat{g}_i/\partial \sigma_{j,g}^l)$ are computed in exactly the same way as (54)–(57), respectively, with the subscripts "e" replaced by "h" and "f" replaced by "g."

Step 4: Update the parameter vectors $\underline{\theta}_f$ and $\underline{\theta}_g$ using the following adaptive law

$$\underline{\dot{\theta}}_f = P \left[\gamma_1 \frac{\partial \hat{f}(\underline{x}|\underline{\theta}_f)}{\partial \underline{\theta}_f} \underline{\epsilon} \text{ if } (|\underline{\theta}_f|^2 < M_f) \right. \\ \left. \text{or } (|\underline{\theta}_f|^2 = M_f \text{ and } \underline{\epsilon}^T \left(\frac{\partial \hat{f}}{\partial \underline{\theta}_f} \right)^T \underline{\theta}_f \leq 0) \right] \\ \text{if } (|\underline{\theta}_f|^2 = M_f \text{ and } \underline{\epsilon}^T \left(\frac{\partial \hat{f}}{\partial \underline{\theta}_f} \right)^T \underline{\theta}_f > 0), \quad (60)$$

$$\underline{\dot{\theta}}_g = P \left[\gamma_2 \frac{\partial \hat{g}(\underline{x}|\underline{\theta}_g)}{\partial \underline{\theta}_g} \underline{\epsilon} u \text{ if } (|\underline{\theta}_g|^2 < M_g) \right. \\ \left. \text{or } (|\underline{\theta}_g|^2 = M_g \text{ and } \underline{\epsilon}^T \left(\frac{\partial \hat{g}}{\partial \underline{\theta}_g} \right)^T \underline{\theta}_g u \leq 0) \right] \\ \text{if } (|\underline{\theta}_g|^2 = M_g \text{ and } \underline{\epsilon}^T \left(\frac{\partial \hat{g}}{\partial \underline{\theta}_g} \right)^T \underline{\theta}_g u > 0) \quad (61)$$

where γ_1 and γ_2 are positive constants, $P[\ast]$ is the projection operator [7]

$$\gamma_1 \frac{\partial \hat{f}}{\partial \underline{\theta}_f} \underline{\epsilon} \equiv \gamma_1 \frac{\partial \hat{f}}{\partial \underline{\theta}_f} \underline{\epsilon} - \gamma_1 \frac{\underline{\epsilon}^T \left(\frac{\partial \hat{f}}{\partial \underline{\theta}_f} \right)^T \underline{\theta}_f}{|\underline{\theta}_f|^2} \underline{\theta}_f, \quad (62)$$

$$P[\gamma_2 \frac{\partial \hat{g}}{\partial \underline{\theta}_g} \underline{\epsilon} u] \equiv \gamma_2 \frac{\partial \hat{g}}{\partial \underline{\theta}_g} \underline{\epsilon} u - \gamma_2 \frac{\underline{\epsilon}^T \left(\frac{\partial \hat{g}}{\partial \underline{\theta}_g} \right)^T \underline{\theta}_g u}{|\underline{\theta}_g|^2} \underline{\theta}_g \quad (63)$$

$\underline{\epsilon} = \underline{x} - \hat{\underline{x}}$, and the initial parameters $\underline{\theta}_f(0)$ and $\underline{\theta}_g(0)$ are determined in the following way: for rules R_f^l and R_g^l in (50) and (51) that agree with the linguistic rules (32) and (33), set their initial parameters equal to the corresponding parameters in the linguistic rules; otherwise, set the initial parameters arbitrarily. Therefore, same as the first fuzzy identifier, we incorporate linguistic descriptions about f and g into the fuzzy identifier by constructing the initial fuzzy identifier based on these linguistic descriptions.

The following theorem summarizes the properties of the second fuzzy identifier.

Theorem 4: The fuzzy identifier (31) with \hat{f} and \hat{g} given by (52) and (53) and the adaptive law (60) and (61) guarantees the following properties:

- a) $|\underline{\theta}_f|^2 \leq M_f$, $|\underline{\theta}_g|^2 \leq M_g$, and $\dot{x} \in L_\infty$;
- b) there exist constants k_1 and k_2 such that

$$\int_0^t |\underline{e}(\tau)|^2 d\tau \leq k_1 + k_2 \int_0^t |\underline{v}(\tau)|^2 d\tau \quad (64)$$

where

$$\begin{aligned} \underline{v} \equiv & \left[\frac{\partial \hat{f}(x|\underline{\theta}_{f0})}{\partial \underline{\theta}_f} - \frac{\partial \hat{f}(x|\underline{\theta}_f^*)}{\partial \underline{\theta}_f} \right]^T (\underline{\theta}_f^* - \underline{\theta}_f) \\ & + \left[\frac{\partial \hat{g}(x|\underline{\theta}_{g0})}{\partial \underline{\theta}_g} - \frac{\partial \hat{g}(x|\underline{\theta}_g^*)}{\partial \underline{\theta}_g} \right]^T (\underline{\theta}_g^* - \underline{\theta}_g) u + \underline{w} \end{aligned} \quad (65)$$

$\underline{\theta}_{f0} = \lambda_1 \underline{\theta}_f + (1 - \lambda_1) \underline{\theta}_f^*$, $\underline{\theta}_{g0} = \lambda_2 \underline{\theta}_g + (1 - \lambda_2) \underline{\theta}_g^*$ for some $\lambda_1, \lambda_2 \in [0, 1]$, and $\underline{w}, \underline{\theta}_f^*, \underline{\theta}_g^*$ are defined in (28)–(30) with Θ_f^* and Θ_g^* replaced by $\underline{\theta}_f^*$ and $\underline{\theta}_g^*$;

- c) if $\underline{v} \in L_2$, then $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$.

Proof of this theorem is given in Appendix A.

Remark 4.1: Because we have much more freedom in choosing the parameters of this fuzzy identifier than the first fuzzy identifier, the \underline{w} for this fuzzy identifier should be smaller than the first one. Therefore, the key factor that influence the value of \underline{v} is the closeness of the $\underline{\theta}_f$ and $\underline{\theta}_g$ to their optimal values $\underline{\theta}_f^*$ and $\underline{\theta}_g^*$. From (65) we see that if $|\underline{\theta}_f^* - \underline{\theta}_f|$ and $|\underline{\theta}_g^* - \underline{\theta}_g|$ are small, then \underline{v} will be small. Because the initial parameters $\underline{\theta}_f(0)$ and $\underline{\theta}_g(0)$ are determined based on the linguistic descriptions about f and g , good descriptions should make $\underline{\theta}_f(0)$ and $\underline{\theta}_g(0)$ close to $\underline{\theta}_f^*$ and $\underline{\theta}_g^*$ and therefore make \underline{v} small.

Remark 4.2: By using the adaptive law (60) and (61), it is possible that some σ parameters are zero at certain points. To deal with this problem, we added a small $\epsilon > 0$ to the fuzzy systems (52) and (53) so that the fuzzy identifier is well defined for zero σ parameters.

V. SIMULATIONS

In this section, we simulate the two fuzzy identifiers for the following chaotic glycolytic oscillator [10]

$$\dot{x}_1(t) = -x_1(t)x_2^2(t) + 0.999 + 0.42 \cos(1.75t) \quad (66)$$

$$\dot{x}_2(t) = x_1(t)x_2^2(t) - x_2(t). \quad (67)$$

Fig. 4 shows the trajectory of this chaotic system in the phase plane from $t = 0$ to $t = 50$ with initial condition $x_1(0) = x_2(0) = 1.5$. For this system, we have $f_1(x) = -x_1x_2^2 + 0.999$, $f_2(x) = x_1x_2^2 - x_2$, $g_1(x) = 0.42$, and $g_2(x) = 0$. For simplicity, we assume that g_1 and g_2 are known, i.e., we only consider the identification of f_1 and f_2 . For each fuzzy identifier, we simulate two cases: 1) without linguistic descriptions about f_1 and f_2 , and 2) with the following linguistic descriptions

R_f^1 : IF x_1 is “near 1” and x_2 is “near 1”,

THEN f_1 is “near 0”. f_2 is “near 0”, (68)

Fig. 4 Trajectory of the chaotic glycolytic oscillator in the phase plane from $t = 0$ to $t = 50$ with initial condition $x_1(0) = x_2(0) = 1.5$

R_f^2 : IF x_1 is “near 1” and x_2 is “near 2”,

THEN f_1 is “near -3”, f_2 is “near 2”, (69)

R_f^3 : IF x_1 is “near 2” and x_2 is “near 1”,

THEN f_1 is “near -1”, f_2 is “near 1” (70)

where “near c ”, $c = 1, 0, 2, -3$, or -1 , is a fuzzy set μ_c with membership function $\mu_c(z) = \exp[-(1/2)((z - c)/0.25)^2]$. $R_f^1 - R_f^3$ are obtained by evaluating f_1 and f_2 at three points $\underline{x} = (1, 1)^T$, $(1, 2)^T$, and $(2, 1)^T$, and then fuzzifying the $\underline{x} - f(\underline{x})$ pairs. For practical systems, this kind of information is provided by human experts who are familiar with the behavior of the systems. In all the simulations in the sequel, we chose $\alpha = 1$, $\gamma_1 = 4$, $M_f = 10^6$, and $\epsilon = 10^{-6}$, and solved the differential equations using the MATLAB command “ode23” which uses the second/third order Runge-Kutta method.

To simulate the first fuzzy identifier, we first need to define some fuzzy sets to cover the state space. From Fig. 4 we see that most values of x_1 and x_2 are in the interval $[0.5, 3.5]$, therefore we define the following seven fuzzy sets F^j ($j = 1, 2, \dots, 7$) for both x_1 and x_2 (i.e., $m_1 = m_2 = 7$): $\mu_{F^j}(x_i) = \exp[-(1/2)((x_i - \bar{x}^j)/0.25)^2]$, where $\bar{x}^j = 0.5 \times j$, $j = 1, 2, \dots, 7$, and $i = 1, 2$. Clearly, these fuzzy sets include the fuzzy sets in the IF parts of $R_f^1 - R_f^3$. For this choice of F^j , we have 49 fuzzy rules to construct each \hat{f}_i ($i = 1, 2$), i.e., each \hat{f}_i has 49 free parameters. We simulated two cases: 1) without incorporating the $R_f^1 - R_f^3$, i.e., all elements of $\Theta_f(0)$ were chosen randomly in the interval $[-2, 2]$; and 2) incorporating the $R_f^1 - R_f^3$, i.e., the elements of $\Theta_f(0)$ that correspond to the conditions in the IF parts of $R_f^1 - R_f^3$ were chosen according the corresponding THEN parts of $R_f^1 - R_f^3$, and other elements were still chosen randomly in the interval $[-2, 2]$. Figs. 5 and 6 show the states $x_1(t)$ and $x_2(t)$ with the corresponding $\hat{x}_1(t)$ and $\hat{x}_2(t)$, respectively, for the first case, and Figs. 7 and 8 show the same results for the second case. Comparing Figs. 5 and 7 and Figs. 6 and 8, we see that

Fig 5 $r_1(t)$ (solid line) and $r_1(t)$ (dashed line) using the first fuzzy identifier without incorporating the linguistic descriptions (68)–(70)

Fig 8 $r_2(t)$ (solid line) and $r_2(t)$ (dashed line) using the first fuzzy identifier after incorporating the linguistic descriptions (68)–(70)

Fig 6 $r_2(t)$ (solid line) and $r_2(t)$ (dashed line) using the first fuzzy identifier without incorporating the linguistic descriptions (68)–(70)

Fig 9 $r_1(t)$ (solid line) and $r_1(t)$ (dashed line) using the second fuzzy identifier without incorporating the linguistic descriptions (68)–(70)

Fig 7 $r_1(t)$ (solid line) and $r_1(t)$ (dashed line) using the first fuzzy identifier after incorporating the linguistic descriptions (68)–(70)

Fig 10 $r_2(t)$ (solid line) and $r_2(t)$ (dashed line) using the second fuzzy identifier without incorporating the linguistic descriptions (68)–(70)

the adaptation speed and accuracy were greatly improved by incorporating the linguistic rules $R_f^1 - R_f^3$.

We simulated the second fuzzy identifier for the same two cases: 1) without incorporating the $R_f^1 - R_f^3$, i.e., all elements of $\theta_f(0)$ were chosen randomly in the interval $[-2, 2]$, and 2) incorporating the $R_f^1 - R_f^3$, i.e., some elements of $\theta_f(0)$ were chosen according to the fuzzy sets in $R_f^1 - R_f^3$, and the remaining elements were chosen randomly in the interval $[-2, 2]$. We chose $N = 10$, so that on average each \hat{f}_i ($i = 1, 2$) contains 40 free parameters [see (52)]. Figures 9, and 10 show the $r_1(t)$, $\hat{r}_2(t)$, and $x_2(t)$, $\hat{x}_2(t)$ curves for the first case, respectively, and Figs 11 and 12 show the same

results for the second case. Comparing Figs 9 and 11 and Figs 10 and 12, we see that the adaptation speed and accuracy were greatly improved by incorporating the linguistic rules $R_f^1 - R_f^3$.

Comparing Figs. 5–8 with the corresponding Figs. 9–12, we see that although the second fuzzy identifier used less free parameters than the first fuzzy identifier, its performance is better. This may be caused by two reasons. 1) although each fuzzy system in the first fuzzy identifier has 49 free parameters, some of them were never used because from Fig. 4 we see that the states of the system never enter some regions in the state space so that the parameters responsible for these regions

Fig. 11. $x_1(t)$ (solid line) and $\hat{x}_1(t)$ (dashed line) using the second fuzzy identifier after incorporating the linguistic descriptions (68)–(70)

Fig. 12. $x_2(t)$ (solid line) and $\hat{x}_2(t)$ (dashed line) using the second fuzzy identifier after incorporating the linguistic descriptions (68)–(70).

have no influence on the performance of the identifier, i.e., the number of actually useful free parameters of the second fuzzy identifier is more than that of the first fuzzy identifier, and 2) the first fuzzy identifier is linear in the parameter so that in principle it should converge to a single solution, whereas the second fuzzy identifier is nonlinear in the parameter so that it has a larger functional space to search. In principle, the second fuzzy identifier has the danger to be trapped at a local minimum; but this seems not happen in our simulations, especially when we incorporated the linguistic rules.

VI. CONCLUSIONS

In this paper two identifiers of nonlinear dynamic systems were developed based on the fuzzy system models. We proved that all signals in the fuzzy identifiers are uniformly bounded and provided conditions under which the identification errors converge to zero. We also proved that the fuzzy identifiers are capable of following the output of a very general nonlinear dynamic system to arbitrary accuracy in any finite time interval. The most important advantage of the fuzzy identifiers is that linguistic descriptions about the systems (in terms of fuzzy IF-THEN rules) can be directly incorporated into the fuzzy identifiers. We simulated the two fuzzy identifiers for the chaotic glycolytic oscillator, and the results show that: 1) they could identify the chaotic system at a reasonable speed and accuracy without using any linguistic descriptions, and 2)

by incorporating some linguistic descriptions, the speed and accuracy of the fuzzy identifiers were greatly improved.

APPENDIX A

Proof of Theorem 2: From (16) we see that \hat{g} and \hat{h} are continuous functions and therefore satisfy the Lipschitz condition in the compact set K of (20), i.e., there exist constants b_g and b_h such that for all $(\underline{x}^{(1)}, \underline{u}), (\underline{x}^{(2)}, \underline{u}) \in K$

$$|\hat{g}(\underline{x}^{(1)}, \underline{u}|\Theta_g) - \hat{g}(\underline{x}^{(2)}, \underline{u}|\Theta_g)| \leq b_g |\underline{x}^{(1)} - \underline{x}^{(2)}|, \quad (\text{A.1})$$

$$|\hat{h}(\underline{x}^{(1)}, \underline{u}|\Theta_h) - \hat{h}(\underline{x}^{(2)}, \underline{u}|\Theta_h)| \leq b_h |\underline{x}^{(1)} - \underline{x}^{(2)}|. \quad (\text{A.2})$$

Define $\underline{e}_x \equiv \hat{\underline{x}} - \underline{x}$, then from (18) and (23) we have

$$\dot{\underline{e}}_x = A\underline{e}_x + \hat{g}(\hat{\underline{x}}, \underline{u}|\Theta_g^*) - g(\underline{x}, \underline{u}) \quad (\text{A.3})$$

whose solution can be expressed as

$$\underline{e}_x(t) = \int_0^t e^{A(t-\tau)} [\hat{g}(\hat{\underline{x}}(\tau), \underline{u}(\tau)|\Theta_g^*) - g(\underline{x}(\tau), \underline{u}(\tau))] d\tau. \quad (\text{A.4})$$

Since A is a Hurwitz matrix, there exist positive constants c and α such that $\|e^{At}\| \leq ce^{-\alpha t}$ for all $t \geq 0$. Let $\epsilon_g = \frac{c\alpha}{2cb_h} e^{-cb_g/\alpha}$, then from (A.4), (A.1), and (21) we have that

$$\begin{aligned} |\underline{e}_x(t)| &\leq \int_0^t \|e^{A(t-\tau)}\| |\hat{g}(\hat{\underline{x}}(\tau), \underline{u}(\tau)|\Theta_g^*) - \hat{g}(\underline{x}(\tau), \underline{u}(\tau)|\Theta_g^*)| d\tau \\ &\quad + \int_0^t \|e^{A(t-\tau)}\| |\hat{g}(\underline{x}(\tau), \underline{u}(\tau)|\Theta_g^*) - g(\underline{x}(\tau), \underline{u}(\tau))| d\tau \\ &\leq \int_0^t ce^{-\alpha(t-\tau)} b_g |\underline{e}_x(\tau)| d\tau \\ &\quad + \int_0^t ce^{-\alpha(t-\tau)} \frac{c\alpha}{2cb_h} e^{-cb_g/\alpha} d\tau \\ &\leq cb_g \int_0^t e^{-\alpha(t-\tau)} |\underline{e}_x(\tau)| d\tau + \frac{\epsilon}{2b_h} e^{-cb_g/\alpha}. \end{aligned} \quad (\text{A.5})$$

Using the Bellman–Gronwall Lemma [9], we obtain

$$\begin{aligned} |\underline{e}_x(t)| &\leq \frac{\epsilon}{2b_h} e^{-cb_g/\alpha} e^{cb_g} \int_0^t e^{-\alpha(t-\tau)} d\tau \\ &\leq \frac{\epsilon}{2b_h} e^{-cb_g/\alpha} [1 + \int_0^t e^{-\alpha(t-\tau)} d\alpha(t-\tau)] \leq \frac{\epsilon}{2b_h}. \end{aligned} \quad (\text{A.6})$$

Therefore, $|\hat{\underline{x}} - \underline{x}^0| \leq |\hat{\underline{x}} - \underline{x}| + |\underline{x} - \underline{x}^0| \leq (\epsilon/2b_h) + b$ from Assumption 2.1. Without loss of generality, we assume that $b_h \geq 1$; therefore, $(\hat{\underline{x}}, \underline{u}) \in K$. Hence, letting $\epsilon_h = \epsilon/2$, using (22), (A.2) and (A.6), and considering the fact that $(\underline{x}, \underline{u}) \in K$ and $(\hat{\underline{x}}, \underline{u}) \in K$, we obtain

$$\begin{aligned} |\hat{\underline{y}}(t) - \underline{y}(t)| &\leq |\hat{h}(\hat{\underline{x}}, \underline{u}|\Theta_h^*) - \hat{h}(\underline{x}, \underline{u}|\Theta_h^*)| \\ &\quad + |\hat{h}(\underline{x}, \underline{u}|\Theta_h^*) - h(\underline{x}, \underline{u})| \\ &\leq b_h |\underline{e}_x(t)| + \epsilon/2 \leq \epsilon \end{aligned} \quad (\text{A.7})$$

for all $t \in [0, T]$.

Q.E.D.

Proof of Theorem 3: a) From (41) and (43) we see that if $\text{tr}(\Theta_f \Theta_f^T) = M_f$, then: if $\underline{e}^T \Theta_f \underline{p}(\underline{x}) \leq 0$, we have

$$\begin{aligned} \frac{d}{dt}[\text{tr}(\Theta_f \Theta_f^T)] &= \text{tr}(\dot{\Theta}_f \Theta_f^T + \Theta_f \dot{\Theta}_f^T) \\ &= \text{tr}(\gamma_1 \underline{e} \underline{p}^T(\underline{x}) \Theta_f^T + \gamma_1 \Theta_f \underline{p}(\underline{x}) \underline{e}^T) \\ &= 2\gamma_1 \underline{e}^T \Theta_f \underline{p}(\underline{x}) \leq 0 \end{aligned} \quad (\text{A.8})$$

where we use the properties of trace in the last equality; and if $\underline{e}^T \Theta_f \underline{p}(\underline{x}) > 0$, we have

$$\begin{aligned} \frac{d}{dt}[\text{tr}(\Theta_f \Theta_f^T)] &= 2 \text{tr} \left(\gamma_1 \underline{e} \underline{p}^T(\underline{x}) \Theta_f^T - \gamma_1 \frac{\underline{e}^T \Theta_f \underline{p}(\underline{x})}{\text{tr}(\Theta_f \Theta_f^T)} \Theta_f \Theta_f^T \right) \\ &= 2\gamma_1 \underline{e}^T \Theta_f \underline{p}(\underline{x}) - 2\gamma_1 \underline{e}^T \Theta_f \underline{p}(\underline{x}) = 0. \end{aligned} \quad (\text{A.9})$$

Hence, we always have $\text{tr}(\Theta_f \Theta_f^T) \leq M_f$. Similarly, we can prove that $\text{tr}(\Theta_g \Theta_g^T) \leq M_g$. To prove $\underline{\hat{x}} \in L_\infty$, define the Lyapunov function candidate

$$V = \frac{1}{2} |\underline{e}|^2 + \frac{1}{2\gamma_1} \text{tr}(\Phi_f \Phi_f^T) + \frac{1}{2\gamma_2} \text{tr}(\Phi_g \Phi_g^T) \quad (\text{A.10})$$

where $\Phi_f \equiv \Theta_f^* - \Theta_f$ and $\Phi_g \equiv \Theta_g^* - \Theta_g$. Subtracting (40) from (27) and using (38) and (39), we obtain the error dynamic equation

$$\dot{\underline{e}} = -\alpha \underline{e} + \Phi_f \underline{p}(\underline{x}) + \Phi_g \underline{p}(\underline{x}) u + \underline{w}. \quad (\text{A.11})$$

The time derivative of V along the solution of (A.11) is

$$\begin{aligned} \dot{V} &= -\alpha |\underline{e}|^2 + \underline{e}^T \Phi_f \underline{p}(\underline{x}) + \underline{e}^T \Phi_g \underline{p}(\underline{x}) u + \underline{e}^T \underline{w} \\ &\quad + \frac{1}{\gamma_1} \text{tr}(\dot{\Phi}_f \Phi_f^T) + \frac{1}{\gamma_2} \text{tr}(\dot{\Phi}_g \Phi_g^T) \\ &= -\alpha |\underline{e}|^2 + \underline{e}^T \underline{w} + \frac{1}{\gamma_1} \text{tr}[(\gamma_1 \underline{e} \underline{p}^T(\underline{x}) - \dot{\Theta}_f) \Phi_f^T] \\ &\quad + \frac{1}{\gamma_2} \text{tr}[(\gamma_2 \underline{e} \underline{p}^T(\underline{x}) u - \dot{\Theta}_g) \Phi_g^T] \\ &= -\alpha |\underline{e}|^2 + \underline{e}^T \underline{w} + I_1^* \frac{\underline{e}^T \Theta_f \underline{p}(\underline{x})}{\text{tr}(\Theta_f \Theta_f^T)} \text{tr}(\Theta_f \Phi_f^T) \\ &\quad + I_2^* \frac{\underline{e}^T \Theta_g \underline{p}(\underline{x}) u}{\text{tr}(\Theta_g \Theta_g^T)} \text{tr}(\Theta_g \Phi_g^T) \end{aligned} \quad (\text{A.12})$$

where $I_1^* = 1$ ($I_2^* = 1$) if the second line of (41) [(42)] is true, $I_1^* = 0$ ($I_2^* = 0$) if the first line of (41) [(42)] is true, and we use the fact that $\dot{\Phi}_f = -\dot{\Theta}_f$. We now prove that $I_1^* (\underline{e}^T \Theta_f \underline{p}(\underline{x}) / \text{tr}(\Theta_f \Theta_f^T)) \text{tr}(\Theta_f \Phi_f^T) \leq 0$. If $I_1^* = 0$, the conclusion is trivial. For $I_1^* = 1$, which means that $\text{tr}(\Theta_f \Theta_f^T) = M_f$ and $\underline{e}^T \Theta_f \underline{p}(\underline{x}) > 0$, we have

$$\begin{aligned} \text{tr}(\Theta_f \Phi_f^T) &= \text{tr} \left[\Theta_f^* \Phi_f^T - \frac{1}{2} \Phi_f \Phi_f^T - \frac{1}{2} \Phi_f \Phi_f^T \right] \\ &= \frac{1}{2} \text{tr}(\Theta_f^* \Theta_f^T) - \frac{1}{2} \text{tr}(\Theta_f \Theta_f^T) - \frac{1}{2} \text{tr}(\Phi_f \Phi_f^T) \leq 0 \end{aligned} \quad (\text{A.13})$$

because $\text{tr}(\Theta_f^* \Theta_f^T) \leq M_f = \text{tr}(\Theta_f \Theta_f^T)$ and $\text{tr}(\Phi_f \Phi_f^T) \geq 0$. Hence, $I_1^* (\underline{e}^T \Theta_f \underline{p}(\underline{x}) / \text{tr}(\Theta_f \Theta_f^T)) \text{tr}(\Theta_f \Phi_f^T) \leq 0$. Similarly,

we can prove that $I_2^* (\underline{e}^T \Theta_g \underline{p}(\underline{x}) u / \text{tr}(\Theta_g \Theta_g^T)) \text{tr}(\Theta_g \Phi_g^T) \leq 0$. Therefore, from (A.12) we have

$$\dot{V} \leq -\alpha |\underline{e}|^2 + \underline{e}^T \underline{w} \leq -\alpha |\underline{e}|^2 + w_0 |\underline{e}| \quad (\text{A.14})$$

(recall that $w_0 \equiv \sup_{t \geq 0} |\underline{w}(t)|$ which is assumed to be finite). Hence, if $|\underline{e}| > (w_0/\alpha)$, we have $\dot{V} < 0$, which means that $\underline{e} \in L_\infty$. Since $\underline{e} = \underline{x} - \underline{\hat{x}}$ and \underline{x} is bounded by assumption, we have $\underline{\hat{x}} \in L_\infty$.

b) From (A.14) we have

$$\begin{aligned} \dot{V} &\leq -\frac{\alpha}{2} |\underline{e}|^2 - \frac{\alpha}{2} \left[|\underline{e}|^2 - \frac{2}{\alpha} \underline{e}^T \underline{w} + \frac{1}{\alpha^2} |\underline{w}|^2 - \frac{1}{\alpha^2} |\underline{w}|^2 \right] \\ &\leq -\frac{\alpha}{2} |\underline{e}|^2 + \frac{1}{2\alpha} |\underline{w}|^2. \end{aligned} \quad (\text{A.15})$$

Integrating both sides of (A.15), we have

$$\int_0^t |\underline{e}(\tau)|^2 d\tau \leq \frac{2}{\alpha} (|V(0)| + |V(t)|) + \frac{1}{\alpha^2} \int_0^t |\underline{w}(\tau)|^2 d\tau. \quad (\text{A.16})$$

Define $k_1 \equiv \frac{1}{\alpha} (|V(0)| + \sup_{t \geq 0} |V(t)|)$ and $k_2 \equiv 1/\alpha^2$, (A.16) becomes (45). k_1 is finite because \underline{e} , $\text{tr}(\Phi_f \Phi_f^T)$ and $\text{tr}(\Phi_g \Phi_g^T)$ are bounded from a), therefore $V \in L_\infty$ [see (A.10)].

c) If $\underline{w} \in L_2$, then from (45) we have that $\underline{e} \in L_2$. Because \underline{e} , Φ_f , Φ_g , $\underline{p}(\underline{x})$, u , and \underline{w} are all bounded ($\underline{p}(\underline{x})$ is bounded because from (37) we see that each element of $\underline{p}(\underline{x})$ is not greater than one), from (A.11) we have that $\dot{\underline{e}} \in L_\infty$. Using the Barbalat's Lemma [29] (if $\underline{e} \in L_2 \cap L_\infty$ and $\dot{\underline{e}} \in L_\infty$, then $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$), we have $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$. Q.E.D.

Proof of Theorem 4: a) From (60) and (62) we see that if $|\underline{\theta}_f|^2 = M_f$, then: if $\underline{e}^T ((\partial \hat{f} / \partial \underline{\theta}_f))^T \underline{\theta}_f \leq 0$, we have that $(d/dt)(|\underline{\theta}_f|^2) = 2 \underline{\theta}_f^T \dot{\underline{\theta}}_f = 2\gamma_1 \underline{e}^T ((\partial \hat{f} / \partial \underline{\theta}_f))^T \underline{\theta}_f \leq 0$; and, if $\underline{e}^T ((\partial \hat{f} / \partial \underline{\theta}_f))^T \underline{\theta}_f > 0$, we have that $(d/dt)(|\underline{\theta}_f|^2) = 2(\gamma_1 \underline{e}^T ((\partial \hat{f} / \partial \underline{\theta}_f))^T \underline{\theta}_f - \gamma_1 \underline{e}^T ((\partial \hat{f} / \partial \underline{\theta}_f))^T \underline{\theta}_f / |\underline{\theta}_f|^2 \underline{\theta}_f^T \underline{\theta}_f) = 0$. Hence, $|\underline{\theta}_f|^2 \leq M_f$. Using the same procedure we can prove that $|\underline{\theta}_g|^2 \leq M_g$. To prove $\underline{x} \in L_\infty$, define the Lyapunov function candidate

$$V_1 = \frac{1}{2} |\underline{e}|^2 + \frac{1}{2\gamma_1} |\underline{\phi}_f|^2 + \frac{1}{2\gamma_2} |\underline{\phi}_g|^2 \quad (\text{A.17})$$

where $\underline{\phi}_f \equiv \underline{\theta}_f^* - \underline{\theta}_f$ and $\underline{\phi}_g \equiv \underline{\theta}_g^* - \underline{\theta}_g$. Using (27) and (31) (replace Θ_f^* and Θ_g^* by $\underline{\theta}_f^*$ and $\underline{\theta}_g^*$), we obtain the error dynamic equation

$$\begin{aligned} \dot{\underline{e}} &= -\alpha \underline{e} + [\hat{f}(\underline{x}|\underline{\theta}_f^*) - \hat{f}(\underline{x}|\underline{\theta}_f)] \\ &\quad + [\hat{g}(\underline{x}|\underline{\theta}_g^*) - \hat{g}(\underline{x}|\underline{\theta}_g)] u + \underline{w}. \end{aligned} \quad (\text{A.18})$$

Using the Taylor series expansions of $\hat{f}(\underline{x}|\underline{\theta}_f^*)$ and $\hat{g}(\underline{x}|\underline{\theta}_g^*)$ around $\underline{\theta}_f$ and $\underline{\theta}_g$, we have

$$\hat{f}(\underline{x}|\underline{\theta}_f^*) - \hat{f}(\underline{x}|\underline{\theta}_f) = \left(\frac{\partial \hat{f}(\underline{x}|\underline{\theta}_f)}{\partial \underline{\theta}_f} \right)^T \underline{\phi}_f + \hat{f}_0, \quad (\text{A.19})$$

$$\hat{g}(\underline{x}|\underline{\theta}_g^*) - \hat{g}(\underline{x}|\underline{\theta}_g) = \left(\frac{\partial \hat{g}(\underline{x}|\underline{\theta}_g)}{\partial \underline{\theta}_g} \right)^T \underline{\phi}_g + \hat{g}_0 \quad (\text{A.20})$$

where \hat{f}_0 and \hat{g}_0 are the higher order terms. Using the Mean Value Theorem, we have

$$\begin{aligned}\hat{f}_0 &\equiv \hat{f}(x|\underline{\theta}_f^*) - \hat{f}(x|\underline{\theta}_f) - \left(\frac{\partial \hat{f}(x|\underline{\theta}_f)}{\partial \underline{\theta}_f} \right)^T \underline{\phi}_f \\ &= \left[\frac{\partial \hat{f}(x|\underline{\theta}_{f0})}{\partial \underline{\theta}_f} - \frac{\partial \hat{f}(x|\underline{\theta}_f)}{\partial \underline{\theta}_f} \right]^T \underline{\phi}_f, \quad (\text{A.21})\end{aligned}$$

$$\begin{aligned}\hat{g}_0 &\equiv \hat{g}(x|\underline{\theta}_g^*) - \hat{g}(x|\underline{\theta}_g) - \left(\frac{\partial \hat{g}(x|\underline{\theta}_g)}{\partial \underline{\theta}_g} \right)^T \underline{\phi}_g \\ &= \left[\frac{\partial \hat{g}(x|\underline{\theta}_{g0})}{\partial \underline{\theta}_g} - \frac{\partial \hat{g}(x|\underline{\theta}_g)}{\partial \underline{\theta}_g} \right]^T \underline{\phi}_g \quad (\text{A.22})\end{aligned}$$

where $\underline{\theta}_{f0} = \lambda_1 \underline{\theta}_f + (1 - \lambda_1) \underline{\theta}_f^*$ and $\underline{\theta}_{g0} = \lambda_2 \underline{\theta}_g + (1 - \lambda_2) \underline{\theta}_g^*$ for some $\lambda_1, \lambda_2 \in [0, 1]$. Substituting (A.19) and (A.20) into (A.18), we have

$$\begin{aligned}\dot{\underline{e}} &= -\alpha \underline{e} + \left(\frac{\partial \hat{f}(x|\underline{\theta}_f)}{\partial \underline{\theta}_f} \right)^T \underline{\phi}_f + \left(\frac{\partial \hat{g}(x|\underline{\theta}_g)}{\partial \underline{\theta}_g} \right)^T \\ &\quad \cdot \underline{\phi}_g u + \hat{f}_0 + \hat{g}_0 u + \underline{w}. \quad (\text{A.23})\end{aligned}$$

The time derivative of V_1 along the solution of (A.23) is

$$\begin{aligned}\dot{V}_1 &= -\alpha |\underline{e}|^2 + \underline{e}^T \left(\frac{\partial \hat{f}}{\partial \underline{\theta}_f} \right)^T \underline{\phi}_f + \underline{e}^T \left(\frac{\partial \hat{g}}{\partial \underline{\theta}_g} \right)^T \underline{\phi}_g u + \underline{e}^T \hat{f}_0 \\ &\quad + \underline{e}^T \hat{g}_0 u + \underline{e}^T \underline{w} \\ &\quad + \frac{1}{\gamma_1} \dot{\underline{\phi}}_f^T \underline{\phi}_f + \frac{1}{\gamma_2} \dot{\underline{\phi}}_g^T \underline{\phi}_g. \quad (\text{A.24})\end{aligned}$$

Using (60)–(63) and $\dot{\underline{\phi}}_f = -\dot{\underline{\theta}}_f$, $\dot{\underline{\phi}}_g = -\dot{\underline{\theta}}_g$, we have that

$$\begin{aligned}\dot{V}_1 &= -\alpha |\underline{e}|^2 + \underline{e}^T \hat{f}_0 + \underline{e}^T \hat{g}_0 u + \underline{e}^T \underline{w} + I_1^* \frac{\underline{e}^T \left(\frac{\partial \hat{f}}{\partial \underline{\theta}_f} \right)^T \underline{\theta}_f}{|\underline{\theta}_f|^2} \underline{\theta}_f^T \underline{\phi}_f \\ &\quad + I_2^* \frac{\underline{e}^T \left(\frac{\partial \hat{g}}{\partial \underline{\theta}_g} \right)^T \underline{\theta}_g u}{|\underline{\theta}_g|^2} \underline{\theta}_g^T \underline{\phi}_g \quad (\text{A.25})\end{aligned}$$

where $I_1^* = 0$ (1) if the condition of the first (second) line of (60) is true, and $I_2^* = 0$ (1) if the condition of the first (second) line of (61) is true. Using the same arguments as in the proof of Theorem 3 and noticing that $|\underline{\theta}|^2 = \text{tr}(\underline{\theta} \underline{\theta}^T)$, we can prove that the last two terms of (A.25) are nonpositive. Hence

$$\begin{aligned}\dot{V}_1 &\leq -\alpha |\underline{e}|^2 + \underline{e}^T \hat{f}_0 + \underline{e}^T \hat{g}_0 u + \underline{e}^T \underline{w} \\ &\leq -\alpha |\underline{e}|^2 + |\underline{e}| \cdot |\hat{f}_0| + |\underline{e}| \cdot |\hat{g}_0| \cdot |u| + |\underline{e}| \cdot |\underline{w}|. \quad (\text{A.26})\end{aligned}$$

From (54)–(59) we see that all the elements of $(\partial \hat{f} / \partial \underline{\theta})$ and $(\partial \hat{g} / \partial \underline{\theta})$ are bounded; therefore, from (A.21) and (A.22) and the boundedness of $\underline{\phi}_f$ and $\underline{\phi}_g$ (we have proven that $|\underline{\theta}_f|^2 \leq M_f$ and $|\underline{\theta}_g|^2 \leq M_g$; $|\underline{\theta}_f^*|^2 \leq M_f$ and $|\underline{\theta}_g^*|^2 \leq M_g$ by definition), we have that $|\hat{f}_0|$ and $|\hat{g}_0|$ are bounded. Hence, $\beta \equiv |\hat{f}_0| + |\hat{g}_0| \cdot |u| + |\underline{w}|$ is finite. From (A.26) we have that if $|\underline{e}| > \beta / \alpha$, then $\dot{V}_1 < 0$; therefore, $|\underline{e}|$ is bounded. Since $\underline{\hat{x}} = \underline{x} - \underline{e}$ and \underline{x} is bounded by assumption, we have $\underline{\hat{x}} \in L_\infty$.

Fig. 13. Network representation of the fuzzy system.

b) From (A.21), (A.22), (65), and the first line of (A.26), we have that

$$\begin{aligned}\dot{V}_1 &\leq -\frac{\alpha}{2} |\underline{e}|^2 - \frac{\alpha}{2} \left(|\underline{e}|^2 - \frac{2}{\alpha} \underline{e}^T \underline{v} + \frac{1}{\alpha^2} |\underline{v}|^2 - \frac{1}{\alpha^2} |\underline{v}|^2 \right) \\ &\leq -\frac{\alpha}{2} |\underline{e}|^2 + \frac{1}{2\alpha} |\underline{v}|^2. \quad (\text{A.27})\end{aligned}$$

Integrating both sides of (A.27) and defining $k_1 \equiv (1/\alpha)(|V_1(0)| + \sup_{t>0} |V(t)|)$ and $k_2 \equiv 1/\alpha^2$, we obtain (64) ($\sup_{t>0} |V(t)|$ is finite because \underline{e} , $\underline{\phi}_f$ and $\underline{\phi}_g$ are all bounded).

c) If $\underline{v} \in L_2$, then from (64) $\underline{e} \in L_2$. From a), $\underline{e} \in L_\infty$. Because in the proof of b) of this theorem we showed that all the variables in the right-hand side of (A.23) are bounded, we have $\dot{\underline{e}} \in L_\infty$. Using the Barbalat's Lemma, we have $\lim_{t \rightarrow \infty} |\underline{e}(t)| = 0$. Q.E.D.

APPENDIX B

The fuzzy system $f_i(x|\underline{\theta}_f)$ of (52) can be represented as the feedforward network of Fig. 13. Using the chain rule on the \hat{f}_i of Fig. 13, we have that

$$\frac{\partial \hat{f}_i}{\partial \bar{y}_{ie}^l} = \frac{c_i^l}{b_i}, \quad (\text{B.1})$$

$$\frac{\partial \hat{f}_i}{\partial \sigma_{ie}^l} = \frac{\partial \hat{f}_i}{\partial c_i^l} \frac{\partial c_i^l}{\partial \sigma_{ie}^l} = \frac{(\bar{y}_{ie}^l - \hat{f}_i)}{b_i} \frac{-2z^l \sigma_{ie}^l}{((\sigma_{ie}^l)^2 + \epsilon)}, \quad (\text{B.2})$$

$$\begin{aligned}\frac{\partial \hat{f}_i}{\partial \bar{x}_{jf}^l} &= \frac{\partial \hat{f}_i}{\partial z^l} \frac{\partial z^l}{\partial \bar{x}_{jf}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{1}{(\sigma_{ie}^l)^2 + \epsilon} \\ &\quad \cdot \frac{z^l (x_j - \bar{x}_{jf}^l)}{(\sigma_{jf}^l)^2 + \epsilon}, \quad (\text{B.3})\end{aligned}$$

$$\begin{aligned}\frac{\partial \hat{f}_i}{\partial \sigma_{jf}^l} &= \frac{\partial \hat{f}_i}{\partial z^l} \frac{\partial z^l}{\partial \sigma_{jf}^l} = \frac{\bar{y}_{ie}^l - \hat{f}_i}{b_i} \frac{1}{(\sigma_{ie}^l)^2 + \epsilon} \\ &\quad \cdot \frac{z^l 2(x_j - \bar{x}_{jf}^l) \sigma_{jf}^l}{((\sigma_{jf}^l)^2 + \epsilon)^2} \quad (\text{B.4})\end{aligned}$$

where $j = 1, 2, \dots, n$, $l = 1, 2, \dots, N$, and a_i , b_i , c_i^l , and z^l are defined in Fig. 13. The $(\partial g_i / \partial \theta_g)$ can be computed in exactly the same way as (B.1)–(B.4), with the subscripts “e” replaced by “h” and “f” replaced by “g.”

Li-Xin Wang (S'90–M'93) received the B.S. and M.S. degrees from Northwestern Polytechnical University, Xian, People's Republic of China, in 1984 and 1987, respectively, and the Ph.D. degree from the University of Southern California, Los Angeles, in 1992, all in electrical engineering.

From 1987 to 1989 he was with the Department of Computer Science and Engineering, Northwestern Polytechnical University. From the fall of 1989 to the spring of 1992 he was a Research/Teaching Assistant with the Department of Electrical Engineering–Systems, University of Southern California, where he was working toward the Ph.D. degree. From the summer of 1992 to the summer of 1993 he was a postdoctoral fellow in the Department of Electrical Engineering and Computer Science, University of California at Berkeley, where he worked with Prof. Zadeh. Since the fall of 1993 he has been an Assistant Professor with the Department of Electrical and Electronic Engineering, the Hong Kong University of Science and Technology, Hong Kong. His research interests include intelligent control, fuzzy systems, and robotics.

Dr. Wang is author of *Adaptive Fuzzy Systems and Control: Design and Stability Analysis* (Prentice-Hall, 1994). He received a Phi Kappa Phi Student Recognition Award in 1992 for his work on fuzzy systems.

Stochastic Approximation with Averaging and Feedback: Rapidly Convergent "On-Line" Algorithms

Harold J. Kushner, *Fellow, IEEE*, and Jichuan Yang

Abstract— Consider the stochastic approximation $X_{n+1} = X_n + a_n g(X_n, \xi_n)$, where $0 < a_n \rightarrow 0$, $\sum_n a_n = \infty$ and $\{\xi_n\}$ is the "noise" sequence. Suppose that $a_n \rightarrow 0$ slowly enough such that $a_n/a_{n+1} = 1 + o(a_n)$. Then various authors have shown that the rate of convergence of the average $\bar{X}_n = \frac{1}{n} \sum_{i=1}^n X_i$ is optimal in the sense that $\sqrt{n}(\bar{X}_n - \theta)$ converged in distribution to a normal random variable with mean zero and covariance V , where V was the smallest possible in an appropriate sense. V did not depend on $\{a_n\}$. The analogs of the advantages of averaging extend to the constant parameter systems $X_{n+1} = X_n + \epsilon g(X_n, \xi_n)$ for small $\epsilon > 0$. The averaging method is essentially "off line" in the sense that the actual SA iterate X_n is not influenced by the averaging. In many applications, X_n itself is of greatest interest, since that is the "operating parameter." This paper deals with the problem of stochastic approximation with averaging and with appropriate feedback of the averages into the original algorithm. It is shown both mathematically and via simulation that it works very well and has numerous advantages. It is a clear improvement over the system X_n by itself. It is fairly robust, and quite often it is much preferable to the use of the above averages without feedback. We will deal, in particular, with "linear" algorithms of the type appearing in parameter estimators, adaptive noise cancellers, channel equalizers, adaptive control, and similar applications. The main development will be for the constant parameter case because of its importance in applications. But analogous results hold for the case where $a_n \rightarrow 0$.

1. INTRODUCTION

CONSIDER the stochastic approximation

$$X_{n+1} = X_n + a_n g(X_n, \xi_n)$$

where $0 < a_n \rightarrow 0$, $\sum_n a_n = \infty$ and $\{\xi_n\}$ is the "noise" sequence. There is a large literature and many sophisticated analyses available for such processes. Under various sets of conditions, there is θ such that $X_n \rightarrow \theta$ either with probability one or weakly. Also, under appropriate conditions $(X_n - \theta)/\sqrt{a_n}$ converges in distribution to a normal random variable with mean zero and some covariance matrix V_0 . The matrix V_0 and the scale factors $\{a_n\}$ are a measure of the "rate of convergence."

Suppose that $a_n \rightarrow 0$ slowly relative to $1/n$. More particularly, let

$$a_n/a_{n+1} = 1 + o(a_n). \quad (1.2)$$

Under some additional conditions, Polyak and Juditsky [11] showed that the rate of convergence of the average

$$\bar{X}_n = \frac{1}{n} \sum_{i=1}^n X_i \quad (1.3)$$

is optimal in an important sense. In particular, $\sqrt{n}(\bar{X}_n - \theta)$ converged in distribution to a normal random variable with mean zero and covariance V , where V was the smallest possible in an appropriate sense. V did not depend on $\{a_n\}$. This development promises to be quite important in applications. By now, extensive simulations have supported the theoretical conclusions. This superiority would not be true if a_n decreased as $O(1/n)$. Choosing the a_n sequence was a major nuisance in the past. The importance of this problem is now much reduced. Larger values of a_n (larger than $O(1/n)$) cause the process to "jump around" more, but the averaging in (1.3) compensates for this and greatly improves the values. Ruppert [12] developed similar results for a one dimensional problem.

Additional work on the averaging problem was done by Yin [14], [15] who generalized the earlier results. In [9], Kushner and Yang showed that the averaging results were generic to stochastic approximation (SA), and held under conditions of considerable generality. That work shed much light on the reasons why the averaging gave a better result when (1.2) held. In general, that reference used sums of the type (1.3), but with various moving windows and where the lower index of summation goes to infinity as $n \rightarrow \infty$. As pointed out in [9], the basic reasons for the success of averaging stem from the fact that the "time scales" of the original sequence X_n and the averaged sequence \bar{X}_n can be separated, with the time scale of the former sequence being "faster." This time scale separation also accounts for the difficulties in the analysis of the averaged sequence. Time scale separations have been used as a standard tool in the analysis of stochastic approximations. But, in the past it was the separation of the scales of the X_n and the noise ξ_n sequences which was used. Now there is a third time scale to be considered. Similar results have been obtained for the constant parameter case

$$X_{n+1} = X_n + \epsilon g(X_n, \xi_n). \quad (1.4)$$

The averaging method is essentially "off line" in the sense that the iterations (1.1) and (1.4) are not influenced by the averaging. In many applications, X_n itself is of greatest interest since that is the "operating parameter." Indeed, if \bar{X}_n were substituted for X_n on the right sides of (1.1) or

(1.4), or in the $g(\cdot)$ function alone, then the advantages of averaging would be totally lost. One can, of course, run a "training" sequence and then use the end value of the averaged sequence as the future operating value. This would often be a useful idea. Nevertheless, the question remains whether it is possible to exploit the averaging to improve the actual primary stochastic approximation $\{X_n\}$. This paper deals with the problem of stochastic approximation with simultaneous use of averaging and feedback. It is shown both mathematically and via simulation that it works well and has numerous advantages. It is a clear improvement over the systems (1.1), (1.4) by themselves.

We will deal only with "linear" algorithms of the type appearing in parameter estimators, adaptive noise cancellers, adaptive antenna arrays, channel equalizers, and similar applications. Stability problems make the general nonlinear problem much harder at present. But, as noted above, the special case has numerous important applications and is the subject of an enormous literature itself. These are adaptive problems of great current interest, particularly in the communications, parameter estimation and signal processing area. For such problems, it is common practice to use (1.4) for small ϵ , even if the parameters of concern are not time varying. So, we concentrate on this case. More detailed discussion and motivation for the constant parameter case is given at the end of Section III to which the reader is referred.

The multiple time scale point of view and the clear (to be seen below) advantages of feedback with which this paper is concerned imply that the use of various types of averaging methods in stochastic approximation is just beginning. In Section II we describe a simple but important averaging result (with no feedback), taken from [9]. While this result will not be used explicitly in the sequel, it illustrates a basic property and value of averaging in a simple context and it is useful for motivation. In Section III the actual problem of interest will be described. We work with (1.4) and use various approximations to (1.3) which are equivalent to different windows of averaging or "forgetting rates." All the results have analogs for the case where $a_n \rightarrow 0$ and (1.2) holds. The basic estimates of the asymptotic orders of the errors for the problem with feedback is given in Section IV. This section makes use of the so-called perturbed Lyapunov function methods. The order estimates show that the averaged iterate (in the feedback case) is still better than what one would get without averaging. Once the estimates of order are available, an asymptotic weak convergence analysis can be done. This appears in Section V, where the limits of the distributions of normalized iterates are obtained. In particular, it will be seen that the limiting distribution is that of the stationary random variable of a Gauss-Markov diffusion, and that the limit covariance of the process with feedback is much better than that for the original sequence without feedback and frequently better than that for the sequence of averages (1.3) of the original sequence (1.1). Numerous simulations have strongly supported the theoretical conclusions, and typical simulation results for canonical systems fitting the framework of the various applications cited above appear in Section VI. The time varying parameter case is discussed in Section V-B.

II. THE ADVANTAGES OF AVERAGING: A SIMPLE EXAMPLE

A very useful and relatively simple result which demonstrates the advantages of averaging without feedback can be readily obtained via a weak convergence method, under quite broad conditions. We will use a "minimal window" of iterates, smaller than in (1.3), yet of considerable practical interest. Our interest in this section is simply in showing that various sets of conditions in stochastic approximation give the desired result. We wish to show only that the averaging works if there is a basic rate of convergence result for X_n , thus implying that the advantages of averaging naturally accompany any classical rate of convergence analysis. The material in this section is taken from [9] and is for motivation only. The result will not be used explicitly in the sequel, but is important for motivation and for putting the subsequent results into perspective.

Let us set up the required terminology. Define the "interpolated time" $t_n = \sum_{i=0}^{n-1} a_i$, with $t_0 = 0$. In this section, we will set $\theta = 0$ [see the definition below (1.1)] for notational simplicity. In the asymptotic analysis, it is usual to examine the tails of the SA sequences. To do this we define the "tail" processes as follows. For each $n \geq 0$, define the interpolated processes $U^n(\cdot)$, $X^n(\cdot)$ by

$$\begin{aligned} U^n(t) &= X_{n+i} / \sqrt{a_{n+i}} \text{ for} \\ t &\in [t_{n+i} - t_n, t_{n+i+1} - t_n], i \geq 0, \\ X^n(t) &= X_{n+i} \text{ for } t \in [t_{n+i} - t_n, t_{n+i+1} - t_n], i \geq 0. \end{aligned}$$

The basic result below is stated in terms of weak convergence. It is not necessary to be familiar with the details of the weak convergence method to deal with the rest of the paper. Loosely speaking, weak convergence of a sequence of processes $U^n(\cdot)$ to a process $U(\cdot)$ means that if $f(\cdot)$ is a continuous functional of the process paths, then $f(U^n(\cdot))$ converges in distribution to $f(U(\cdot))$. It is a considerable extension of the usual convergence in distribution for vector valued random variables. Of course, to speak of convergence in a function or path space implies a particular path space and topology on it. The most frequently used path space is the space of functions which are continuous on the right and with left hand limits. The most commonly used topology on this space (and the one used here) is the so-called Skorohod topology $D^r[0, \infty)$ [2], [3], [6], where r is the dimension of X . All that we need to know here is that the topology is weaker than that determined by uniform convergence on bounded time intervals. Thus, if $y_n(\cdot)$ is a sequence of paths in $D^r[0, \infty)$ and $y_n(\cdot) \rightarrow y(\cdot)$ in the sup norm on each bounded time interval, then the convergence is also in the Skorohod topology. Let \Rightarrow denote weak convergence.

In Theorem 2.1, we will use the following assumption.

A 2.1: There is a matrix G whose eigenvalues lie in the open left-half plane and a positive semidefinite symmetric matrix R_0 such that $X^n(\cdot) \Rightarrow$ zero process and $U^n(\cdot) \Rightarrow U(\cdot)$, where $U(\cdot)$ is the stationary solution to

$$dU = GU dt + R_0^{\frac{1}{2}} dw \quad (2.1)$$

where $w(\cdot)$ is a standard R^r -valued Wiener process.

Comment on (A2.1): We state condition (A2.1) in the given form since it is the most convenient way to illustrate the main point. Many different sets of conditions imply (A2.1) and getting such a result has been one of the main goals of work in stochastic approximation. Our primary goal in this section is to show that such a commonly available weak convergence result can be easily extended to show the possibilities in improvement in the rate of convergence due to averaging. The references [1], [6], [7], [10] contain various sets of conditions which guarantee (A2.1).

For $T > 0$, define $Z^n(\cdot)$ by

$$Z^n(T) = \frac{1}{\sqrt{T/a_n}} \sum_{i=n}^{n+T/a_n} X_i. \quad (2.2)$$

In sums such as (2.2), the limits of summation are always taken to be the integer parts of the indexes.

A. A Convergence Theorem

Theorem 2.1: Assume (1.2) and (A2.1) and define $V = G^{-1}R_0(G')^{-1}$. For each T , $Z^n(T)$ converges in distribution to a random variable with mean zero and covariance $V_T = V + O(1/T)$.

Discussion: The proof of the theorem is in [9]. By the weak convergence in (A2.1), as $n \rightarrow \infty$ we have (loosely speaking and in the sense of distributions) $X_n \sim N(0, a_n V_0)$, where $N(0, M)$ denotes the normal distribution with covariance M and mean zero, and V_0 is the stationary covariance of (2.1). The theorem implies that for large T and large n , $\bar{X}_n \sim N(0, a_n V/T)$. Thus for large T , averaging is a distinct advantage. The sum in (2.2) can be replaced by $\sum_{i=n-T/a_n}^n$. Other relevant comments are in [9], [11], [14], with various windows of averaging.

Minimality of V : It is noted in [9], [11] that V is minimal in an important sense, which we now describe. Suppose that (1.1) is used and $U_n = X_n/\sqrt{a_n}$ converged in distribution to a normally distributed random variable \tilde{U} with mean zero. Then the fastest asymptotic rate of convergence is obtained with $a_n = K/n$, for K a positive definite matrix. Then, under appropriate conditions (see, e.g., [1], [6]) $U^n(\cdot) \Rightarrow \tilde{U}(\cdot)$, where $\tilde{U}(\cdot)$ is the stationary solution to

$$d\tilde{U} = \left(\frac{I}{2} + KG\right)\tilde{U}dt + KR_0^{\frac{1}{2}}dw \quad (2.3)$$

where G and R_0 are as in (A2.1), and it is supposed that $(\frac{I}{2} + KG)$ is a stable matrix. If we optimize the trace of the covariance matrix of (2.3) over K , we get the best value of K as

$$K = -G^{-1}.$$

With this value of K , the covariance of $\tilde{U}(0)$ is just the V used in Theorem 2.1. In this sense, the result in [9], [11] and of Theorem 2.1 is optimal.

Constant Gains: Suppose that $a_n = \varepsilon$, a small gain parameter. Define

$$Z^n(T) = \frac{1}{\sqrt{T/\varepsilon}} \sum_{i=n}^{n+T/\varepsilon} X_i.$$

Then if n and T are large enough, we have $X_n \sim N(0, \varepsilon V_0)$, and $\bar{X}_n \sim N(0, \varepsilon V/T)$, again an advantage over the nonaveraged variate.

III. AVERAGING WITH FEEDBACK FORMULATION

In this section, we describe the algorithm of concern. The analysis will be done in the following section. We would like to be concerned with algorithms of the general type, for positive real valued A

$$X_{n+1} = X_n + \varepsilon g(X_n, \xi_n) + \varepsilon A(\bar{X}_n - X_n)$$

where the feedback is linear and proportional to the gain ε . This form does allow the use of the averaged iterates in an intuitively reasonable way in the primary algorithm. Indeed, the results of the sequel suggest that a larger feedback will not work well. It is hard to analyze the fully nonlinear case, and we will work with a simpler form which is very important in applications.

The Model: Consider a classical algorithm for parameter identification. Let θ denote the system parameter, ϕ_n a sequence of random "input vectors" with $E\phi_n\phi_n' = G > 0$ (positive definite), ψ_n a sequence of real valued random variables (with mean zero, without loss of generality) and ϕ' is the transpose of ϕ . The observed output is the real valued $y_n \equiv \theta' \phi_n + \psi_n$. A common form of the identification (alternatively, adaptive noise canceller, etc.) algorithm is

$$\hat{\theta}_{n+1} = \theta_n + \varepsilon \phi_n [y_n - \hat{\theta}_n' \phi_n] \quad (3.1)$$

where $\hat{\theta}_n$ is the n th estimate of θ . Define

$$\bar{\theta}_n = \frac{1}{n} \sum_{i=1}^n \hat{\theta}_i. \quad (3.2)$$

One also might use the finite window of averaging, where $\bar{\theta}_n$ is defined by (for $T > 0$)

$$\bar{\theta}_n = \frac{1}{T/\varepsilon} \sum_{i=n-T/\varepsilon}^n \hat{\theta}_i.$$

Then (see comment after the proof of Theorem 2.1) the theory of the last section (equivalently, of [9]) can be used to show that for large T , the average $\bar{\theta}_n$ has a much smaller asymptotic covariance than does the original $\hat{\theta}_n$.

A Feedback Form of (3.1), (3.2). Consider the following form of (3.1) and (3.2), where the average is fed back. For $A > 0$, redefine θ_n and $\bar{\theta}_n$ by

$$\begin{aligned} \hat{\theta}_{n+1} &= \hat{\theta}_n + \varepsilon \phi_n [y_n - \hat{\theta}_n' \phi_n] + \varepsilon A[\bar{\theta}_n - \theta_n] \\ \bar{\theta}_n &= \frac{1}{n} \sum_{i=1}^n \hat{\theta}_i. \end{aligned} \quad (3.3)$$

Defining $X_n = \hat{\theta}_n - \theta$, $\bar{X}_n = \bar{\theta}_n - \theta$, rewrite (3.3) as

$$X_{n+1} = [I - \varepsilon G]X_n + \varepsilon \xi_n + \varepsilon A[\bar{X}_n - X_n], \quad (3.4a)$$

$$\bar{X}_n = \frac{1}{n} \sum_{i=1}^n X_i. \quad (3.4b)$$

where

$$\xi_n = [G - \phi_n \phi_n'] X_n + \phi_n \psi_n \equiv \Phi_n X_n + \rho_n$$

where the definitions of Φ_n and ρ_n are obvious.

The sequence $\{X_n\}$ can be arbitrarily well approximated for large n by the solution to the equation

$$\begin{aligned} \bar{X}_0 &= \bar{X}_1 = X_0 \quad \text{and, for } n > 1, \\ \bar{X}_{n+1} &= \left(1 - \frac{1}{n}\right) \bar{X}_n + \frac{X_n}{n}. \end{aligned} \quad (3.5)$$

In fact, we will work with the more general forms defined by either (3.6) or (3.7)

$$\bar{X}_{n+1} = (1 - b_n) \bar{X}_n + b_n X_n \quad (3.6)$$

where

$$b_n \rightarrow 0, \quad \sum b_n = \infty$$

or

$$\bar{X}_{n+1} = (1 - \alpha c) \bar{X}_n + \alpha c X_n \quad (3.7)$$

where $\alpha > 0$ is small. The form

$$\bar{X}_n = \alpha c \sum_{i=0}^{n+1/\alpha c} X_i$$

seems to be better in simulations although it is much harder to analyze.

Algorithms of the form (3.1) are commonly used in adaptive applications throughout communication theory and in signal processing [13], [5]. The simulations in Section VI are for a canonical problem in these areas. In such applications, one generally lets ϵ be a constant, selected *a priori*. The decreasing gain case $a_n \rightarrow 0$ is more rarely used, even when the basic parameters to be adjusted to are thought to be constant. This is due partly to the way that the systems are automated. Also, in applications one often seeks the largest value of ϵ for which the system will be stable and still have reasonably small noise effects. It is important to keep in mind that the errors are relative to a bias, since the system order is rarely known. (In this biased case the results here hold, as they should, for the errors centered about the bias.)

A possibly ideal algorithm, in lieu of (3.1), would be linearized least squares. This has excellent asymptotic properties, but due to the heavy computational overhead, one generally prefers to avoid it in the applications cited. A possible alternative to linearized least squares replaces ϵ by $a_n \rightarrow 0$. This is often unsatisfactory. The best rate is $a_n = O(1/n)$, which has serious robustness problems. Furthermore, unless $a_n = K/n$ for an appropriate matrix K , the data for the different coordinates can be greatly skewed. In many applications one prefers not to use such a matrix due to the more complex implementation and the difficulty in getting a good value for it.

As seen from Section II, letting a_n go to zero slowly enough and using averaging accomplishes the same thing asymptotically as does the use of linearized least squares,

without much additional computation, since (loosely speaking) $X_n \sim N(0, V/n)$, where V is minimal. The best algorithms of Section II use a window of averaging which is of the order of n , the current iterate number. One might wish to avoid this due to robustness considerations. In addition, the benefits of averaging do not extend to the iterate X_n itself. If $a_n \rightarrow 0$ slowly enough, then over practical operating ranges there is not much difference between using a fixed ϵ or $a_n \rightarrow 0$. We work with a constant window of averaging and the constant gain case. The scheme will be seen to be robust. In Section IV it is shown that the use of averaging and feedback and a finite window does not hurt the iterate and yields an average that is $O(\epsilon^3)$ in typical cases. This is a vast improvement over the widely used constant gain case. In Section V, it is shown that the result is actually much better, and the result is quantified in terms of the feedback gain and the window of averaging. The considerable improvement that it can provide over the standard fixed gain case for both the direct iterate and the average are clearly seen from the estimates in Sections IV and V, and from the simulation results.

IV. ASYMPTOTIC ORDERS

Stability results and estimates of the orders of the asymptotic errors generally form the basis of asymptotic analysis of stochastic approximations. Such estimates are the subject of this section. Informal calculations suggest that the estimates (4.1b) and (4.1c) might be conservative. The stability estimates will be exploited in the next section, where we will get more precise asymptotics and a more explicit estimate of the errors as a function of the feedback gains and the window of averaging. As written, Theorem 4.1 shows that the use of feedback does not hurt the direct iterate and that the averaged iterate is much better than what one would get without feedback and averaging. In Sections V and VI, it will be seen that the direct iterate can be much better as well.

Assumptions: Define E_n as the conditional expectation given $\{X_0, \phi_i, \psi_i, i < n\}$. For real K_0 , we require, uniformly in n

$$\sum_{m=n}^{\infty} E_n \Phi_m \leq K_0, \quad (A4.1)$$

$$\sum_{m=n}^{\infty} E_n \rho_m \leq K_0. \quad (A4.2)$$

$$\{\Phi_i, \rho_i, i < \infty\} \text{ is bounded.} \quad (A4.3)$$

Note: Conditions such as (A4.1)–(A4.3) are quite convenient and not too restrictive in practice. They imply a certain rate of decrease of the correlation; i.e., a rate of decrease of the expectation of future “noise values” given the remote past. They are implied by various types of mixing conditions. See [3], [6] for examples. They do exclude the Gaussian case, but would include any reasonable truncation of a Gaussian sequence.

Theorem 4.1: Assume (A4.1)–(A4.3). Then, for (3.4a), (3.6)

$$\limsup E|X_n|^2 = O(\epsilon). \quad (4.1a)$$

$$\limsup_n E|\bar{X}_n|^2 = O(\varepsilon^2). \quad (4.1b)$$

If $E_n \rho_i = 0, i \geq n$, then

$$\limsup_n E|\bar{X}_n|^2 = O(\varepsilon^3). \quad (4.1c)$$

If (3.7) is used, then the right-hand sides of (4.1b), (4.1c) are replaced by $O(\varepsilon)$.

Comment: We have $E_n \rho_i = 0, i \geq n$, if the observation noises $\{\psi_n\}$ are mutually independent, have mean zero, and are independent of the $\{\phi_n\}$.

Proof: The proof will be divided into several parts. The basic technique is the perturbed Lyapunov function method [6], which has been found to be very useful for stability problems with non-Markovian systems. In Part 1, we try to apply a standard Lyapunov function method to the X_n , \bar{X}_n sequences and show that there is a problem due to certain "bad" terms. We then proceed to define the perturbed Lyapunov function, which is designed to deal with these bad terms. The procedure is straightforward, but a little tedious. The technique requires that a certain "fixed parameter" system be defined, and this is done in Part 2. Certain auxiliary functions (the perturbations) are defined in Part 3. In Part 4, the perturbed Lyapunov function is defined and appropriate estimates of the perturbation given.

Part 1: First, we use $b_n \rightarrow 0$ and attempt to use standard stochastic Lyapunov functions. It will be seen that these will not yield inequalities which can be used to prove the estimates (4.1). The problem concerns certain "bad" terms which appear and the inability of a classical Lyapunov function approach to exploit time scale differences. We will be able to cancel the effects of these bad terms via the use of suitable perturbations to the Lyapunov functions, which allow us to exploit time scale differences.

Define $C = [AI + G]^{-1}A$, and $Q = AI + G$. It is convenient to work first with a "centered" process defined by $\tilde{X}_n = X_n - C\bar{X}_n$. We can write

$$\tilde{X}_{n+1} = (I - cQ)X_n + c\xi_n + b_n C'(\bar{X}_n - X_n) \quad (4.2)$$

where the noise term ξ_n is defined by

$$\xi_n = \Phi_n X_n + \rho_n = \Phi_n[\tilde{X}_n + C'\bar{X}_n] + \rho_n. \quad (4.3)$$

We can write

$$\begin{aligned} E_n|\tilde{X}_{n+1}|^2 - |\tilde{X}_n|^2 &= 2\tilde{X}_n' E_n[\tilde{X}_{n+1} - \tilde{X}_n] + E_n|\tilde{X}_{n+1} - \tilde{X}_n|^2, \quad (4.4a) \\ 2\tilde{X}_n' E_n[\tilde{X}_{n+1} - \tilde{X}_n] &= -2\varepsilon\tilde{X}_n' Q\tilde{X}_n + 2\varepsilon\tilde{X}_n' E_n\xi_n + 2b_n\tilde{X}_n' C' \\ &\quad \times [\bar{X}_n - X_n]. \quad (4.4b) \end{aligned}$$

We now put (4.4b) into a form which will allow a better estimate to be obtained. For small positive k_1 , we will use the inequality

$$b_n|\tilde{X}_n||\bar{X}_n| \leq b_n \left[\frac{\varepsilon k_1}{b_n} |\tilde{X}_n|^2 + \frac{b_n}{\varepsilon k_1} |\bar{X}_n|^2 \right]. \quad (4.5)$$

The k_1 above and the positive real numbers k_2, k, q which will be introduced below can be as small as needed. But they

do not depend on ε, n . The purpose of inequalities such as (4.5) is to facilitate use of the time scale differences between \bar{X}_n and X_n , as will be seen. We use (4.5) in several of the following inequalities. If the term linear in k_1 is dominated by other terms for small k_1 , then we might omit it and adjust the orders appropriately.

Using the inequality (4.5) and writing $X_n = \tilde{X}_n + C\bar{X}_n$, yields

$$\begin{aligned} 2\tilde{X}_n' E_n[\tilde{X}_{n+1} - \tilde{X}_n] &\leq -2\varepsilon\tilde{X}_n' Q\tilde{X}_n + 2\varepsilon\tilde{X}_n' E_n\xi_n \\ &\quad + k_1 O(\varepsilon)|\tilde{X}_n|^2 + O\left(\frac{b_n^2}{\varepsilon}\right) \frac{1}{k_1} |\bar{X}_n|^2. \end{aligned}$$

Since we are concerned with asymptotic analysis, where $n \rightarrow \infty$ and ε is small, we always suppose (without loss of generality) that ε and the ratio b_n/ε are small, the latter going to zero with n . Then in all of the following estimates, we omit the terms which are dominated by others which appear; e.g., if for any "quantity" there is a term $O(\varepsilon) \times \text{quantity} + O(b_n) \times \text{quantity}$, we will omit $O(b_n) \times \text{quantity}$. From (4.4a), we can now write

$$\begin{aligned} E_n|\tilde{X}_{n+1}|^2 - |\tilde{X}_n|^2 &\leq -\varepsilon\tilde{X}_n' Q\tilde{X}_n + 2\varepsilon\tilde{X}_n' E_n\xi_n \\ &\quad + O\left(\frac{b_n^2}{\varepsilon}\right) \frac{1}{k_1} |\bar{X}_n|^2 + O(\varepsilon^2) E_n|\xi_n|^2. \quad (4.6) \end{aligned}$$

Using $X_n = \tilde{X}_n + C\bar{X}_n$, we can also write

$$\begin{aligned} |\bar{X}_{n+1}|^2 - |\bar{X}_n|^2 &= -2b_n|\bar{X}_n|^2 + 2b_n\bar{X}_n'(\tilde{X}_n + C'\bar{X}_n) \\ &\quad + O(b_n^2)(|\tilde{X}_n|^2 + |\bar{X}_n|^2). \quad (4.7) \end{aligned}$$

We will bound the right side of (4.7) by a more manageable function by using a form of (4.5), as follows. For small $k_2 > 0$, use

$$b_n|X_n||\bar{X}_n| \leq b_n \left[\frac{1}{k_2} |\tilde{X}_n|^2 + k_2 |\bar{X}_n|^2 \right]. \quad (4.8)$$

Again, when (4.8) is used, if the term linear in k_2 is dominated by other terms when k_2 is small, then we might omit it and adjust the orders appropriately. Now rewrite (4.7) as

$$\begin{aligned} |\bar{X}_{n+1}|^2 - |\bar{X}_n|^2 &\leq -2b_n\bar{X}_n'(I - C')\bar{X}_n \\ &\quad + O(b_n)k_2|\bar{X}_n|^2 + O(b_n)|X_n|^2 \frac{1}{k_2}. \quad (4.9) \end{aligned}$$

Part 2—Auxiliary Processes: Inequalities (4.6) and (4.9) cannot be used directly to get the moment estimates due to the appearance of certain "bad" terms. To deal with the "bad" term $2\varepsilon\tilde{X}_n' E_n\xi_n$ in (4.6), we need to exploit the time scale differences between the \tilde{X}_n and ξ_n sequences. This will be done by modifying the Lyapunov functions slightly. But first, we need to introduce various "fixed- r " processes. These are needed since the noise is not only correlated, but depends on the state. The approach is analogous to the one used successfully in [6]. First, we define some auxiliary sequences. In the next part of the proof, perturbations to the Lyapunov functions $|X_n|^2$ and $|\bar{X}_n|^2$ which use these auxiliary sequences will be defined and estimates of their values obtained. The proof will be completed in the Parts 4–6.

The noise ξ_n in (4.3) depends on the state X_n . Exploitation of the time scale differences is aided by the introduction of "fixed- x " noise process. This useful idea has wide applicability for getting limit results, whenever the noise is state dependent; e.g., see [6]. For each x , define the "fixed- x " noise process $\xi_n(x) = \Phi_n x + \rho_n$. For each n , define the noise sequence $\{\xi_m^n, m \geq n\}$ by

$$\xi_m^n = \Phi_m X_n + \rho_m. \quad (4.10)$$

Analogously, for each n and $m \geq n$ define the "fixed- x process" $\tilde{X}_m^n(x, x)$ by $\tilde{X}_m^n(r, x) = \tilde{x}$, and for $m \geq n$

$$\tilde{X}_{m+1}^n(x, \tilde{x}) = (I - \varepsilon Q) \tilde{X}_m^n(r, \tilde{x}) + \varepsilon \xi_m^n(x) \quad (4.11)$$

Note that x and \tilde{x} are parameters here. Define $\{X_m^n, m \geq n\}$ by $\tilde{X}_n^n = \tilde{X}_n$, and $X_m^n = X_m^n(X_n, \tilde{X}_n)$ for $m > n$ i.e., for $m \geq n$

$$\tilde{X}_{m+1}^n = (I - \varepsilon Q) \tilde{X}_m^n + \varepsilon \xi_m^n, \quad X_n^n = X_n \quad (4.12)$$

Thus, the parameter (x, \tilde{x}) in (4.11) is set to (X_n, X_n) , i.e., in $\{X_m^n, m \geq n\}$, the noise evolves (after time n) as though the state never changes, thus the term "fixed x " process.

Part 3 We will define various auxiliary sequences, which will be used for the Lyapunov function perturbations and obtain some estimates of their values. For each n , define the sequence

$$f_n^1 = \sum_{m=n}^{\infty} b_m E_n X_m^n \quad (4.13)$$

In the Appendix, it will be shown that

$$|f_n^1| = O\left(\frac{b_n}{\varepsilon}\right)(|X_n| + |\bar{X}_n|) + O(b_n) \quad (4.14a)$$

If $E_n \rho_n = 0$, $\varepsilon \geq n$, then we will get the estimate

$$|\hat{f}_n^1| = O\left(\frac{b_n}{\varepsilon}\right)(|X_n| + |\bar{X}_n|) \quad (4.14b)$$

To unify terminology, and write estimates such as (4.14a) and (4.14b) as one compact expression, we will use the symbol I : If we assume $E_n \rho_n = 0$, $\varepsilon \geq n$, then $I = 0$, otherwise it takes the value 1.

In the Appendix it is shown that the conditional difference satisfies

$$E_n f_{n+1}^1 - \hat{f}_n^1 = -b_n X_n + O\left(\frac{b_n^2}{\varepsilon} + b_n \varepsilon\right) \times (|\bar{X}_n| + |\tilde{X}_n|) + IO(b_n \varepsilon) \quad (4.15)$$

We have

$$E_n f_{n+1}^1 - \hat{f}_n^1 = -b_n X_n + \sum_{m=n+1}^{\infty} b_m E_n [\tilde{X}_m^{n+1} - \tilde{X}_m^n] \quad (4.16)$$

We now define one last perturbation. Define

$$\hat{f}_n^2 = 2\varepsilon \tilde{X}_n' \sum_{m=n+1}^{\infty} E_n \xi_m^n. \quad (4.17a)$$

Then

$$\hat{f}_n^2 = O(\varepsilon)(|\tilde{X}_n|^2 + |\bar{X}_n|^2) + IO(\varepsilon) \quad (4.17b)$$

where the estimate follows from (A4.1)–(A4.3). This perturbation will be used to cancel the $2\varepsilon \tilde{X}_n' E_n \xi_n$ term in (4.6). Now, evaluate the conditional difference (recall that $\xi_n^n = \xi_n$)

$$E_n \hat{f}_{n+1}^2 - \hat{f}_n^2 = -2\varepsilon \tilde{X}_n' E_n \xi_n + T_n^1 + T_n^2 \quad (4.18)$$

where we define

$$T_n^1 = 2\varepsilon E_n (\tilde{X}_{n+1} - \tilde{X}_n)' \sum_{m=n+1}^{\infty} E_{n+1} \xi_m^{n+1}$$

$$T_n^2 = 2\varepsilon \tilde{X}_n' \sum_{m=n+1}^{\infty} E_n [\xi_m^{n+1} - \xi_m^n].$$

We have

$$|T_n^1| + |T_n^2| = O(\varepsilon^2 + b_n \varepsilon) + O(\varepsilon^2 + b_n \varepsilon) \times (|X_n|^2 + |\bar{X}_n|^2) \quad (4.19)$$

Part 4 We are now prepared to define and use the perturbed stochastic Lyapunov functions. Define the perturbed Lyapunov function $V_n = |\tilde{X}_n|^2 + \hat{f}_n^2$. Then, via (4.6), (4.18), and cancelling terms where possible or where they are dominated by others

$$E_n V_{n+1} - V_n \leq -\frac{\varepsilon}{2} X_n' Q X_n + O\left(\frac{b_n^2}{\varepsilon} + \varepsilon^2\right) |\bar{X}_n|^2 \frac{1}{K_1} + O(\varepsilon^2) \quad (4.20)$$

Note, in particular, that the $-2\varepsilon \tilde{X}_n' E_n \xi_n$ in (4.18) cancels a term in (4.6). This is the essential reason for the form selected for \hat{f}_n^2 . Now, using the bound on the right side of (4.17), we see that there is some $K_1 > 0$ such that

$$E_n V_{n+1} - V_n \leq -\varepsilon K_1 V_n + O\left(\frac{b_n^2}{\varepsilon} + \varepsilon^2\right) |\bar{X}_n|^2 + O(\varepsilon^2). \quad (4.21)$$

Next, for $K_2 > 0$ define the Lyapunov function $V_n = K_2 b_n V_n / \varepsilon + |\tilde{X}_n|^2$. For large enough K_2 , there is $K_3 > 0$ such that (4.21), (4.9), and the fact that $I - C'$ is positive definite, imply that

$$E_n V_{n+1} - V_n \leq -b_n K_3 V_n + O(\varepsilon b_n) \quad (4.22)$$

Thus, taking expectations, iterating, and using the condition $\sum b_n = \infty$, yields

$$\limsup_n EV_n = O(\varepsilon) \quad (4.23)$$

Since $(K_2 b_n / \varepsilon) |f_n^2| = O(b_n)(|X_n|^2 + |\bar{X}_n|^2 + 1)$, for small ε and b_n we have

$$|\bar{X}_n|^2 \leq 2V_n + O(b_n)$$

Thus (4.23) implies that

$$\limsup_n E|\bar{X}_n|^2 = O(\varepsilon). \quad (4.24)$$

Now, taking expectations in (4.21), and substituting (4.24) into (4.21) yields

$$\limsup E(|X_n|^2 + \hat{f}_n^2) = O(\varepsilon)$$

Now, (4.1a) follows from this and the bound in (4.17).

Part 5: To date, we have mainly exploited the time scale differences between the $\{\tilde{X}_n, \bar{X}_n\}$ and $\{\Phi_n, \rho_n\}$ sequences. To improve the estimate (4.1a), we need to do a finer analysis. This will require the use of an additional perturbation, to exploit the time scale differences between the \tilde{X}_n and \bar{X}_n sequences. We get the estimates in this part and do the final Lyapunov function analysis in Part 6.

Define $\bar{f}_n^1 = 2\bar{X}_n' \tilde{f}_n^1$. By (4.14) and the inequality $|\bar{f}|O(b) \leq O(b) + O(b)|\bar{f}|^2$, we get

$$|\bar{f}_n^1| = O\left(\frac{b_n}{\varepsilon}\right)[|\tilde{X}_n|^2 + |\bar{X}_n|^2] + \hat{I}O(b_n). \quad (4.25)$$

We next evaluate the conditional difference, $E_n \bar{f}_{n+1}^1 - \bar{f}_n^1$. We can write

$$\begin{aligned} E_n \bar{f}_{n+1}^1 - \bar{f}_n^1 &= -2b_n \bar{X}_n' \tilde{X}_n \\ &\quad + 2E_n(\bar{X}_{n+1} - \bar{X}_n)' E_{n+1} \tilde{f}_{n+1}^1 \\ &\quad + 2\bar{X}_n' \sum_{m=n+1}^{\infty} b_m E_n[\tilde{X}_m^{n+1} - \tilde{X}_m^n] \\ &\equiv -2b_n \bar{X}_n' \tilde{X}_n + \bar{T}_n^1 + \bar{T}_n^2 \end{aligned} \quad (4.26)$$

where the \bar{T}_n^i are defined in the obvious way. From (4.14b),

$$\begin{aligned} |\bar{T}_n^1| &= O(b_n)(|\bar{X}_n| + |\tilde{X}_n|)O\left(\frac{b_n}{\varepsilon}\right)[|\bar{X}_n| + |\tilde{X}_n| + O(\varepsilon)] \\ &= O\left(\frac{b_n^2}{\varepsilon}\right)[|\tilde{X}_n|^2 + |\bar{X}_n|^2] + O(b_n^2). \end{aligned} \quad (4.27)$$

For $k > 0$ and $q > 0$ (which will be small numbers, but not going to zero with n or ε), we can write

$$\begin{aligned} |\bar{X}_n||\tilde{X}_n| &\leq \frac{k}{\varepsilon}|\bar{X}_n|^2 + \frac{\varepsilon}{k}|\tilde{X}_n|^2, \\ O(b_n\varepsilon)\hat{I}|\bar{X}_n| &\leq O(b_n\varepsilon)\hat{I}\left[\frac{q}{\varepsilon}|\bar{X}_n|^2 + \frac{\varepsilon}{q}\right]. \end{aligned}$$

Using these bounds and the estimates of the sum in (4.16) contained in the two right-hand terms of (4.15), we get

$$\begin{aligned} |\bar{T}_n^2| &= O\left(\frac{b_n^2}{\varepsilon} + b_n\varepsilon\right)\left(1 + \frac{k}{\varepsilon}\right)|\bar{X}_n|^2 \\ &\quad + O\left(\frac{b_n^2}{\varepsilon} + b_n\varepsilon\right)\frac{\varepsilon}{k}|\tilde{X}_n|^2 + \hat{I}O(b_n\varepsilon)\left[\frac{q}{\varepsilon}|\bar{X}_n|^2 + \frac{\varepsilon}{q}\right]. \end{aligned} \quad (4.28)$$

Part 6: We now improve the estimate (4.1a) and get (4.1b, c). Define the perturbed Lyapunov function $\bar{V}_n = |\bar{X}_n|^2 + \bar{f}_n^1$. Then, from (4.7), (4.26)–(4.28), and cancelling or dominating terms where possible, we get (where k, k_1 and q are as small as desired, but do not go to zero with n and ε)

$$\begin{aligned} E_n \bar{V}_{n+1} - \bar{V}_n &\leq -2b_n \bar{X}_n' (I - C) \bar{X}_n \\ &\quad + O\left(\frac{b_n^2}{\varepsilon}\right)(|\tilde{X}_n|^2 + |\bar{X}_n|^2) \\ &\quad + O(b_n^2) + O\left(\frac{b_n^2}{\varepsilon} + b_n\varepsilon\right)\left(\frac{k}{\varepsilon} + 1\right)|\bar{X}_n|^2 \\ &\quad + O\left(\frac{b_n^2}{\varepsilon} + b_n\varepsilon\right)\frac{\varepsilon}{k}|\tilde{X}_n|^2 + \hat{I}O(b_n\varepsilon)\left[\frac{q}{\varepsilon}|\bar{X}_n|^2 + \frac{\varepsilon}{q}\right]. \end{aligned}$$

Note, in particular, that the term $-2b_n \bar{X}_n' \tilde{X}_n$ in (4.26) cancels a similar term in (4.7). Taking expectations, dominating terms where possible, and using $\limsup E|\tilde{X}_n|^2 = O(\varepsilon)$ yields for small $\delta > 0$ (which goes to zero as $n \rightarrow \infty$ and $\varepsilon \rightarrow 0$)

$$\begin{aligned} E\bar{V}_{n+1} - \bar{V}_n &\leq -b_n E\bar{X}_n' (I - C - \delta I) \bar{X}_n \\ &\quad + O(b_n^2 + b_n\varepsilon^3) + \hat{I}O(b_n\varepsilon^2). \end{aligned}$$

For large enough n and small enough ε , there is $\delta_1 > 0$ such that

$$E\bar{V}_{n+1} - \bar{V}_n \leq -\delta_1 b_n E\bar{V}_n + O(b_n^2 + b_n\varepsilon^3) + \hat{I}O(b_n\varepsilon^2).$$

Thus

$$\limsup_n E\bar{V}_n = O(\varepsilon^3) + \hat{I}O(\varepsilon^2).$$

Now, for small b_n and ε

$$|\bar{X}_n|^2 \leq 2\bar{V}_n + O\left(\frac{b_n}{\varepsilon}\right)|\tilde{X}_n|^2 + O(b_n).$$

Equations (4.1b)–(4.1c) follow from (4.1a) and the last two equations.

The last assertion of the theorem (where $b_n = \alpha\varepsilon$) also follows from the above estimates.

V. RATES OF CONVERGENCE LIMITS OF NORMALIZED ITERATES

A. Stochastic Differential Equations for the Asymptotic Normalized Errors

In Theorem 4.1, it was shown that the use of feedback yields an asymptotic error of $O(\varepsilon)$ for X_n , and of $O(\varepsilon^2)$ or $O(\varepsilon^3)$ for \bar{X}_n . This does not tell the full story. Using these results, we will get a finer estimate of the asymptotic variances in this subsection. In the following subsection, similar results will be obtained for the time varying parameter case. We obtain weak convergence or rate of convergence results analogous to that assumed in (A2.1). The improvement in behavior due to feedback will become even clearer. Define $U_n = X_n/\sqrt{\varepsilon}$, $\bar{U}_n = \bar{X}_n/\sqrt{\varepsilon}$. Define the continuous parameter interpolations $U^\varepsilon(\cdot)$ by: $U^\varepsilon(t) = U_n$ for $t \in [n\varepsilon, (n+1)\varepsilon)$, and similarly define $\bar{U}^\varepsilon(\cdot)$. By (3.4a)

$$U_{n+1} = (I - \varepsilon Q)U_n + \sqrt{\varepsilon}\xi_n + \varepsilon A\bar{U}_n. \quad (5.1)$$

The methods in either [6] or in [8], [1] can be used to get the asymptotic distributions of both $U^\varepsilon(t)$ and $\bar{U}^\varepsilon(t)$ for large t . To simplify our work, we adapt the method of [6, Chapter 8, Section 3]. This requires the addition of two conditions which are quite unrestrictive. Recall that if $X_n = 0$ (the limit value), then $\xi_n = \phi_n \psi_n \equiv \rho_n$. Let us assume the following.

(A5.1): The sequence of processes $\sqrt{\varepsilon} \sum_{i=1}^{n+t/\varepsilon} \rho_i$, ($\rho_n = \phi_n \psi_n$) converges weakly to a Wiener process with covariance $R_0 = \sum_{i=1}^{\infty} E\rho_i \rho_i'$, as $\varepsilon \rightarrow 0$.

(A5.2): There are $n_\varepsilon \rightarrow \infty$ as $\varepsilon \rightarrow 0$ such that $\varepsilon n_\varepsilon \rightarrow$ and such that (in the sense of probability)

$$\frac{1}{n_\varepsilon} \sum_{i=n_\varepsilon}^{n+n_\varepsilon} \phi_i \phi_i' \rightarrow G,$$

$$\frac{1}{n_\varepsilon} \sum_{i=n_\varepsilon}^{n+n_\varepsilon} \phi_i \psi_i \rightarrow 0.$$

Comment on the Assumption: The second expression in (A5.2) is implied by (A5.1), but we keep it to help matching of the conditions with those in the reference. In the development in [6], the limit of the second sum in (A5.2) can be any constant vector. This simply creates a bias and can be used here too. (A5.2) is just a law of large numbers. Condition (A5.1) is also not very restrictive. It seems preferable to word the condition as it is since there is a very large literature on convergence of such sums to a Wiener process [6], [2], [3], and the convergence occurs under many different sets of more explicit and practical assumptions.

Theorem 5.1: Assume (A4.1)–(A4.3), (A5.1), (A5.2), and let $b_n \rightarrow 0$. Then there are $N_\varepsilon \rightarrow \infty$ such that $U^\varepsilon(\varepsilon N_\varepsilon + \cdot)$ converges weakly to the stationary solution of

$$-QUdt + R_0^{1/2}dW \quad (5.2)$$

where $W(\cdot)$ is a standard Wiener process.

If $b_n = \alpha\varepsilon$ for small ε , then Theorem 4.1 says that $\limsup_n E|\bar{X}_n|^2 = O(\varepsilon)$. But the actual situation is much better, and an analysis of this case gives additional insight into the case where $b_n \rightarrow 0$. The constant b_n case is of practical importance, since it is the case where there is slow "exponential forgetting," and is similar to the case where we average with a window of size $O(1/\varepsilon\alpha)$.

Theorem 5.2: Assume (A4.1)–(A4.3), (A5.1), (A5.2), and let $b_n = \alpha\varepsilon$ for small α . Then there are $N_\varepsilon \rightarrow \infty$ such that $(U^\varepsilon(\varepsilon N_\varepsilon + \cdot), \bar{U}^\varepsilon(\varepsilon N_\varepsilon + \cdot))$ converges weakly to the stationary solution of

$$dU = -QUdt + A\bar{U}dt + R_0^{1/2}dW$$

$$d\bar{U} = \alpha Udt - \alpha\bar{U}dt \quad (5.3)$$

where $W(\cdot)$ is a standard vector valued Wiener process.

Proof of Theorem 5.1: In view of the stability estimates of Theorem 4.1, the proof is essentially that in [6, Chapter 8, Section 3], and we only discuss the minor alterations. Note that our notation is different from that in the reference. Let $b_n \rightarrow 0$. The proof in [6] concerns the asymptotics without the feedback. But the only difference between that case and ours is the $\varepsilon A\bar{U}_n$ term in (5.1). Since $\limsup_n E|\bar{U}_n|^2 = O(\varepsilon)$ by Theorem 4.1, the added term does not contribute to the limit. The cited proof shows that there is a sequence of real numbers $t_\varepsilon \equiv \varepsilon N_\varepsilon \rightarrow \infty$ such that $U^\varepsilon(t_\varepsilon + \cdot) \Rightarrow U(\cdot)$ where $U(\cdot)$ is the stationary solution to (5.1), and R_0 is defined as in (A5.1).

Q.E.D.

Comment on Theorem 5.1: Loosely speaking, (5.2) implies that $X_n \sim N(0, \varepsilon V_0(Q))$, where $V_0(Q)$ is the stationary covariance of the solution to (5.2) and is

$$V_0(Q) = \int_0^\infty -Q^s R_0 e^{-Q^s} ds.$$

This means that the stationary covariance of U^ε goes down as A increases, being $O(1/A)$ for large A , i.e., for small fixed ε , as A increases the asymptotic covariance of X_n decreases. This is an immediate benefit of the feedback. Of course, one cannot let A grow without bound if ε is fixed since the algorithm will become unstable. We find in practice that the asymptotic results improve until near the point where stability does become a problem.

Proof of Theorem 5.2: Again, the proof is a mild extension of that in [6 Chapter 8, Section 3], and only a few comments will be made. We can write

$$U_{n+1} = (I - \varepsilon Q)U_n + \sqrt{\varepsilon}\xi_n + \varepsilon A\bar{U}_n, \quad (5.4)$$

$$\bar{U}_{n+1} = (1 - \alpha\varepsilon)\bar{U}_n + \varepsilon\alpha U_n. \quad (5.5)$$

Using the stability results in Theorem 4.1, the analysis in [6] can be readily extended to get that there is a sequence of real numbers $t_\varepsilon \rightarrow \infty$ such that

$$(U^\varepsilon(t_\varepsilon + \cdot), \bar{U}^\varepsilon(t_\varepsilon + \cdot)) \Rightarrow (U(\cdot), \bar{U}(\cdot))$$

where the limit process is the stationary solution to (5.3).

The Order of the Errors in Theorem 5.2 for Small α and Large: $\alpha \rightarrow A$. We will show that (for the stationary solution)

$$E|U(t)|^2 = O(1/A), \quad (5.6a)$$

$$E|\bar{U}(t)|^2 = O(\alpha/A). \quad (5.6b)$$

Thus, the asymptotic variances of $\bar{U}(t)$ is inversely proportional to the effective window of averaging, as for the case of Section II without feedback.

Proof of Claim: Since G is positive definite and symmetric, we can diagonalize (5.3). Write $G = P^{-1}DP$, $P^{-1} = P'$, where P is orthonormal and D is diagonal with positive entries. Let d_m denote the smallest diagonal entry in D . Define $V = PU$, $\bar{V} = P\bar{U}$, with coordinate variables V_i , etc. Then

$$dV = -(D + AI)Vdt + A\bar{V}dt + PR_0^{1/2}dW$$

$$d\bar{V} = \alpha(V - \bar{V})dt. \quad (5.8)$$

By Itô's Lemma and using $|R_0| = \text{trace } R_0$

$$\frac{dE|\bar{V}_i|^2}{dt} = 2\alpha(EV_i\bar{V}_i - E\bar{V}_i^2), \quad (5.9a)$$

$$\frac{dE|V|^2}{dt} = -2AE|V|^2 - 2E\bar{V}'DV + 2AEV'\bar{V} + |R_0|, \quad (5.9b)$$

$$\frac{dEV'\bar{V}}{dt} = \alpha E|V|^2 - \alpha V'\bar{V} - E\bar{V}'DV$$

$$+ A(E|\bar{V}|^2 - E\bar{V}'V). \quad (5.9c)$$

The deterministic part of the system (5.8) is stable. For the stationary solution, we have

$$EV_i\bar{V}_i = E\bar{V}_i^2, \quad (5.10a)$$

$$2AE|V|^2 + 2EV'\bar{V} = 2AE|\bar{V}|^2 + |R_0|. \quad (5.10b)$$

$$\alpha E|\bar{V}|^2 + E\bar{V}'DV = \alpha E|V|^2. \quad (5.10c)$$

In (5.10c), we used (5.10a) to cancel the coefficient of A in the right side of (5.9c). Using (5.10a) again and taking lower

bounds in (5.10b) and (5.10c) yields

$$(d_m + \alpha)E|\bar{V}|^2 \leq \alpha E|V|^2, \quad (5.11)$$

$$2(A + d_m)E|V|^2 \leq 2AE|\bar{V}|^2 + |R_0| \quad (5.12)$$

from which we get (5.6).

B. Tracking Time Varying Parameters

Feedback and averaging can also be used when the parameters to be tracked vary with time. Extensive analyses of tracking algorithms are in [1], [4]. We view the main practical applications of averaging with feedback to be for constant parameter systems, and the applications to communications, parameter estimation, adaptive noise cancellation and elsewhere in signal processing cited earlier. But, for robustness considerations it is important to know that the basic behavior is continuous under small time variations (small β below). The dependence on β is seen in (5.16). If $\beta = o(\alpha)$, then (5.16) can be improved.

Let $b_n = \alpha\epsilon$, and let θ_n denote the value of the parameter (replacing θ) at time n . For β a real number, suppose that the parameter evolves according to

$$\theta_{n+1} = \theta_n + \beta\epsilon w_n.$$

Here, $\{w_n\}$ is a driving sequence of bounded random variables with mean zero, independent of $\{\phi_n, \psi_n\}$ and satisfying

$$\sum_{m=0}^{\infty} E_n w_m \leq K_0 \quad (A5.3)$$

for some $K_0 < \infty$ and all n , a condition analogous to (A4.1). Note that we do not require $\{w_n\}$ to be mutually independent. We will also use the conditions [the analogs of (A5.1), (A5.2)]

(A5.4): The sequence of processes $\sqrt{\epsilon} \sum_{i=n}^{n+t/\epsilon} w_i$ converges weakly to a Wiener process with covariance matrix $R_1 = \sum_{i=0}^{\infty} E w_i w_i^T$.

(A5.5): There is a sequence of real numbers $n_\epsilon \rightarrow \infty$ as $\epsilon \rightarrow 0$ such that $\epsilon n_\epsilon \rightarrow 0$ and (in the sense of probability)

$$\frac{1}{n_\epsilon} \sum_{i=0}^{n+n_\epsilon} w_i \rightarrow 0.$$

The Evolution Equation: Redefine $X_n = \hat{\theta}_n - \theta_n$, $\bar{X}_n = \bar{\theta}_n - \theta_n$, where

$$\bar{\theta}_n = (I - \alpha\epsilon)\bar{\theta}_{n-1} + \alpha\epsilon\hat{\theta}_{n-1}.$$

Then (the analog of (3.4a))

$$X_{n+1} = (I - \epsilon G)X_n + \epsilon\xi_n + \epsilon A(\bar{X}_n - X_n) + (\theta_n - \theta_{n+1})$$

where ξ_n is defined as in Section III, and

$$\bar{X}_{n+1} = (1 - \alpha\epsilon)\bar{X}_n + \alpha\epsilon X_n + (\theta_n - \theta_{n+1}).$$

The entire analysis for the non time-varying case can be carried over to the present case with only trivial changes. By a proof almost identical to that of Theorem 4.1, we have the following result.

Theorem 5.3: Assume (A4.1)–(A4.3) and (A5.1)–(A5.3). Then for small β and α

$$\limsup_n E|X_n|^2 = O(\epsilon),$$

$$\limsup_n E|\bar{X}_n|^2 = O(\epsilon).$$

With Theorem 5.3 in hand, precise analogs of Theorem 5.2 can be obtained by exactly the same analysis, and we will only write the appropriate formulation. Redefine $U_n = X_n/\sqrt{\epsilon}$, $\bar{U}_n = \bar{X}_n/\sqrt{\epsilon}$. Then

$$U_{n+1} = (I - \epsilon Q)U_n + \sqrt{\epsilon}\xi_n + \epsilon A\bar{U}_n - \sqrt{\epsilon}\beta w_n, \quad (5.13)$$

$$\bar{U}_{n+1} = (1 - \alpha\epsilon)\bar{U}_n + \epsilon\alpha U_n - \sqrt{\epsilon}\beta w_n. \quad (5.14)$$

Then the analysis which led to Theorem 5.2 and the order estimates which followed yield the following.

Theorem 5.4: Assume (A4.1)–(A4.3) and (A5.1)–(A5.5). Then, for small β and α , there are $N_\epsilon \rightarrow \infty$ such that $(U^\epsilon(\epsilon N_\epsilon + \cdot), \bar{U}^\epsilon(\epsilon N_\epsilon + \cdot))$ converges weakly to the stationary solution of

$$dU = -QUdt + A\bar{U}(t)dt + R_0^{1/2}dW + \beta R_1^{1/2}dW_1$$

$$d\bar{U} = \alpha Udt - \alpha\bar{U}dt + \beta R_1^{1/2}dW_1 \quad (5.15)$$

where $W(\cdot)$ and $W_1(\cdot)$ are mutually independent vector valued Wiener processes. If $\beta = O(\alpha)$, then (for the stationary solution)

$$E|U(t)|^2 = O\left(\frac{A\beta^2}{\alpha}\right) + O(1/A), \quad (5.16a)$$

$$E|\bar{U}(t)|^2 = O\left(\frac{A\beta^2}{\alpha}\right) + O(\alpha/A). \quad (5.16b)$$

VI. SIMULATION DATA

Numerous simulations have supported the theoretical conclusions, and the following tables are typical of the runs taken. The simulations were made with a five-dimensional system, where the five-dimensional vector ϕ_n was computed as $\phi_n = (\phi_n, \phi_{n-1}, \phi_{n-2}, \phi_{n-3}, \phi_{n-4})$, where the sequence of random variables ϕ_n is obtained from the dynamical equation $\phi_{n+1} = \phi_n/2 + \zeta_n$ where ζ_n is a sequence of mutually independent Gaussian random variables with mean zero and variance 1.0. The parameter θ is fixed at $\theta = (4.0, -4.2, 3.0, 2.7, -3.0)$. The standard deviation of the observation noise ψ_n was 6.0. The noise level was chosen high enough to allow us to distinguish the general differences among the algorithms, since for small noise levels all the algorithms worked well. If one wishes to distinguish between the small errors at low observation noise levels, the nonfeedback algorithm is often preferable. Asymptotically, the best values of ϵ are very small and decrease as the run size increases. But for run lengths of fixed finite size, the performance will degenerate if ϵ becomes too small. Generally, we have tried to compare the performance of the algorithms with and without feedback using the parameters at which each works well. The actual averaged value that was used in the (both feedback and

nonfeedback) algorithm was

$$\bar{X}_n = \frac{1}{\text{window}} \sum_{n-\text{window}}^{n} X_i$$

The averaging started at iteration 50, using a growing window of averaging until the desired window size was reached, after which we averaged only over the desired window size. The computation of the mean square errors commenced at the 300th iteration so as to minimize the effect of the transient period. The tables list the sample mean square errors at 5000 iterations; namely

$$\frac{1}{5000 - 300} \sum_{n=300}^{5000} |\theta'_n - \theta'|^2$$

where θ' is the i th component of θ . The sum is quite stable and the values were essentially the same after 1000 iterations. Hence, they can be taken for good approximations to the actual mean square errors. Generally, the algorithm with feedback is not as sensitive to the value of ϵ and can work well at somewhat larger values of ϵ , although ϵ cannot be made too large without causing stability problems. This ability to work well with somewhat larger ϵ is a considerable advantage, in that it yields a shorter transient period.

In all cases, both with and without feedback, it can be seen that averaging yields substantial improvements. This was true even when the original iterates X_n were poor, as in Table III (and also Tables I, II, V, VI, to some extent) for the algorithm without feedback. Clearly, as expected, the performance improves as the window of averaging increases. Refer to Table III, where ϵ and $A\epsilon$ are too large for good performance. But even there, with the poor values given by the X_n , averaging was a distinct advantage and more so for the feedback case.

If the observation noise level is not too small, then the averaged iterate \bar{X}_n for the feedback case is generally better than that for the nonfeedback case and is often much better as seen from the tables. For such a case, the errors X_n are also generally smaller in the feedback case. This is important if

one wishes a good "on-line" algorithm. Indeed, in some cases the errors X_n with feedback are as good as the errors \bar{X}_n without feedback. While the last word has not been said on the general family of algorithms considered and more testing and comparison needs to be done (as is usual for a new idea), it is clear that the use of feedback is quite promising and has many advantages, particularly for an algorithm where one wants a good estimate "on line."

We also note that the use of feedback makes the behavior of the X_n less sensitive to the value of G , as seen from the forms of the stochastic differential equations derived in Section V.

APPENDIX

DETAILS OF ESTIMATES IN THEOREM 4.1

Proof of (4.14) By definition, for $m \geq n$

$$\hat{X}_m^n = (I - \epsilon Q)^{m-n} \hat{X}_n + \sum_{i=n}^{m-1} \epsilon (I - \epsilon Q)^{m-i-1} \xi_i^n. \quad (\text{A.1a})$$

We will also use the representation [(A 1a), but starting at time $n + 1$]

$$\tilde{X}_m^n = (I - \varepsilon Q)^{m-n-1} \tilde{X}_{n+1}^n + \sum_{i=n+1}^m \varepsilon (I - \varepsilon Q)^{m-i-1} \xi_i^n \quad (\text{A } 1b)$$

By (A 1a)

$$\begin{aligned} \tilde{f}_n^1 &= \sum_{m=n}^{\infty} b_m (I - \varepsilon Q)^{m-n} X_n \\ &+ \sum_{m=n}^{\infty} \sum_{i=n}^{m-1} b_m \varepsilon (I - \varepsilon Q)^{m-i-1} E_n \xi_i^n \end{aligned} \quad (\text{A } 2)$$

Using the fact that $\sum_{m=0}^{\infty} (I - \varepsilon Q)^m = O(1/\varepsilon)$, the first term on the right side of (A 2) is $O(b_n/\varepsilon)|X_n|$. Using (A4.1)–(A4.3) and the definition (4.10) to evaluate the second term on the right side of (A 2) yields $O(b_n)(|\tilde{X}_n| + |\bar{X}_n|) + \tilde{I}O(b_n)$. Thus (4.14) holds.

Proof of (4.15) Using (A4.1)–(A4.3) and the representation for \tilde{X}_m^n from (A 1b) and for X_m^{n+1} from (A 1a) (with $n+1$ replacing n there), the component of the sum in (4.16) which is due to the “propagation of the initial conditions” (rather than due to the noise sequences $\{\xi_m^n, \xi_m^{n+1}, m \geq n+1\}$) can be seen to be

$$\begin{aligned} E_n \sum_{m=n+1}^{\infty} b_m (I - \varepsilon Q)^{m-n-1} X_{n+1} \\ - \sum_{m=n+1}^{\infty} b_m (I - \varepsilon Q)^{m-n-1} X_{n+1} \end{aligned}$$

Since

$$\begin{aligned} X_{n+1} &= (I - \varepsilon Q) \tilde{X}_n + \varepsilon \xi_n + b_n C'(\bar{X}_n - X_n) \\ &= \tilde{X}_{n+1}^n + b_n C'(\bar{X}_n - X_n) \end{aligned}$$

the above difference equals

$$\sum_{m=n+1}^{\infty} b_m (I - \varepsilon Q)^{m-n-1} b_n C'(\bar{X}_n - X_n) \quad (\text{A } 3)$$

which equals

$$O\left(\frac{b_n^2}{\varepsilon}\right)(|\tilde{X}_n| + |\bar{X}_n|) \quad (\text{A } 4)$$

The component of the sum in (A 4) due to the “noise” $\{\xi_m^n, \xi_m^{n+1}, m \geq n+1\}$ is

$$\sum_{m=n+1}^{\infty} \sum_{i=n+1}^{m-1} b_m \varepsilon (I - \varepsilon Q)^{m-i-1} E_n [\xi_i^{n+1} - \xi_i^n]$$

Noting that $\xi_i^{n+1} - \xi_i^n$ equals $\Phi_i(X_{n+1} - X_n)$, and using (A4.1)–(A4.3), we get the order [recall the definition of I below (4.14b)]

$$O(b_n \varepsilon + b_n^2)(|\tilde{X}_n| + |\bar{X}_n|) + IO(b_n \varepsilon) \quad (\text{A } 5)$$

(A 4) and (A 5) yield the right side of (4.15)

Dr. Yang is currently working in a postdoctoral position in the Division of Applied Mathematics, Brown University. His current research interests include numerical methods in stochastic control, optimization, stochastic approximation algorithms, and financial derivative securities pricing models.

Exponential Stabilization of Nonholonomic Chained Systems

O. J. Sørдалen, *Member, IEEE*, and O. Egeland, *Member, IEEE*

Abstract—This paper presents a feedback control scheme for the stabilization of two-input, driftless, chained nonholonomic systems, also called chained form. These systems are controllable but not asymptotically stabilizable by a smooth static-state feedback control law. In addition, exponential stability cannot be obtained with a smooth, time-varying feedback control law. Here, global, asymptotical stability with exponential convergence is achieved about any desired configuration by using a nonsmooth, time-varying feedback control law. The control law depends, in addition to the state and time, on a function which is constant except at predefined instants of time where the function is recomputed as a nonsmooth function of the state. The inputs are differentiable with respect to time and tend exponentially toward zero. For use in the analysis, a lemma on the exponential convergence of a stable time-varying nonlinear system perturbed by an exponentially decaying signal is presented. Simulation results are also shown.

I. INTRODUCTION

NONHOLONOMIC chained systems can be used to represent a large class of mechanical systems. Important and well-known examples are unicycles, four-wheeled cars and n -trailer systems. Accordingly, control schemes for nonholonomic chained systems has a potential of being applied to a large number of mechanical systems. The problem of designing stabilizing feedback controllers for nonholonomic chained systems is a challenging one since the system is not stabilizable by a smooth static-state feedback law [4]. Moreover, the problem of exponential stabilization, which is the topic of this paper, cannot be solved by any smooth feedback law [10].

The nonholonomic chained system considered in this paper is the chained form [26]

$$\begin{aligned}\dot{x}_1 &= u_1 \\ \dot{x}_2 &= u_2 \\ \dot{x}_i &= x_{i-1}u_1, \quad i \in \{3, \dots, n\}.\end{aligned}$$

A constructive procedure to transform a nonholonomic system with two inputs into this chained form was presented by [25] under certain conditions on the input vectors. Necessary and

sufficient conditions for converting a nonholonomic system into chained form were derived in [23] based on the theory of exterior differential systems using the Goursat normal form theorem. One of the results from this work is that all two-input, regular nonholonomic systems in three and four dimensions are locally feedback equivalent to a nonholonomic chained form. In [33], the kinematic model of a car with n trailers was converted into chained form. This conversion was global in the position of the system and local in the orientations. Another conversion into chained form was proposed in the framework of exterior differential systems in [35] based on [33], [23], and [30]. This conversion of the kinematics of the n -trailer system allowed any orientation of the last trailer. Control strategies for nonholonomic chained systems can, therefore, be used for the control of a broad class of nonholonomic, mechanical systems.

The control of chained form and of more general nonholonomic systems is a very active field of research. The problem of nonholonomic motion planning was introduced by [17] who proved that a car-like robot with one nonholonomic constraint is controllable. Open-loop planners for low-dimensional mobile robots have been proposed in [18], [1], [19]. Because of the invertible transformation in [33], these planners can also be used to plan a path for low-dimensional chained systems. Other open-loop strategies have explored control theoretic approaches using differential geometry tools to control nonholonomic systems. Sinusoids were proposed by [24] to steer in open-loop nonholonomic systems on a special canonical form including chained form. A generalization of the use of sinusoidal inputs to generate motion at a given level of Lie brackets of the input vectors was given in [16], [15], [12], [22] for nilpotent and nilpotentizable systems using an extended system with additional input vectors corresponding to higher order Lie brackets of the original system. Since the nonholonomic chained system is nilpotent, these open-loop strategies can also be used to steer such a system in open loop.

To make the control more robust with respect to disturbances and errors in the initial condition, some stabilizing closed-loop approaches have also been proposed. Characteristic for the nonholonomic systems encountered in robotics is that they cannot be stabilized by a smooth static-state feedback control law which has been shown with Brockett's theorem [4]. This has been further discussed by [2] and [8] for nonholonomic mechanical systems. Therefore, a discontinuous feedback control law was proposed by [5] to make the kinematic model of a three-dimensional robot globally, exponentially converge to a given configuration. This system is equivalent to a three-dimensional chained form. Another

discontinuous feedback approach was proposed by [3] for the same system with acceleration inputs instead of velocity inputs. This approach makes the system reach the origin in finite time in the case of no disturbances.

The use of time-varying feedback control laws is another approach to stabilize nonholonomic systems about a constant configuration. This approach was first studied by [30] for the stabilization of a cart. This approach was further developed in [29] for a car-like mobile robot with a steering wheel. This system is locally equivalent to a four-dimensional chained form. Constructive approaches were presented in [31], [28]. The existence of stabilizing time-varying feedback control laws for more general nonholonomic systems was studied in [6]. The design methods in [28] were extended in [7] to the more general situation given in [6]. An algorithm for computing time-periodic feedback solutions for nonholonomic motion planning was presented in [10]. This approach considered the extended system using Lie bracket completion vectors such as in the open-loop strategy of [16]. This feedback algorithm was based on multi-scaling averaging techniques and highly oscillatory inputs. These time-dependent approaches also work for chained form. Another time-varying smooth feedback control law to stabilize chained form was derived in [34] for power forms based on the work on the use of sinusoids.

These smooth time-varying feedback control laws yield asymptotic stability but not exponential since time-periodic smooth feedback cannot be exponentially stabilizing [9], [10]. To improve the rate of convergence, a feedback control law was proposed by [27] to obtain local exponential convergence to a neighborhood of the origin for a three-dimensional chained form. The asymptotic behavior was obtained by letting the control law be time varying. The exponential convergence to the neighborhood was obtained by letting the control law be nonsmooth at the origin. No feedback control law, however, has been presented in previous work that exponentially stabilizes a nonholonomic chained form of an arbitrary dimension about any constant configuration.

In this paper, the problem of exponential stabilization is addressed and a new feedback approach is proposed for chained form. The stabilization is achieved by letting the state feedback control law depend on time and on a function which is nonsmooth with respect to the state at discrete instants of time. The proposed feedback control law globally stabilizes the system about the origin with exponential convergence. Asymptotic stability about any desired configuration is obtained by using a coordinate transformation. The resulting closed-loop system is not exponentially stable as defined by [14, p. 168], but it is shown to have a property which will be termed \mathcal{K} -exponential stability.

The paper is organized as follows: The concept of \mathcal{K} -exponential stability is proposed in Section II. A lemma on the exponential convergence of a nonlinear time-varying system which is perturbed by an exponentially decaying signal is given in Section III. The nonholonomic chained system is presented in Section IV. The control law is presented in Section V. The convergence of a part of the system is analyzed in Section VI. The stability of the total system is analyzed in Section VII. In Section VIII, a coordinate transformation

is presented such that a control law to control the chained form to the zero configuration can be used for the control to any desired configuration. The stabilizing feedback strategy is illustrated by a simulation example in Section IX. The conclusions are given in Section X.

II. \mathcal{K} -EXPONENTIAL STABILITY

In this section, the concept of \mathcal{K} -exponential stability is introduced. It will be shown in later sections that the controller proposed in this paper makes the chained system \mathcal{K} -exponentially stable. First, we need the following notion [11, Definition 2.5].

Definition 1: A continuous function $\alpha: R^+ \rightarrow R^+$ is said to be of class \mathcal{K} (or belong to class \mathcal{K}) if it is strictly increasing and $\alpha(0) = 0$.

One property of class \mathcal{K} functions is that, [14] and [11]

$$\alpha_1, \alpha_2 \in \text{class } \mathcal{K} \Rightarrow \alpha_1 \circ \alpha_2 \in \text{class } \mathcal{K}. \quad (1)$$

We then define the following.

Definition 2: Consider the nonlinear, time-varying system

$$\dot{x} = f(x, t) \quad x \in D \subset R^n, \quad t \geq t_0. \quad (2)$$

System (2) is \mathcal{K} -exponentially stable about x_p iff there exist a neighborhood $\Omega_p \subset D$ about x_p , a positive constant λ , and a function $h(\cdot)$ of class \mathcal{K} such that all solutions $x(t)$ of (2) satisfy

$$\forall x(t_0) \in \Omega_p \forall t \geq t_0, \|x(t) - x_p\| \leq h(\|x(t_0) - x_p\|)e^{-\lambda(t-t_0)} \quad (3)$$

where the constant λ and the neighborhood Ω_p are independent of t_0 , and $\|\cdot\|$ denotes a norm in R^n .

If (3) is satisfied for $\Omega_p = D$, then system (2) is globally, \mathcal{K} -exponentially stable about x_p . According to this definition, if system (2) is \mathcal{K} -exponentially stable at x_p , then it is uniformly asymptotically stable as defined by e.g., [14, 4.3], and in addition it has an exponential rate of convergence.

The concept of \mathcal{K} -exponential stability is called exponential stability in [21]. The term exponential stability is however often used for the special case where the function $h(\cdot)$ is linear, [11] and [14], i.e.,

$$h(\|x(t_0) - x_p\|) = r\|x(t_0) - x_p\|.$$

Here, r is a positive constant independent of t_0 and $x(t_0)$. This means that \mathcal{K} -exponential stability corresponds to a weaker form of stability than the usual concept of exponential stability. \mathcal{K} -exponential stability and exponential stability are equal, however, with respect to the rate of convergence. Therefore, the notion "exponential stabilization" is used in the title of this paper; although, only \mathcal{K} -exponential stability will be proved.

Locally, a similar definition of exponential stability was introduced in [13] in terms of homogeneous norms. This concept has been used in [20] to investigate the convergence rates for controllers for low dimensional nonholonomic systems in so-called power form which is equivalent to chained form, [34].

III. A LEMMA ON EXPONENTIAL CONVERGENCE

The following lemma is useful for establishing exponential convergence for a class of time-varying systems. It will be used in the convergence analysis of the control law.

Lemma 1: Consider the nonlinear, one-dimensional, time-varying system

$$\dot{x} = -a(x, t)x + d(x, t), \quad t \geq t_0, \quad x(t_0) \in R \quad (4)$$

under the following assumptions:

- There exists a solution $x(t)$ of (4) for any $x(t_0)$ and any $t \geq t_0$; see Remark 2 below.
- $a(x, t)$ has the property that for all $x(t)$

$$\left| \int_{t_0}^t (a(x(\tau), \tau) - \lambda) d\tau \right| \leq P, \quad \forall t \geq t_0 \quad (5)$$

where λ and P are positive constants.

- The signal $d(x, t)$ is bounded for any $t \geq t_0$ and any $x(t)$ by

$$|d(x(t), t)| \leq D e^{-\gamma(t-t_0)} \quad (6)$$

for some positive constants D and γ .

Then

$$\forall \epsilon > 0, \quad |x(t)| \leq \epsilon (|x(t_0)| + D) e^{-(\alpha - \epsilon)(t-t_0)}$$

where

$$\alpha = \min\{\lambda, \gamma\} > 0, \quad \epsilon = \max\left\{\epsilon^P, \frac{\epsilon^{2P}}{\epsilon}\right\}.$$

Proof We denote

$$F(t) = \int_{t_0}^t a(x(\tau), \tau) d\tau$$

where $x(t)$ is a solution of (4). Multiplying (4) with $e^{F(t)}$ gives

$$\frac{d}{dt}(x(t)e^{F(t)}) = d(x(t), t)e^{F(t)}.$$

This implies

$$x(t)e^{F(t)} = x(t_0) + \int_{t_0}^t d(x(\tau), \tau)e^{F(\tau)} d\tau.$$

Dividing by $e^{F(t)}$ then gives the following (implicit) expression for $x(t)$

$$x(t) = e^{-F(t)} \left(x(t_0) + \int_{t_0}^t e^{F(\tau)} d(x(\tau), \tau) d\tau \right). \quad (7)$$

Property (5) implies that

$$|F(t) - \lambda(t - t_0)| \leq P \quad (8)$$

which is equivalent to

$$-P + \lambda(t - t_0) \leq F(t) \leq P + \lambda(t - t_0). \quad (9)$$

By using (7), (9), and (6) we get

$$|x(t)| \leq e^P e^{-\lambda(t-t_0)} \left(|x(t_0)| + D \int_{t_0}^t e^P e^{(\lambda-\gamma)(\tau-t_0)} d\tau \right).$$

In the case that $\lambda = \gamma$ we find

$$|x(t)| \leq e^P |x(t_0)| e^{-\lambda(t-t_0)} + D e^{2P} (t - t_0) e^{-\lambda(t-t_0)}$$

In the case that $\lambda \neq \gamma$ we find

$$|x(t)| \leq e^P |x(t_0)| e^{-\lambda(t-t_0)} + \frac{D e^{2P}}{\lambda - \gamma} (e^{-\gamma(t-t_0)} - e^{-\lambda(t-t_0)})$$

Since

$$1 - e^{-b} \leq b, \quad \forall b \geq 0$$

then

$$|x(t)| \leq e^P |x(t_0)| e^{-\lambda(t-t_0)} + D e^{2P} (t - t_0) e^{-\alpha(t-t_0)} \quad (10)$$

for all $\lambda > 0$ and $\gamma > 0$ where $\alpha = \min\{\lambda, \gamma\}$. From (10) we have that

$$\begin{aligned} |x(t)| &\leq (\rho(t - t_0) + \sigma) e^{-\alpha(t-t_0)} \\ &= (\rho(t - t_0) + \sigma) e^{-(t-t_0)} e^{-(\alpha-\epsilon)(t-t_0)} \end{aligned} \quad (11)$$

where

$$\rho = D e^{2P}, \quad \sigma = e^P |x(t_0)| \quad (12)$$

since $e^{-(\lambda-\alpha)(t-t_0)} \leq 1$ for $t \geq t_0$. By comparison we find that

$$(\rho t + \sigma) e^{-\epsilon t} \leq \xi \quad \forall t \geq 0 \quad (13)$$

if

$$\xi = \begin{cases} \frac{\rho}{\epsilon} e^{\frac{\epsilon^2}{\rho}}, & \rho > \epsilon \sigma \\ \frac{\rho}{\epsilon \sigma}, & \rho \leq \epsilon \sigma. \end{cases}$$

Since

$$e^{\frac{\epsilon^2}{\rho}} < e$$

when $\rho > \epsilon \sigma$, (13) will also be satisfied with the following choice of ξ

$$\xi = \begin{cases} \frac{\rho}{\epsilon}, & \rho > \epsilon \sigma \\ \frac{\rho}{\epsilon \sigma}, & \rho \leq \epsilon \sigma \end{cases} \quad (14)$$

Then, from (11), (12), (13) and (14) we get that

$$\begin{aligned} |x(t)| &\leq \xi e^{-(\alpha-\epsilon)(t-t_0)} \\ &\leq \left(\frac{\rho}{\epsilon} + \sigma \right) e^{-(\alpha-\epsilon)(t-t_0)} \\ &\leq \epsilon (|x(t_0)| + D) e^{-(\alpha-\epsilon)(t-t_0)} \end{aligned}$$

where $\alpha = \min\{\lambda, \gamma\}$ and $\epsilon = \max\{\epsilon^P, \frac{\epsilon^{2P}}{\epsilon}\}$ \square

This lemma implies that a solution $x(t)$ of (4) converges exponentially to zero if $a(x, t)$ and $d(x, t)$ have the properties (5) and (6).

Remark 1. By choosing $\epsilon = \alpha$ we see that

$$\max_{t \geq t_0} |x(t)| \leq (|x(t_0)| + D) \max \left\{ e^P, \frac{e^{2P}}{\alpha} \right\}$$

where $\alpha = \min\{\lambda, \gamma\} > 0$.

Remark 2: If $a(x, t)$ and $d(x, t)$ are continuous in x and t , then there exists at least one solution of (4), [21, Theorem 2.3].

IV. THE SYSTEM

The nonholonomic chained system considered in this paper is the so-called chained form introduced in [26]

$$\begin{aligned}\dot{x}_1 &= u_1 \\ \dot{x}_2 &= u_2 \\ \dot{x}_3 &= x_2 u_1 \\ &\vdots \\ \dot{x}_n &= x_{n-1} u_1.\end{aligned}\quad (15)$$

The input vector fields are

$$\begin{aligned}g_1(x) &= [1, 0, x_2, x_3, \dots, x_{n-1}]^T, \\ g_2(x) &= [0, 1, 0, 0, \dots, 0]^T\end{aligned}$$

where $x = [x_1, x_2, \dots, x_n]^T$. Repeated Lie brackets can be defined recursively by

$$\text{ad}_{g_1}^0 g_2 = g_2, \quad \text{ad}_{g_1}^i g_2 = [g_1, \text{ad}_{g_1}^{i-1} g_2].$$

It can easily be shown that for system (15)

$$\text{ad}_{g_1}^{j-2} g_2 = (-1)^j e_j, \quad j \in \{2, 3, \dots, n\}$$

where $e_j \triangleq [\delta_{1j}, \delta_{2j}, \dots, \delta_{nj}]^T$ where δ_{ij} is the Kronecker delta. Since

$$\forall x \in R^n, \quad \text{span}\{g_1, \text{ad}_{g_1}^0 g_2, \dots, \text{ad}_{g_1}^{n-2} g_2\}(x) = R^n$$

the chained form (15) is completely controllable and the degree of nonholonomy is $n - 1$. In spite of the controllability, (15) cannot be stabilized by a smooth static-state feedback control law as stated by Brockett's Theorem [4]. From [10] we know that to exponentially stabilize (15), the controller cannot be smooth, even if it is time dependent.

V. THE CONTROL LAW

A. Outline of the Control Law and Analysis

In this section, we will propose a control law to globally, \mathcal{K} -exponentially stabilize the nonholonomic chained system (15) about the origin. Since there is no smooth static-state feedback control law which can stabilize (15), we let the feedback control law be time dependent, as first proposed by [32] for a nonholonomic cart. The main idea of the control scheme to be presented is based on the observation that if u_1 is a function of time only, then the state variables

$$z \triangleq [x_2, \dots, x_n]^T \quad (16)$$

satisfy a linear time-varying state space model with input u_2 . This linear time-varying system with input u_2 and state z can be made \mathcal{K} -exponentially stable using feedback from z , which will be shown in the following. The problem which remains to be solved is how to achieve \mathcal{K} -exponential stability when x_1 is included into the state vector, that is, when the complete system with state vector x and inputs u_1 and u_2 is considered. The solution proposed in this paper is as follows: Define

a sequence (t_0, t_1, t_2, \dots) where the equidistant terms are defined by

$$t_i \triangleq iT \quad (17)$$

where T is a strictly positive constant. Then, the control u_1 is given by $u_1 = u_1(t, x(t_i))$, $t \in [t_i, t_{i+1})$, that is, u_1 is a function of time and not of the state whenever $t_i < t < t_{i+1}$. By appropriately selecting $u_1(t, x(t_i))$, it is then possible to achieve exponential convergence in $x_1(t)$ and, in addition, by patching together the solutions for $z(t)$, \mathcal{K} -exponential stability for the complete system can be established. To obtain exponential convergence, the time-varying feedback control law is nonsmooth in the origin with respect to the state $x(t_i)$.

In this section the control laws are presented without further explanation. Then, in the following sections the stability of the closed-loop system is analyzed, and it is shown that the proposed control laws have the desired properties. The analysis is done in two steps: First the stability of the linear system with state vector z and input u_2 is analyzed. To this end a vector $z^d(x, t): R^n \times R_+ \rightarrow R^{n-1}$ is defined, and it is shown that for the proposed control law the vector $\tilde{z}(x, t) \triangleq z - z^d(x, t)$ converges exponentially to zero. Then, this result is used to prove exponential convergence of $z(t)$. At this point the state x_1 is included, and \mathcal{K} -exponential stability of the complete system with state vector x is established.

Concerning the notation, throughout the paper the one-norm will be used, i.e., the norm of an n dimensional vector $x = [x_1, \dots, x_n]^T$ is given by

$$\|x\| \triangleq \sum_{j=1}^n |x_j|. \quad (18)$$

Furthermore, the index i will refer to terms in the time sequence (t_0, t_1, \dots) .

B. The Control Law for u_1

Let $k(\cdot)$ be a bounded function

$$k: R^n \rightarrow R \quad (19)$$

which satisfies for a strictly positive constant K

$$\forall x \in R^n |k(x)| \leq K, \quad \forall x \in R^n / \{0\} k(x) \neq 0, \quad k(0) = 0. \quad (20)$$

The idea is now to let u_1 be given by a time-varying function multiplied with the function $k(x(t_i))$ such that the part of the system which is represented by the state variables z with input u_2 is linear and time-varying in the time interval (t_i, t_{i+1}) . The input u_2 is then used to make $[x_2(t), \dots, x_n(t)]^T$ exponentially converge to zero. The sign and magnitude of $k(x(t_i))$ will be chosen such that $x_1(t)$ also converges exponentially to zero, and the inputs remain bounded.

We introduce a time-varying function $f: R_+ \rightarrow R$ which has the following properties:

- P1) $f(t) \in C^\infty[t_0, +\infty)$
- P2) $0 \leq f(t) \leq 1, \forall t \geq t_0$

P3) $f(t_i) = 0$, $t_i \in \{t_0, t_1, t_2, \dots\}$

P4) for any $j \in \{3, \dots, n\}$, there are positive constants η_j and P_j such that

$$\forall t_p \in \{t_0, t_1, \dots\}, \forall t \geq t_p \quad \int_{t_p}^t [f^{2j-3}(\tau) - \eta_j] d\tau \leq P_j.$$

A function satisfying conditions P1)–P4) is

$$f(t) = (1 - \cos \omega t)/2, \quad \omega = \frac{2\pi}{T} \quad (21)$$

where $T = t_{i+1} - t_i$ is a constant, (17). Incidentally, the function $f(t)$ is not restricted to be time-periodic to satisfy P1)–P4).

The control law for u_1 is defined by

$$u_1 = k(x(t_i))f(t), \quad t \in [t_i, t_{i+1}) \quad (22)$$

where

$$k(x) = \text{sat}(-[x_1 + \text{sgn}(x_1)G(\|z\|)]\beta, K). \quad (23)$$

Here

$$\text{sat}(q, k) \triangleq \begin{cases} q & |q| < K \\ K \text{sgn}(q) & |q| \geq K \end{cases}$$

and

$$G(\|z\|) = \kappa \|z\|^{\frac{1}{2n-1}} \quad (24)$$

$$\beta = \frac{1}{\int_{t_i}^{t_{i+1}} f(\tau) d\tau} \quad (25)$$

where κ is a positive constant and $\text{sgn}(x_1)$ is defined as

$$\text{sgn}(x_1) = \begin{cases} 1, & x_1 \geq 0 \\ -1, & x_1 < 0 \end{cases}.$$

All the norms are one-norms as defined in (18). The saturation function is used to guarantee global stability. The idea of using saturation functions was also used in [34].

Note that due to P1)–P3) and the bound on $k(\cdot)$, the control u_1 is bounded and continuous with respect to time.

C. The Control Law for u_2

With the input u_1 given by (22), we get from (15) and (16) that \dot{z} is given by

$$\dot{x}_2 = u_2$$

$$\dot{x}_3 = k(x(t_i))f(t)x_2$$

$$\dot{x}_n = k(x(t_i))f(t)x_{n-1}. \quad (26)$$

In this subsection, we derive a feedback control law for u_2 to make $z(t) = [x_2(t), \dots, x_n(t)]^T$ globally, exponentially converge to zero.

Define $g_{jm}: R_+ \rightarrow R$ for $j, m \in \{2, \dots, n\}$ by

$$g_{n-1,n} = -\lambda_n \quad (27)$$

$$g_{j-1,m}(t) = -g_{jm}[\lambda_j f^{2j-2}(t) + 2(j-1)\dot{f}(t) + f(t)(\dot{g}_{jm}(t) + g_{j,m+1}(t)f(t))] \quad (28)$$

$$g_{j-1,j}(t) = -\lambda_j + f^2(t)g_{j,j+1}(t) \quad (29)$$

$$g_{jp} = 0 \quad \text{if } p \leq j \text{ or } p = n+1 \quad (30)$$

where λ_j , $j \in \{2, \dots, n\}$, are any positive constants. Incidentally, we see from this definition of $g_{jm}(t)$ and P1)–P4) that $g_{jm}(t)$ is smooth.

The definition of $g_{jm}(t)$ from (27)–(30) can be illustrated by the following diagram where $a \rightarrow b$ means that b depends on a .

The control law for u_2 is defined for $t \in [t_i, t_{i+1})$ by

$$u_2 = \begin{cases} \Gamma(k(x(t_i)), t)^T z, & x(t_i) \neq 0 \\ 0, & x(t_i) = 0 \end{cases} \quad (31)$$

where

$$z = [x_2, \dots, x_n]^T \in R^{n-1},$$

$$\Gamma(k, t) = [\Gamma_2(k, t), \dots, \Gamma_n(k, t)]^T \in R^{n-1}$$

and for $j \in \{3, \dots, n\}$

$$\Gamma_2(k, t) = -\lambda_2 + f^3 g_{2,3}$$

$$\Gamma_j(k, t) = f(\lambda_2 f g_{2j} + 2\dot{f} g_{2j} + f\dot{g}_{2j} + f^2 g_{2,j+1}) \frac{1}{k^{j-2}}.$$

The smooth functions $g_{2j}(t)$ are given by (27)–(30). The function $k(x(t_i))$ is given by (23).

The feedback control law (22) and (31) depends on $k(\cdot)$ which is a nonsmooth function of the state $x(t_i)$. One might, therefore, raise the question about the existence and uniqueness of the solution $x(t)$ of (15). Since in each time interval $[t_i, t_{i+1})$ the closed-loop system (15) with the control law (22) and (31) becomes a linear, time-varying system, global existence and uniqueness of $x(t)$ can be shown in any time interval $[t_i, t_{i+1})$ for any $x(t_i)$ by applying e.g., Theorem 2.3 in [14]. The time intervals can then be patched together to show existence and uniqueness of $x(t)$ for all $t \in R_+$ and for all initial conditions $x(t_0)$.

VI. CONVERGENCE ANALYSIS OF $z(t)$

In this section, it is shown that the control law (22) and (31) makes $z(t)$ (16) globally exponentially converge to zero.

To this end, define the functions $z^d = [x_2^d, \dots, x_n^d]^T: R_+ \times R_+ \rightarrow R^{n-1}$ as follows for $t \in [t_i, t_{i+1})$

$$x_n^d \triangleq 0 \quad (32)$$

$$x_j^d(x, t) \triangleq \begin{cases} f^{2j-2}(t) \sum_{m=j+1}^n g_{jm}(t) \frac{1}{k^{m-j}(x(t_i))} x_m, & x(t_i) \neq 0 \\ 0, & x(t_i) = 0 \end{cases} \quad (33)$$

Note from this definition of x_j^d that the control law for u_2 (31) satisfies

$$u_2 = -\lambda_2(x_2 - x_2^d) + \dot{x}_2^d \quad (34)$$

whenever $x(t_i) \neq 0$. This relation will be used in the convergence analysis.

By assuming that the control laws yield a continuous solution $x(t)$ of (15), we see from the definition (33) of $x_j^d(x, t)$, P1), and P3) that $x_j^d(x(t), t)$ is continuous for all $t > 0$ and $x_j^d(x(t_i), t_i) = 0$. In addition, z^d has the properties shown in the following lemma.

Lemma 2: Let $z^d = [x_2^d, \dots, x_n^d]^T$ be defined by (32) and (33). Then, for $j \in \{3, \dots, n\}$, $t \in [t_i, t_{i+1})$

$$\dot{x}_n^d = 0 \quad (35)$$

$$x_{j-1}^d k(x(t_i)) f(t) = -\lambda_j f^{2j-3}(t) [x_j - x_j^d(x, t)] + \dot{x}_j^d(x, t). \quad (36)$$

Proof: Equation (35) is trivially satisfied from (32). Equation (36) will be proved by calculating $\dot{x}_j^d(x, t)$. The arguments of the functions $f(t)$, $k(x(t_i))$, and $x_j^d(x, t)$ will be omitted in the proof for simplicity. From the definition of x_j^d , (33), we find for $t \in (t_i, t_{i+1})$ in the case $x(t_i) \neq 0$ by using $\dot{x}_m = x_{m-1} k f$ from (15)

$$\begin{aligned} \dot{x}_j^d &= (2j-2)f^{2j-3} \dot{f} \sum_{m=j+1}^n g_{jm} \frac{1}{k^{m-j}} x_m \\ &+ f^{2j-2} \sum_{m=j+1}^n \left[\dot{g}_{jm} \frac{1}{k^{m-j}} x_m + g_{jm} \frac{f}{k^{m-j-1}} x_{m-1} \right]. \end{aligned} \quad (37)$$

We see that by assuming a continuous solution $x(t)$ of (15), we have due to P1) and P3)

$$\lim_{t \rightarrow t_i^+} \dot{x}_j^d(x(t), t) = \lim_{t \rightarrow t_i} \dot{x}_j^d(x(t), t) = 0.$$

Therefore, (37) is valid for all $t > 0$. Now, we will express x_{j-1}^d by using \dot{x}_j^d from (37). From (33), (28)–(30) we find

$$\begin{aligned} x_{j-1}^d &= f^{2j-4} \sum_{m=j}^n g_{j-1,m} \frac{1}{k^{m-(j-1)}} x_m \\ &= f^{2j-4} \left\{ x_j \left(-\frac{\lambda_j}{k} + f^2 g_{j,j+1} \frac{1}{k} \right) \right. \\ &\quad + \sum_{m=j+1}^n \frac{x_m}{k^{m-j+1}} [(\lambda_j f^{2j-2} + 2(j-1)\dot{f}) g_{jm} \\ &\quad \left. + f(\dot{g}_{jm} + g_{j,m+1} f)] \right\} \\ &= -\frac{\lambda_j}{k} f^{2j-4} \left(x_j - f^{2j-2} \sum_{m=j+1}^n g_{jm} \frac{1}{k^{m-j}} x_m \right) \\ &\quad + f^{2j-4} \left\{ (2j-2)\dot{f} \sum_{m=j+1}^n g_{jm} \frac{1}{k^{m-j+1}} x_m \right. \\ &\quad \left. + f \sum_{m=j+1}^n \left[\dot{g}_{jm} \frac{1}{k^{m-j+1}} x_m + g_{jm} \frac{f}{k^{m-j}} x_{m-1} \right] \right\} \\ &= -\frac{\lambda_j}{k} f^{2j-4} (x_j - x_j^d) + \frac{1}{kf} \dot{x}_j^d. \end{aligned} \quad (38)$$

Equation (36) follows readily. \square

Define the functions $\tilde{z} = [\tilde{x}_2, \dots, \tilde{x}_n]^T: R^n \times R_+ \rightarrow R^{n-1}$ by

$$\tilde{x}_j(x, t) \triangleq x_j - x_j^d(x, t), \quad j \in \{2, \dots, n\}. \quad (39)$$

From the model (15), Lemma 2, and the control law (22) and (31) with the expression (34) for the input u_2 , we find that \tilde{z} satisfies

$$\dot{\tilde{x}}_2 = -\lambda_2 \tilde{x}_2 \quad (40)$$

$$\dot{\tilde{x}}_3 = \lambda_3 f^3(t) \tilde{x}_3 + k f(t) \tilde{x}_2$$

$$\vdots$$

$$\dot{\tilde{x}}_n = -\lambda_n f^{2(n-2)+1}(t) \tilde{x}_n + k f(t) \tilde{x}_{n-1}. \quad (41)$$

The following lemma shows that $\tilde{x}_j(x(t), t)$ tends exponentially toward zero.

We denote

$$\underline{z}_j = [x_2, x_3, \dots, x_j]^T, \quad j \in \{2, \dots, n\} \quad (42)$$

and use the one-norm $\|\cdot\|$ as defined by (18).

Lemma 3: Consider system (15) with the control law (22) and (31). Let $\tilde{z}(x(t), t)$ be defined by (39) where $x(t)$ is the solution of (15). Then, for any $j \in \{2, \dots, n\}$, there is a $\delta > 0$ such that

$$\forall \varepsilon_2, \quad \varepsilon_j \in (0, \delta),$$

$$\exists c_j > 0, \exists \gamma_j > 0,$$

$$\forall t_p \in \{t_0, t_1, \dots\}, \forall \underline{z}_j(t_p) \in R^{j-1}$$

$$|\tilde{x}(x(t), t)| \leq c_j \|\underline{z}_j(t_p)\| e^{-\gamma_j(t-t_p)}, \quad \forall t \geq t_p \quad (43)$$

where the constants γ_j can be defined as

$$\gamma_j = \alpha_j - \varepsilon_j > 0 \quad (44)$$

$$\alpha_q = \min\{\lambda_q \eta_q, \alpha_{q-1} - \varepsilon_{q-1}\}, \quad q \in \{3, \dots, j\} \quad (45)$$

$$\alpha_2 = \lambda_2. \quad (46)$$

The constants η_q are found from Property P4) of $f(t)$.

Proof The proof will be given by induction. Assume that (43) is satisfied for $j = m-1 \in \{2, \dots, n-1\}$ for a $t_p \in \{t_0, t_1, \dots\}$. Then, from (40)–(41) we have that

$$\begin{aligned} \dot{\tilde{x}} &= -\lambda_m f^{2m-3}(t) \tilde{x}_m + k(x(t_i)) f(t) \tilde{x}_{m-1} \\ &= -a(t) \tilde{x}_m + d(t) \end{aligned}$$

where

$$a(t) = \lambda_m f^{2m-3}(t)$$

$$d(t) = k(x(t_i)) f(t) \tilde{x}_{m-1}(x(t), t).$$

From Property P4) of $f(t)$ we have that for all $t_p \in \{t_0, t_1, \dots\}$ and for all $t \geq t_p$

$$\int_{t_p}^t (a(\tau) - \lambda_m \eta_m) d\tau \leq \lambda_m P_m.$$

Since (43) is assumed to be satisfied for $j = m-1$ and since $|f(t)| \leq 1$ from P1), and $|k(x)| \leq K$ from (20) and (23) we have

$$|d_m(t)| \leq D_m e^{-\gamma_{m-1}(t-t_p)}$$

here $D_m \triangleq K c_{m-1} \|\bar{z}_{m-1}(t_p)\|$. From the definition of $x_j(t)$ (39) and since $x_j^d(x(t_p), t_p) = 0$ for all $t_p \in \{0, t_1, \dots\}$, Section V-C, we have $\bar{x}_m(x(t_p), t_p) = x_m(t_p) = \bar{z}_m(t_p)$. From Lemma 1 we can then conclude that

$$\begin{aligned} \forall \varepsilon_m > 0 \exists c_m \exists \gamma_m \forall \bar{z}_{m-1} | \\ |\bar{x}_m(t)| &\leq c_m (\|\bar{z}_{m-1}(t_p)\| + |\bar{x}_m(t_p)|) e^{-\gamma_m(t-t_p)} \\ &= c_m \|\bar{z}_{m-1}(t_p)\| e^{-\gamma_m(t-t_p)} \end{aligned}$$

where the constants γ_m and c_m can be defined as

$$\begin{aligned} \gamma_m &= \alpha_m - \varepsilon_m \\ \alpha_m &= \min\{\lambda_m \eta_m, \gamma_{m-1}\} \\ c_m &= \max\left\{e^{\lambda_m P_m}, e^{2\lambda_m P_m} \frac{K c_{m-1}}{\varepsilon_m}\right\}. \end{aligned}$$

The constant γ_m is strictly positive if

$$0 < \varepsilon_j < \alpha_j, \quad j \in \{2, \dots, m\}.$$

Consequently, there exists a constant δ such that $\varepsilon_2, \dots, \varepsilon_n \in (0, \delta)$ implies that $\gamma_m > 0$.

We have, therefore, proved that if (43) is satisfied for $j = m-1$ for a $t_p \in \{t_0, t_1, \dots\}$, then (43) is satisfied for $j = m$, for all $m \in \{3, \dots, n\}$. The induction is completed by showing that (43) is satisfied for $j = 2$. From (40) we find that for all $x(t_p), t_p \in \{t_0, t_1, \dots\}$

$$\begin{aligned} |\bar{x}_2(x(t), t)| &= |\bar{x}_2(x(t_p), t_p)| e^{-\lambda_2(t-t_p)} \\ &= \|\bar{z}_2(t_p)\| e^{-\lambda_2(t-t_p)} \end{aligned}$$

since $x_j^d(x(t_p), t_p) = 0$ for $t_p \in \{t_0, t_1, \dots\}$ and hence $x_j(x(t_p), t_p) = x_j(t_p)$. Equation (43) is then satisfied for $j = 2$ by choosing $\varepsilon_2 = 1$. (In this case, (43) is also satisfied for $\varepsilon_2 = 0$.) Since (43) is satisfied for all $t_p \in \{t_0, t_1, \dots\}$ when $j = 2$ then (43) is proved by induction to be satisfied for all $t_p \in \{t_0, t_1, \dots\}$. \square

Remark: Note from (45) that arbitrarily large values for $\alpha_2, \dots, \alpha_n$ can be obtained by choosing $\lambda_2, \dots, \lambda_n$ appropriately, which means that the exponential rate of convergence $\gamma_j = \alpha_j - \varepsilon_j$ can be chosen arbitrarily large since ε_j can be chosen arbitrarily close to zero.

The definitions of x^d (32)–(33) and \hat{x} (39) can be used to show that the state x_j can be expressed as a weighted sum of the functions $\tilde{x}_r, r \in \{j, \dots, n\}$ as stated in the following lemma.

Lemma 4: Let $x_j^d(x, t)$ be defined by (32)–(33) and $\hat{x}_j(x, t)$ by (39) for $j \in \{2, \dots, n\}$ and $t \in [t_i, t_{i+1})$. If $x(t_i) \neq 0$ then x_j satisfies for all $j \in \{2, \dots, n-1\}$

$$x_j = \tilde{x}_j(x, t) + f^{2j-2}(t) \sum_{r=j+1}^n \tilde{g}_{jr}(t) \frac{1}{k^{r-j}(x(t_i))} \hat{x}_r(x, t). \quad (47)$$

The functions $\tilde{g}_{jr}: R_+ \rightarrow R$ are bounded and smooth.

Proof: See Appendix A. \square

From Lemmas 3 and 4 we can now show global, exponential convergence of $z(t)$ to zero.

Theorem 1: Consider system (15) with the control (22) and (31) and z defined in (16). There are a class \mathcal{K} function $h_z: R_+ \rightarrow R_+$ of class \mathcal{K} and a constant $\gamma_z > 0$ such that, for any initial condition $z(t_0) \in R^{n-1}$

$$\|z(t)\| \leq h_z(\|z(t_0)\|) e^{-\gamma_z(t-t_0)}, \quad \forall t \geq t_0$$

The constant γ_z can be given by

where γ_n is given from (44). \square

Proof: See Appendix A. \square

VII. STABILITY ANALYSIS OF $x(t)$

In this section, we prove global \mathcal{K} -exponential stability of the state $x(t)$ of the system (15) about zero.

By showing that $u_1 = k(x(t))f(t)$, (22), makes $x_1(t)$ converge to zero as $z(t)$ converge to zero, Theorem 1 can be used to show the following lemma.

Lemma 5: Let the control law be given by (22) and (31). Then, system (15) is \mathcal{K} -exponentially stable about the origin, i.e., in a neighborhood Ω about $x = 0$ there exist a function $h(\cdot; T)$ of class \mathcal{K} and a constant $\gamma > 0$ such that

$$\forall x(t_0) \in \Omega \|x(t)\| \leq h(\|x(t_0); T\|) e^{-\gamma(t-t_0)}, \quad \forall t \geq t_0 \quad (49)$$

where the function $h(\cdot; T)$ depends on time parameter $T = t_{i+1} - t_i$, (17). \square

Proof: See Appendix A. \square

The neighborhood Ω is given by

$$\Omega = \left\{x \mid |x_1| < \frac{K}{2\beta}, \quad G(h_2(\|z\|)) < \frac{K}{2\beta}\right\} \quad (50)$$

where $h_z(\cdot)$ is a function of class \mathcal{K} from Theorem 1 and $z = [x_2, \dots, x_n]^T$ (16). The function $G(\cdot)$ is defined in (24), and β is defined in (25). The constant γ can be defined as

$$\begin{aligned} \gamma &= \frac{\gamma_z}{2n-4} > 0 \\ \gamma_z &= \frac{\gamma_n}{2} \end{aligned}$$

where γ_n is given from Lemma 3.

Remark 1: The exponential convergence rate γ in (49) can be selected arbitrarily large by choosing $\lambda_2, \dots, \lambda_n$ appropriately, that is large enough. See also the remark to Lemma 3 in Section VI. For all $\lambda_2, \dots, \lambda_n > 0$ the system is \mathcal{K} -exponentially stable for all positive T where $T = t_{i+1} - t_i$. The class \mathcal{K} function $h(\cdot; T)$ increases exponentially, however, with the parameter T . This is due to the fact that it takes at least the time T for the input u_1 to drive x_1 to an arbitrarily small neighborhood about zero.

Remark 2. The neighborhood Ω can be chosen arbitrarily large by choosing the parameters K , \mathcal{K} and β (or $T = t_{i+1} - t_i$) appropriately. Therefore, the stability is semi-global.

Remark 3: The bounds on $\|x(t)\|$ given by the function $h(\cdot; T)$, (88), and γ_s can be very conservative and do not in general provide quantitative information.

Lemma 5 does not prove global, \mathcal{K} -exponential stability because of the saturation function in the definition of $k(x(t))$, (23). A function $h_x(\cdot)$ of class \mathcal{K} , however, can be constructed to yield also global, \mathcal{K} -exponential stability as shown in the following theorem.

Theorem 2: Let the control law be given by (22) and (31). Then system (15) is globally, \mathcal{K} -exponentially stable about the origin, i.e., there exist a function $h_x(\cdot; T)$ of class \mathcal{K} and a constant $\gamma > 0$ such that $\forall t \geq t_0$

$$\forall x(t_0) \in R^n \|x(t)\| \leq h_x(\|x(t_0)\|; T e^{-\gamma(t-t_0)}). \quad (51)$$

Proof: See Appendix A. \square

As for Lemma 5, the constant γ can be defined as follows

$$\gamma = \frac{\gamma_s}{2n-1} > 0$$

$$\gamma_s = \frac{\gamma_n}{2}$$

where γ_n is given from Lemma 3.

The remarks after Lemma 5 on the rate of convergence γ and the dependence of T for the class \mathcal{K} function $h_x(\cdot; T)$ also apply here.

VIII. STABILIZATION ABOUT ARBITRARY CONFIGURATION

We have shown that the controller (22) and (31), and (23) makes system (15) globally, \mathcal{K} -exponentially stable about the origin, i.e., about $[x_1, \dots, x_n]^T = 0$. In this section we show that the same control law can be used to \mathcal{K} -exponentially stabilize the chained form (15) about any configuration. Indeed, here we show that any strategy to control the chained form to the origin can be used to control it to any desired configuration.

Let the desired constant configuration be given by

$$x^p = [x_1^p, x_2^p, \dots, x_n^p]^T \in R^n, \quad \dot{x}^p \equiv 0.$$

Now we introduce the following variables

$$x_m^r \triangleq x_m^p + \sum_{j=2}^{m-1} x_j^p \frac{1}{(m-j)!} (x_1 - x_1^p)^{m-j}, \quad m \in \{1, \dots, n\} \quad (52)$$

Here, x_i is a state variable of the chained form (15) satisfying $\dot{x}_1 = u_1$. The vector $x^r = [x_1^r, \dots, x_n^r]^T$ is thus given from (52) as a smooth function $x^r = \phi(x_1; x^p)$.

Lemma 6: Let $x^r = [x_1^r, \dots, x_n^r]^T$ be given by (52). Then

$$\dot{x}_1^r = 0 \quad (53)$$

$$\dot{x}_2^r = 0 \quad (54)$$

$$\dot{x}_m^r = x_{m-1}^r u_1, \quad m \in \{3, \dots, n\}. \quad (55)$$

Proof: From (52) we have that $x_1^r = x_1^p$ and $x_2^r = x_2^p$. Since x_1^p and x_2^p are constants, (53)–(54) follow readily. Equation (55) can be proved by induction. Assume that there is an index $m \in \{3, \dots, n-1\}$ such that

$$\dot{x}_m^r = x_{m-1}^r u_1.$$

Since $\dot{x}_m^p = 0$, $m \in \{1, \dots, n\}$, differentiating x_{m+1}^r from (52) gives

$$\begin{aligned} \dot{x}_{m+1}^r &= \sum_{j=2}^m x_j^p \frac{1}{(m+1-j)!} (m+1-j) \\ &\quad \times (x_1 - x_1^p)^{m-j} (\dot{x}_1 - \dot{x}_1^p) \\ &= \sum_{j=2}^m x_j^p \frac{1}{(m-j)!} (x_1 - x_1^p)^{m-j} u_1 \\ &= \left[x_m^p + \sum_{j=2}^{m-1} x_j^p \frac{1}{(m-j)!} (x_1 - x_1^p)^{m-j} \right] u_1 \\ &= x_m^r u_1. \end{aligned}$$

Consequently, if (55) is satisfied for index m then (55) is satisfied for $m+1$, too. The proof is then completed by showing that $\dot{x}_1^r = x_2^r u_1$. From (52) we get

$$\dot{x}_1^r = \frac{d}{dt} [x_2^p (x_1 - x_1^p) + x_1^p] = x_2^p u_1 = x_2^r u_1.$$

\square

We now define

$$\bar{x}_m \triangleq x_m - x_m^p, \quad m \in \{1, \dots, n\}. \quad (56)$$

From system (15) and Lemma 6 it follows that

$$\dot{\bar{x}}_1 = u_1 \quad (57)$$

$$\dot{\bar{x}}_2 = u_2 \quad (58)$$

$$\dot{\bar{x}}_m = \bar{x}_{m-1} u_1, \quad m \in \{3, \dots, n\}. \quad (59)$$

This system has the same structure as the chained form (15). A control law for (15) controlling $x = [x_1, \dots, x_n]^T$ to zero can be used to control $\bar{x} = [\bar{x}_1, \dots, \bar{x}_n]^T$ to zero. The coordinate transformation between x and \bar{x} is then given from (52) and (56) by

$$\bar{x} = x - x^p = x - \phi(x_1; x^p) \triangleq \tau(x; x^p)$$

$$x = \bar{x} + x^p = \bar{x} + \phi(x_1; x^p)$$

$$= \bar{x} + \phi(x_1 + x_1^p; x^p) \triangleq \bar{\tau}(\bar{x}; x^p)$$

where $\tau(\cdot; x^p)$ and $\bar{\tau}(\cdot; x^p)$ are smooth functions.

We can then conclude with the following theorem.

Theorem 3: Given the system (57)–(59) where \bar{x}_m and x_m^r are given by (56) and (52). Then, a control law for (57)–(59) making $\bar{x} = [\bar{x}_1, \dots, \bar{x}_n]^T$ converge to zero makes x converge to the desired configuration x^p . The convergence of x to x^p is exponential if \bar{x} converges exponentially to zero.

Proof. From (56) and (52) we have that

$$\begin{aligned} x_m &= x_m^r + \bar{x}_m = x_m^p + \sum_{j=2}^{m-1} x_j^p \frac{1}{(m-j)!} \bar{x}_1^{m-j} \\ &\quad + \bar{x}_m, \quad m \in \{1, \dots, n\}. \end{aligned}$$

Therefore, the control of \bar{x} to zero implies the control of x to x^p . We also see that exponential convergence of \bar{x} to zero implies exponential convergence of x to x^p . \square

IX. SIMULATIONS

A simulation with $n = 4$ was done in MATLAB at a SPARC station 1. The control law for u_1 was chosen as follows

$$u_1 = k(x(t_i))f(t), \quad f(t) = (1 - \cos t)/2$$

where

$$k = \text{sat}(-[x_1(t_i) + \text{sgn}(x_1(t_i))G(\|z(t_i)\|)]\beta, K), \quad K = 2$$

as defined in (23). By studying the time integral of $f^3(t)$ and $f^5(t)$, we see that Property P4) of $f(t)$ is satisfied by choosing

$$\eta_3 = \frac{5}{16}, \quad \eta_4 = \frac{63}{256}, \quad P_3 = \frac{1}{2}, \quad P_4 = \frac{1}{2}.$$

The controller parameter κ in $G(\cdot)$, (24), was taken to $\kappa = 3$. The constant β is given by (25)

$$\beta = 1 / \int_0^T f(\tau) d\tau = \frac{1}{\pi}$$

where T is the time-period of the function $f(t)$, i.e., $T = 2\pi$. The instants of time t_i where $k(x(t_i))$ may switch are given by the set $\{0, 2\pi, 4\pi, 6\pi, \dots\}$.

We find the control law for u_2 from (31) and (27)–(30)

$$\begin{aligned} u_2 = & -(\lambda(1 + f^3 + f^5))x_2 \\ & - (f\lambda + f^3\lambda + f^5\lambda + 2\dot{f} + 8f^2\dot{f})/k x_3 \\ & - (f\lambda(f^5\lambda^2 + 4f\lambda\dot{f} + 6f^4\lambda\dot{f} + 8\dot{f}^2 + 4f\ddot{f})/k^2)x_4. \end{aligned}$$

Here, we have chosen

$$\lambda = \lambda_2 = \lambda_3 = \lambda_4.$$

In the simulation, λ was taken to $\lambda = 1$.

The initial state was chosen as

$$(x_1(0), x_2(0), x_3(0), x_4(0)) = (0, -0.1, 0.1, 1).$$

Euler's method was applied for the numerical integration where the time-step was taken to 0.05. In Fig. 1, $z(t) = [x_2(t), x_3(t), x_4(t)]^T$ is plotted versus time showing the convergence to zero. The state variable $x_1(t)$ is plotted in Fig. 2. We see that $x_1(t)$ converges to zero, too. Note, however, from the time-axes that the rate of convergence of $x_1(t)$ is slower than the one of $z(t)$. This coincides with the relation between γ and γ_z in Lemma 5 where $\gamma = \gamma_z/4$. To show that the convergence is exponential, $\log \|x(t)\|$ is plotted in Fig. 3 where the one-norm is chosen. We see from this figure that $\log \|x(t)\|$ decreases toward $-\infty$ implying that $\|x(t)\|$ exponentially converges to zero.

By using the coordinate transformation from [33], we can interpret the variables x_1 and x_4 as the x - and y -position of the midpoint of the rear axle of a four-wheeled car. The path $(x(t), y(t))$ is presented in Fig. 4. We see that the motion seems natural when interpreted as a parking maneuver.

In Figs. 5 and 6 the inputs $u_1(t)$ and $u_2(t)$ are shown as functions of time. We see that they are continuous and converge exponentially to zero.

Fig. 1. Exponential convergence of $z(t) = [x_2, x_3, x_4]^T$ to zero

Fig. 2. Exponential convergence of $x_1(t)$ to zero

Fig. 3. Convergence of $\log \|x(t)\|$ to $-\infty$.

X. SUMMARY AND CONCLUSION

A feedback control law has been proposed to globally stabilize a chained nonholonomic system of any dimension.

Fig. 4. The resulting path in the xy -plane when applying the exponentially convergent control law. The variables $x = x_1$ and $y = x_4$ are interpreted as the planar position of a four-wheeled car

Fig. 6. The input $u_2(t)$ from the exponentially convergent control law

Fig. 5. The input $u_1(t)$ from the exponentially convergent control law

The resulting rate of convergence is exponential and global, \mathcal{K} -exponential stability was achieved. \mathcal{K} -exponential stability is a weaker form of stability than exponential stability in the usual sense, but it possesses the same rate of convergence.

The feedback control law depends on a time-varying function, not necessarily periodic, and on a function which is nonsmooth with respect to the state at predefined discrete instants of time. The exponential rate of convergence can be arbitrarily fast by choosing the controller parameters appropriately. The controller cannot, however, drive the system to an arbitrary small neighborhood of the desired configuration in shorter time than T i.e., the length of the time intervals used in the control law. The class \mathcal{K} function which defines a initial-state-dependent upper bound of the time-evolution of the system, has T as a parameter. Simulation of a four dimensional chained form indicated the exponential convergence. By using a coordinate transformation similar to the transformation from chained form to power form, a strategy to control the state to zero can be used to control the state of any desired configuration.

The idea of introducing a function which varies with the state at discrete instants of time seems, therefore, to be a useful approach to obtain good stability properties for nonholonomic systems. The control law has a simple structure, though the stability analysis is quite involved because of few existing mathematical tools for such systems.

A drawback of this approach is the possibility for numerical problems at digital computers as the parameter $k(x(t_i))$ approaches zero, since there are divisions by $k(x(t_i))$ in the control law for u_2 . (These divisions do not cause unbounded quantities, since $k(x(t_i))$ always dominates the numerator.) Such numerical problems were, however, not observed during the simulations. Since the parameter $k(x(t_i))$ only changes at $t_i \in \{t_0, t_1, \dots\}$, the control of x_1 may be more sensitive to disturbances and modeling imperfections than if $k = k(x(t))$ i.e., function of the state at all $t \geq t_0$. Depending on the physical application, feedback from the state only at $t_i \in \{t_0, t_1, \dots\}$ may be sufficient to make x_1 exponentially converge to zero. Note that the state variables $z = [x_2, \dots, x_n]^T$ are controlled by the control law $u_2 = u_2(z(t), k)$ which depends on $z(t)$ for all $t \geq t_0$.

In further work, an extension from $k = k(x(t_i))$ to $k = k(x(t))$ by redefining z^d , (32)–(33), can be studied. The structure of $k(x(t_i))$ in the present control law indicates that the use of $k = k(x(t))$ results in a nonsmooth, time-varying feedback control law. Also, more mathematical tools are needed to analyze such systems. The need for the definition of \mathcal{K} -exponential stability for the stabilization with exponential convergence of chained systems and other nonholonomic systems should also be analyzed.

APPENDIX PROOFS

Proof of Lemma 4: The arguments of $k(x(t_i))$, $\tilde{x}(x, t)$, $x^d(x, t)$, $f(t)$, and $g_{j,r}(t)$ will mostly be omitted for simplicity. From the definition (39) of \tilde{x}_{n-1} we have that

$$x_{n-1} = \tilde{x}_{n-1} + x_{n-1}^d. \quad (60)$$

om (32) we have that $x_n^d = 0$ which means that $\hat{x}_n = x_n$. It trivially seen from Lemma 2 assuming that $x(t_i) \neq 0$ that

$$x_{n-1} = \hat{x}_{n-1} + x_{n-1}^d = \hat{x}_{n-1} + f^{2n-4}(-\lambda_n) \frac{1}{k} \hat{x}_n \quad (61)$$

which implies that

$$\hat{g}_{n-1,n} = g_{n-1,n} = -\lambda_n. \quad (62)$$

We can then calculate from the definition (33) of x_{n-2}^d and (60)–(62)

$$\begin{aligned} x_{n-2} &= \hat{x}_{n-2} + x_{n-2}^d \\ &= \hat{x}_{n-2} + f^{2n-6} \left(g_{n-2,n-1} \frac{x_{n-1}}{k} + g_{n-2,n} \frac{x_n}{k^2} \right) \\ &= \hat{x}_{n-2} + f^{2n-6} \left[g_{n-2,n-1} \frac{1}{k} \hat{x}_{n-1} \right. \\ &\quad \left. + (g_{n-2,n} + g_{n-2,n-1} \hat{g}_{n-2,n} f^{2n-4}) \frac{x_n}{k^2} \right] \\ &= \hat{x}_{n-2} + f^{2n-6} \left[\hat{g}_{n-2,n-1} \frac{1}{k} \hat{x}_{n-1} + \hat{g}_{n-2,n} \frac{1}{k^2} \hat{x}_n \right] \end{aligned} \quad (63)$$

where

$$\hat{g}_{n-2,n-1} = g_{n-2,n-1} \quad (64)$$

$$\hat{g}_{n-2,n} = g_{n-2,n} + g_{n-2,n-1} g_{n-1,n} f^{2n-4}. \quad (65)$$

The rest of the proof will be given by induction. Assume that (47) is satisfied for $j+1, j+2, \dots, n-1$, i.e.,

$$x_{m+1} = \hat{x}_{m+1} + f^{2m} \sum_{r=m+2}^n \hat{g}_{m+1,r} \frac{1}{k^{r-m-1}} \hat{x}_r \quad (66)$$

where $m \in \{j, j+1, \dots, n-2\}$. We then find from the definition (33) of x_j^d assuming that $x(t_i) \neq 0$

$$\begin{aligned} x_j &= \hat{x}_j + x_j^d \\ &= \hat{x}_j + f^{2j-2}(t) \sum_{r=j+1}^n g_{jr} \frac{1}{k^{r-j}} x_r \\ &= \hat{x}_j + f^{2j-2}(t) \sum_{r=j+1}^n g_{jr} \frac{1}{k^{r-j}} \\ &\quad \times \left[\hat{x}_r + f^{2r-2} \sum_{m=r+1}^n \hat{g}_{rm} \frac{1}{k^{m-r}} \hat{x}_m \right] \\ &= \hat{x}_j + f^{2j-2}(t) \sum_{r=j+1}^n g_{jr} \\ &\quad \times \left[1 + f^{2r-2} \sum_{m=j+1}^{r-1} \hat{g}_{mr} \right] \frac{1}{k^{r-j}} \hat{x}_r \\ &= \hat{x}_j + f^{2j-2}(t) \sum_{r=j+1}^n \hat{g}_{jr} \frac{1}{k^{r-j}} \hat{x}_r \end{aligned} \quad (67)$$

where

$$\hat{g}_{jr} = g_{jr} \left[1 + f^{2r-2} \sum_{m=j+1}^{r-1} \hat{g}_{mr} \right]. \quad (68)$$

Equation (67) shows that if (47) is satisfied for $j+1, \dots, n$, then (47) is satisfied for j as well. Thus, (61)–(62) and (67) imply that (47) is satisfied for all $\{2, \dots, n-1\}$. We see that \hat{g}_{jr} is given by g_{mr} and q_i which are known. Because of the smoothness and boundedness of $f(t), g_{jr}(t)$ and $\hat{g}_{mr}(t)$ for $m \in \{j+1, \dots, n-1\}$, \hat{g}_{jr} will be smooth and bounded as well.

Proof of Theorem 1: The point of time t_i denotes the largest term in the sequence (t_0, t_2, \dots) such that $t \geq t_i$. If $x(t_i) = 0$ then $[u_1(t), u_2(t)]^T = 0$ from the control law (22) and (31) for $t \in [t_i, t_{i+1})$. From the model (15) we then see that $x(t) = 0$, for $t \in [t_i, t_{i+1})$, implying that $[u_1(t), u_2(t)]^T = 0$ for $t \in [t_{i+1}, t_{i+2})$, etc. and $x(t) = 0$ for all $t \geq t_i$. In that case, relation (48) is satisfied for all $t \geq t_i$ for any function $h_z(\cdot)$ of class \mathcal{K} . In the following, we analyze the case where $x(t_i) \neq 0$. The norm $\|\cdot\|$ denotes the one-norm (18).

From Lemma 4 we have that for $j \in \{2, \dots, n-1\}$

$$\begin{aligned} x_j(t) &= \hat{x}_j(x(t), t) + f^{2j-2}(t) \\ &\quad \times \sum_{r=j+1}^n \hat{g}_{jr}(t) \frac{1}{k^{r-j}(x(t), t)} \hat{x}_r(x(t), t) \end{aligned}$$

where the functions $\hat{g}_{jr}(t)$ are bounded, say by the constant G , such that $|\hat{g}_{jr}(t)| \leq G$ for all $t \geq t_0$. Since $|f(t)| \leq 1$, Property P2) of $f(t)$, we get

$$\begin{aligned} |x_j(t)| &\leq |\hat{x}_j(x(t), t)| + \sum_{r=j+1}^n G \frac{1}{|k(x(t), t)|^{r-j}} |\hat{x}_r(x(t), t)|, \\ j &\in \{2, \dots, n-1\}. \end{aligned} \quad (69)$$

Now, we will show that there are constants κ_j such that

$$|k(x(t_i))| = K \text{ or } |k(x(t_i))| \geq \kappa_j |x_j(x(t), t)|^{\frac{1}{2^{j-1}}} \quad (70)$$

for all $j \in \{3, \dots, n\}$. From (23) we find that if $|k(x(t_i))| < K$ then

$$|k(x(t_i))| = \|x_1(t_i)\| + G(\|z(t_i)\|)\beta.$$

Combining this with the definition of $G(\cdot)$, (24), implies

$$\begin{aligned} |k(x(t_i))| &\geq G(\|z(t_i)\|)\beta = \beta \kappa \|z(t_i)\|^{\frac{1}{2^{n-4}}} \\ &\geq \beta \kappa \|\hat{z}_j(t_i)\|^{\frac{1}{2^{n-4}}} \\ j &\in \{2, \dots, n\}. \end{aligned} \quad (71)$$

Lemma 3 implies

$$\begin{aligned} |k(x(t_i))| &\geq \beta \kappa \left(\frac{1}{c_j} |\hat{x}_j(x(t), t)| \right)^{\frac{1}{2^{j-1}}} \\ &= \beta \kappa c_j^{\frac{1}{2^{j-1}}} |\hat{x}_j(x(t), t)|^{\frac{1}{2^{j-1}}}, \quad j \in \{3, \dots, n\}. \end{aligned} \quad (72)$$

Therefore, (70) is satisfied by defining $\kappa_j = \beta \kappa c_j^{\frac{1}{2^{j-1}}}$.

From (70) and (69) we then get

$$\begin{aligned} |x_j(t)| &\leq |\hat{x}_j(x(t), t)| + G \sum_{r=j+1}^n \left[\frac{1}{K^{r-j}} |\hat{x}_r(x(t), t)| \right. \\ &\quad \left. + \frac{1}{\kappa_r^{r-j}} |\hat{x}_r(x(t), t)|^{1-\frac{r-j}{2^{n-4}}} \right] \end{aligned} \quad (73)$$

for all $j \in \{2, \dots, n-1\}$. From Lemma 3 we get, with $t_p = t_0$

$$\begin{aligned} |x_j(t)| &\leq c_j \|z_j(t_0)\| e^{-\gamma_j(t-t_0)} \\ &\quad + G \sum_{r=j+1}^n \left[\frac{1}{K^{r-j}} c_r \|z_r(t_0)\| e^{-\gamma_r(t-t_0)} \right. \\ &\quad \left. + \left(\frac{c_r}{K^{r-j}} \|z_r(t_0)\| e^{-\gamma_r(t-t_0)} \right)^{1-\frac{r-j}{2n-4}} \right] \\ &\leq h_j(\|z(t_0)\|) e^{-\zeta_j(t-t_0)} \end{aligned}$$

for all $j \in \{2, \dots, n-1\}$, since $\|z(t_0)\| \geq \|z_r(t_0)\|$, where

$$\begin{aligned} h_j(q) &= c_j q + G \sum_{r=j+1}^n \left[\frac{1}{K^{r-j}} c_r q + \left(\frac{c_r}{K^{r-j}} q \right)^{1-\frac{r-j}{2n-4}} \right] \\ \zeta_j &= \min_r \left\{ \gamma_r \left(1 - \frac{r-j}{2n-4} \right) \right\}, \quad r \in \{j, \dots, n\}. \end{aligned} \quad (74)$$

From (44)–(46) we see that

$$0 < \gamma_n < \gamma_{n-1} < \dots < \gamma_2 < \lambda_2.$$

Equation (74) then implies that

$$\zeta_j = \gamma_n \left(1 - \frac{n-j}{2n-4} \right).$$

Note that the function $h_j(q)$ is of class \mathcal{K} . Since $x_n^d \triangleq 0$ we have from Lemma 3

$$|x_n(t)| = |\tilde{x}_n(x(t), t)| \leq c_n \|z(t_0)\| e^{-\gamma_n(t-t_0)}.$$

We define $h_n(\|z(t_0)\|) = c_n \|z(t_0)\|$ and $\zeta_n = \gamma_n$ such that from Lemma 3

$$|x_n(t)| = |\tilde{x}_n(t)| \leq h_n(\|z(t_0)\|) e^{-\gamma_n(t-t_0)}.$$

The proof is completed by noting that

$$\begin{aligned} \|z(t)\| &= |x_2(t)| + \dots + |x_n(t)| \\ &\leq \sum_{j=2}^n h_j(\|z(t_0)\|) e^{-\zeta_j(t-t_0)} = h_z(\|z(t_0)\|) e^{-\gamma_z(t-t_0)} \end{aligned}$$

where

$$h_z(q) = \sum_{j=2}^n h_j(q) \quad (75)$$

$$\gamma_z = \min\{\zeta_2, \dots, \zeta_n\} = \zeta_2 = \frac{\gamma_n}{2}. \quad (76)$$

□

Proof of Lemma 5: The outline of the proof is to show that we can find a small enough neighborhood Ω of the origin such that the controller u_1 does not get saturated due to the convergence of $z(t)$ from Theorem 1. It will then be shown that the control law $u_1 = k(x(t_i))f(t)$ is chosen such that $x_1(t)$ converges to zero as $z(t)$ converges. A function $h(\cdot; T)$ will be constructed. The norm $\|\cdot\|$ denotes the one-norm (18).

Let the neighborhood be given by

$$\Omega = \left\{ x \mid |x_1| < \frac{K}{2\beta}, G(h_z(\|z\|)) < \frac{K}{2\beta} \right\}$$

where $h_z(\cdot)$ is a function of class \mathcal{K} from Theorem 1 and $z = [x_2, \dots, x_n]^T$ (16). The function $G(\cdot)$ is defined in (24),

and β is defined in (25). By induction, we will show that if $x(t_0) \in \Omega$, then

$$|k(x(t_i))| < K, \quad \forall t_i \in \{t_0, t_1, \dots\} \quad (77)$$

which implies from the definition of $k(\cdot)$, (23)

$$\begin{aligned} k(x(t_i)) &= -[x_1(t_i) + \text{sgn}(x_1(t_i))G(\|z(t_i)\|)]\beta, \\ \forall t_i &\in \{t_0, t_1, \dots\}. \end{aligned} \quad (78)$$

Note from Theorem 1 that

$$\|z(t)\| \leq h_z(\|z(t_0)\|), \quad \forall t \geq t_0.$$

Since $G(\cdot)$ is of class \mathcal{K} , (24), this implies

$$G(\|z(t)\|) \leq G(h_z(\|z(t_0)\|)), \quad \forall t \geq t_0.$$

Assume for a $t_m \in \{t_0, t_1, \dots\}$ that

$$k(x(t_m)) = -[x_1(t_m) + \text{sgn}(x_1(t_m))G(\|z(t_m)\|)]\beta.$$

Integrating $\dot{x}_1 = u_1 = k(x(t_m))f(t)$ from t_m to t_{m+1} then gives

$$x_1(t_{m+1}) = -\text{sgn}(x_1(t_m))G(\|z(t_m)\|) \quad (79)$$

which implies that

$$|x_1(t_{m+1})| = G(\|z(t_m)\|) \leq G(h_z(\|z(t_0)\|)).$$

By assumption, $x(t_0) \in \Omega$ which implies that $G(h_z(\|z(t_0)\|)) < \frac{K}{2\beta}$ and therefore

$$|x_1(t_{m+1})| < \frac{K}{2\beta}.$$

Since

$$[|x_1(t_{m+1})| + G(\|z(t_{m+1})\|)]\beta < \left(\frac{K}{2\beta} + \frac{K}{2\beta} \right)\beta = K$$

then from the definition of $k(\cdot)$, (23)

$$k(x(t_{m+1})) = -[x_1(t_{m+1}) + \text{sgn}(x_1(t_{m+1}))G(\|z(t_{m+1})\|)]\beta.$$

Equations (77) and (78) are proved by noting that since $x(t_0) \in \Omega$, then

$$[|x_1(t_0)| + G(\|z(t_0)\|)]\beta < \left(\frac{K}{2\beta} + \frac{K}{2\beta} \right)\beta = K$$

which implies that

$$k(x(t_0)) = -[x_1(t_0) + \text{sgn}(x_1(t_0))G(\|z(t_0)\|)]\beta.$$

Integrating $\dot{x}_1 = u_1$ in (15) from t_i to $t < t_{i+1}$ with $u_1 = k(x(t_i))f(t)$ and k constant gives

$$\begin{aligned} |x_1(t)| &\leq |x_1(t_i)| + |k| \int_{t_i}^t f(\tau) d\tau \\ &\leq |x_1(t_i)| + |k| \int_{t_i}^{t_{i+1}} f(\tau) d\tau \\ &= |x_1(t_i)| + |x_1(t_{i+1}) - x_1(t_i)| \\ &\leq 2|x_1(t_i)| + |x_1(t_{i+1})|. \end{aligned} \quad (80)$$

once $x(t_0) \in \Omega$ then $k(x(t_i))$ is given by (78) and we get from (79) and (80)

$$r_1(t) \leq 2G(\|z(t_{i-1})\|) + G(\|z(t_i)\|), \quad i \in \{1, 2, \dots\}. \quad (81)$$

From Theorem 1 we have that

$$\|z(t_k)\| \leq h_z(\|z(t_0)\|)e^{-\gamma_z(t_k-t_0)}. \quad (82)$$

From the definition of $G(\cdot)$, (24), we have

$$G(ae^{-bt}) = \kappa(ae^{-bt})^{\frac{1}{2n-4}} = e^{\frac{-bt}{2n-4}} G(a) \quad (83)$$

where a and b are positive constants. We denote for simplicity

$$q = h_z(\|z(t_0)\|).$$

Equation (83) combined with (81) and (82) implies

$$\begin{aligned} |x_1(t)| &\leq 2G(qe^{-\gamma_z(t_{i-1}-t_0)}) + G(qe^{-\gamma_z(t_i-t_0)}) \\ &= 2G(q)e^{\frac{-\gamma_z}{2n-4}(t_{i-1}-t_0)} + G(q)e^{\frac{-\gamma_z}{2n-4}(t_i-t_0)} \\ &\leq 3G(q)e^{\frac{-\gamma_z}{2n-4}(t_{i-1}-t_0)}. \end{aligned}$$

By convention we have for all $i \in \{1, 2, \dots\}$

$$t_{i-1} = t_{i+1} - 2T \geq t - 2T$$

since $t \in [t_i, t_{i+1})$. This implies

$$|x_1(t)| \leq 3G(q)e^{\frac{-\gamma_z 2T}{2n-4}} e^{\frac{-\gamma_z(t-t_0)}{2n-4}}, \quad t \geq t_1. \quad (84)$$

If $t \in [t_0, t_1)$ we find the following bound on $|x_1(t)|$ by integrating $\dot{x}_1 = k(x(t_0))f(t)$ where k is given by (78) and $f(t) \geq 0$

$$\begin{aligned} |x_1(t)| &\leq |x_1(t_0)| + \int_{t_0}^t f(\tau) d\tau \\ &\leq 2|x_1(t_0)| + G(\|z(t_0)\|). \end{aligned}$$

Since $t \in [t_0, t_1)$ this implies

$$|x_1(t)| \leq [2|x_1(t_0)| + G(\|z(t_0)\|)]e^{-\frac{\gamma_z(t-t_0)}{2n-4}}, \quad t \in [t_0, t_1). \quad (85)$$

Combining (84) and (85) and using $t_1 - t_0 = T$ implies

$$\begin{aligned} |x_1(t)| &\leq \{3G(h_z(\|z(t_0)\|))e^{\frac{\gamma_z 2T}{2n-4}} \\ &\quad + [2|x_1(t_0)| + G(\|z(t_0)\|)]e^{\frac{\gamma_z T}{2n-4}}\}e^{\frac{-\gamma_z(t-t_0)}{2n-4}} \\ &\leq h_1(\|x(t_0)\|; T)e^{\frac{-\gamma_z(t-t_0)}{2n-4}}, \quad t \geq t_0 \end{aligned} \quad (86)$$

where

$$\begin{aligned} h(\|x(t_0)\|; T) &= 3G(h_z(\|x(t_0)\|))e^{\frac{\gamma_z 2T}{2n-4}} \\ &\quad + [2\|x(t_0)\| + G(\|x(t_0)\|)]e^{\frac{\gamma_z T}{2n-4}}. \end{aligned}$$

Since $G(\cdot)$ and $h_z(\cdot)$ are functions of class \mathcal{K} , $h_1(\cdot; T)$ is also of class \mathcal{K} , (1). The proof is completed by noting from Theorem 1 and (86) that

$$\begin{aligned} \|x(t)\| &= |x_1(t)| + \|z(t)\| \\ &\leq h_1(\|x(t_0)\|; T)e^{\frac{-\gamma_z(t-t_0)}{2n-4}} + h_z(\|z(t_0)\|)e^{-\gamma_z(t-t_0)} \\ &\leq [h_1(\|x(t_0)\|; T) + h_z(\|z(t_0)\|)]e^{\frac{-\gamma_z(t-t_0)}{2n-4}} \\ &= h(\|x(t_0)\|; T)e^{-\gamma(t-t_0)}, \quad t \geq t_0 \end{aligned} \quad (87)$$

where

$$\begin{aligned} h(\|x(t_0)\|; T) &= h_1(\|x(t_0)\|) + h_z(\|z(t_0)\|), \\ \gamma &= \frac{\gamma_z}{2n-4} \end{aligned}$$

where γ_z is given from Theorem 1.

Proof of Theorem 2. The theorem will be proved by showing that $z(t) = [x_2(t), \dots, x_n(t)]^T$ and $x_1(t)$ are bounded and reach the neighborhood Ω defined in Lemma 5 in finite time. After this finite time, exponential convergence of $x(t)$ is ensured by Lemma 5. A function $h_z(\|z(t_0)\|; T)$ is constructed by using expressions for the finite time and the bounds on $\|x(t)\|$ and $h(\|x(t_0)\|; T)$ in Lemma 5. The norm $\|\cdot\|$ denotes the one-norm (18).

We will seek a time $\tau(\|x(t_0)\|)$ such that for all $t \geq \tau$, $x(t) \in \Omega$. First, define the time function $T_z: R_+ \rightarrow R_+$ as

$$T_z(q) \triangleq \begin{cases} \frac{1}{\gamma_z} \ln G(h_z(h_z(q))) \frac{2\beta}{K}, & G(h_z(h_z(q))) \geq \frac{K}{2\beta} \\ 0, & G(h_z(h_z(q))) < \frac{K}{2\beta} \end{cases} \quad (89)$$

Consider $G(h_z(\|z(t)\|))$. By inserting (48) and accounting for $\|z\| \leq \|x\|$ and the fact that $G(\cdot)$ and $h_z(\cdot)$ are of class \mathcal{K} , it is seen that

$$\forall t > T_z(\|x(t_0)\|) + t_0, \quad G(h_z(\|z(t)\|)) < \frac{K}{2\beta}. \quad (90)$$

Then, integrating $\dot{x}_1 = u_1 = k(x(t))f(t)$ from t_i to t_{i+1} gives

$$x_1(t_{i+1}) = \begin{cases} -\text{sgn}(x_1(t_i))G(\|z(t_i)\|), & |k(x(t_i))| < K \\ x_1(t_i) - \text{sgn}(x_1(t_i))\frac{K}{\beta}, & |k(x(t_i))| = K \end{cases} \quad (91)$$

Define the time function $\tau: R_+ \rightarrow R_+$ as

$$\tau(q) = \max \left\{ T_z(q), \frac{\beta}{K} q \right\}. \quad (92)$$

One can show from (90) and (91) that for all $t_m \in \{t_0, t_1, \dots\}$ which satisfies $t_m > t_0 + \tau(\|x(t_0)\|)$

$$|x_1(t_m)| < \frac{K}{2\beta}. \quad (93)$$

By integrating $\dot{x}_1 = k(x(t_m))f(t)$ one can show that $x_1(t)$ is a linear interpolation between $x_1(t_m)$ and $x_1(t_{m+1})$ for all $t \in [t_m, t_{m+1})$. From the definition of Ω , (50), and from (90) and (93) we find

$$\forall t > t_0 + \tau(\|x(t_0)\|), \quad x(t) \in \Omega.$$

Denote by t_p the smallest element in the sequence $\{t_0, t_1, \dots\}$ such that $t_p > t_0 + \tau(\|x(t_0)\|)$. From Lemma 5 it then follows that

$$\forall t \geq t_p, \quad \|x(t)\| \leq h(\|x(t_p)\|; T)e^{-\gamma(t-t_p)}. \quad (94)$$

To include $t \in [t_0, t_p)$, an expression for the maximum of $\|x(t)\|$ must be found.

We can show from (91) by using the convergence property of $z(t)$, Theorem 1, that

$$\begin{aligned} \max_{t \geq t_0} \|x_1(t)\| &\leq \max\{\|x_1(t_0)\|, G(h_z(\|z(t_0)\|))\} \\ &\leq \max\{\|x(t_0)\|, G(h_z(\|x(t_0)\|))\} \\ &\triangleq x_{1m}(\|x(t_0)\|) \end{aligned} \quad (95)$$

since $\|x(t_0)\| \geq \|z(t_0)\|$, and $h_z(\cdot)$ are of class \mathcal{K} . Here, we have defined the function $x_{1m}: R_+ \rightarrow R_+$ which is of class \mathcal{K} .

From (95) and Lemma 5 we have

$$\begin{aligned} \|x(t)\| &\leq x_{1m}(\|x(t_0)\|) + h_z(\|x(t_0)\|) \\ &\triangleq x_{mx}(\|x(t_0)\|), \quad \forall t \geq t_0. \end{aligned}$$

Here, we have defined the function $x_{mx}: R_+ \rightarrow R_+$ which is of class \mathcal{K} . The bound in (94) can then be extended to an exponential bound for all $t \geq t_0$ and all $x(t_0) \in R^n$

$$\|x(t)\| \leq [h(x_{mx}(q); T) + x_{mx}(q)]e^{\gamma\tau(q)}e^{-\gamma(t-t_0)}$$

where q denotes $\|x(t_0)\|$. From the definition of $\tau(\cdot)$, (92), we then obtain for all $t \geq t_0$

$$\forall x(t_0) \in R^n, \quad \|x(t)\| \leq h_x(\|x(t_0)\|; T)e^{-\gamma(t-t_0)}$$

where the class \mathcal{K} function $h_x: R_+ \rightarrow R_+$ is defined as

$$h_x(q; T) \triangleq [h(x_{mx}(q); T) + x_{mx}(q)]e^{\gamma\tau(q)}$$

and q denotes $\|x(t_0)\|$. \square

ACKNOWLEDGMENT

The authors would like to thank Dr. C. Canudas de Wit for valuable discussions on the stabilization of nonholonomic systems and Dr. C. Samson for comments on the stabilization about any configuration.

include nonlinear control of mechanical systems and nonholonomic systems.

Olav Egeland (S'85-M'86) was born in Leirvik, Norway, in 1959. He received the Siv. Ing. degree in 1984 and the Dr. Ing. degree in 1987 in Electrical Engineering at the Norwegian Institute of Technology, Trondheim, Norway.

Dr. Egeland became Assistant Professor in 1987 and Professor of Robotics in 1989 at the Department of Engineering Cybernetics, the Norwegian Institute of Technology. In the academic year 1988/89 he was a Visiting Scientist at the German Aerospace Research Establishment (DLR) in Oberpfaffenhofen, Germany.

His research interests include control of manipulators, surface vessels, flexible structures and nonholonomic vehicles.

Global Total Least Squares Modeling of Multivariable Time Series

Berend Roorda and Christiaan Heij, *Member, IEEE*

Abstract—In this paper we present a novel approach for the modeling of multivariable time series. The model class consists of linear systems, i.e., the solution sets of linear difference equations. Restricting the model order, the aim is to determine a model with minimal l_2 -distance from the observed time series. Necessary conditions for optimality are described in terms of state-space representations. These conditions motivate a relatively simple iterative algorithm for the nonlinear problem of identifying optimal models. Attractive aspects of the proposed method are that the model error is measured globally, it can be applied for multi-input, multi-output systems, and no prior distinction between inputs and outputs is required. We give an illustration by means of some numerical simulations.

I. INTRODUCTION

THE basic problem in time series modeling is to find a reasonably simple model which gives a sufficiently accurate description of the data. Procedures which have been developed for this problem differ in the specification of the model class and in the way the complexity and accuracy of models is evaluated.

In this paper we will restrict our attention to models described by linear difference equations with fixed coefficients and finite lags. Within this classical setting several modeling procedures have been developed. For an overview, we refer to the textbooks [1], [4], [6]. Well-known examples are the least squares identification of input-output systems in polynomial form and, more generally, the maximum likelihood identification of ARMAX systems, i.e., input-output models where the disturbances follow a moving average process. These and most other methods require that several structural aspects of the model should be specified *a priori*.

- 1) The number of equations, that is, the number of inputs and outputs of the system, and the decomposition of the system variables into inputs and outputs.
- 2) The orders of each of the equations, that is, the so-called structural indices of the system.
- 3) The stochastic properties of the disturbances, in particular the joint correlation structure between inputs, outputs, and disturbances.
- 4) The choice of a canonical parameterization, to avoid problems of nonidentifiable parameters.

The identification procedure that we propose in this paper differs in some crucial aspects from the methods just described. Our aim is to decompose a given multivariable time series, denoted by w , into two parts, i.e.,

$$w = \hat{w} + \tilde{w} \quad (1)$$

where \hat{w} represents a regular part and \tilde{w} the corresponding deviation. The aim is to keep the approximation error as small as possible, under the condition that the approximating time series \hat{w} is sufficiently regular. To make this more explicit we next describe our notions of regularity and model error.

A time series is called regular if it satisfies linear, time-invariant difference equations of finite lag. Let q denote the number of system variables, p the number of independent equations, and n the total lag, i.e., the sum of the lags of the individual equations. Time series are more regular when $m := q - p$ and n are smaller, i.e., the more equations they satisfy and the smaller the number of initial conditions. This can also be formulated as follows. Define the complexity of a linear, time-invariant, finite dimensional system by the pair (m, n) , where m is the number of system inputs and n the (minimal) number of state variables. A system is called less complex if it has fewer inputs, i.e., unexplained variables, and if it has less states, i.e., initial degrees of freedom. Then a time series is more regular if it can be generated by a less complex system.

The model error is evaluated as follows. For expository reasons we restrict ourselves in this paper to time series which are specified over the infinite time axis \mathbb{Z} and which are square summable, i.e., we assume that $w \in l_2^q$. The main results in this paper can be extended for modeling time series observed over a finite time interval, but we will not treat this issue here to simplify the presentation. The error in approximating an observed time series w by a regular part \hat{w} is measured by the l_2 -norm of the deviation $\tilde{w} = w - \hat{w}$, denoted by $\|\tilde{w}\| := \{\sum_{t=-\infty}^{\infty} \tilde{w}(t)^T \tilde{w}(t)\}^{1/2}$.

In our approach we will assume that the required regularity of the approximating time series \hat{w} has been specified *a priori*. Stated otherwise, we impose an upper bound on the complexity of the system that can generate the approximation. We denote by $\mathcal{B}^{q,m,n}$ the set of all time series that can be generated by systems with m inputs, $q - m$ outputs, and n states, i.e., all time series that satisfy $q - m$ independent linear, time-invariant difference equations with total lag n . Under this restriction we wish to minimize the approximation error as defined above, i.e.,

$$\min\{\|w - \hat{w}\|; \hat{w} \in \mathcal{B}^{q,m,n}\}. \quad (2)$$

Solving this problem for different values of (m, n) gives an impression of the involved trade-off between the required regularity and the resulting approximation error. The search for an acceptable model complexity is facilitated by the fact that the error decreases for increasing (m, n) , as $\mathcal{B}^{q \times m \times n} \subset \mathcal{B}^{(m_2 \times n_2) \times m_1 \times n_1}$ if $m_1 \leq m_2$ and $n_1 \leq n_2$. Note that this criterion follows for deviations in all the system variables and that the error is not measured locally (e.g., as a prediction error) but as the global l_2 -distance between the observation and the regular part. Therefore we give the name 'global total least squares' to the identification criterion (2).

As compared to classical procedures, our formulation of the time series modeling problem involves less *a priori* specifications. With respect to the four structural aspects discussed before, our approach has the following features:

- 1) The number of inputs and outputs is specified *a priori* but the system variables are all treated alike so that there is no need for a specification of inputs and outputs.
- 2) The structural indexes need not be specified but only the total lag and this can be varied easily.
- 3) The problem formulation involves no stochastic specifications although these may be incorporated by adjusting the norm on l_2 .
- 4) The criterion is nonparametric so that any representation may be chosen as it suits.

This paper has the following structure. To give some feeling for the global total least squares problem we first describe the well-known and relatively simple case of static total least squares in Section II. The basis for our modeling theory is the behavioral approach to systems and this is briefly discussed in Section III. For further treatment of the behavioral approach in systems theory we refer to [10] and [11]. In Sections IV and V we develop a highly structured type of system representations: isometric state representations which form the cornerstone of our modeling theory. Section VI concerns the question of how to determine an optimal approximation of an observed time series within a given model. This linear optimization problem is solved by a projection algorithm which was introduced in [12]. In Section VII we treat the problem of determining an optimal system. This is a nonlinear optimization problem over a nonconvex set. We propose three model improvement constructions based on the results in Section VI. These constructions are used in Section VIII to estimate locally optimal models. In Section IX we describe three simulation experiments that illustrate the use of the global total least squares method, and Section X contains some conclusions.

II. STATIC TOTAL LEAST SQUARES

We first consider the well-known case of total least squares in static models. Although it may be somewhat artificial in this case to consider observations in l_2 i.e., on an infinite time interval, it gives a better introduction for the dynamic case.

Static total least squares involves the approximation of a given time series by a regular one that satisfies linear nondynamic relations. For a required number of independent equations, the objective is to keep the approximation error

as small as possible, i.e. to minimize $\|u\|$ where u denotes the observed time series and w the approximation. If the required number of independent equations is p then the regularity of the approximation in l_2 is characterized by $Rw = 0$ for some matrix R of rank p . This means that the approximation w has rank at most $m - q - p$. In Section II (2), this class of regular time series is given by $\mathcal{B}^{(m-q-p) \times 1}$ with $n = 0$ corresponding to the exclusion of dynamic equations. This leads to the following formulation of static total least squares.

Definition 2.1 (Static Total Least Squares) For a given time series $u \in l_2^q$ and minimal required number of independent relations $p = q - m$ find a decomposition $u = w + u$ with $w \in \mathcal{B}^{q \times m \times 0}$ and with $\|u\|$ minimal.

The solution to this problem is given by the singular value decomposition (SVD). We denote the usual Euclidean norm on \mathbb{R}^q by $\|\cdot\|$ and the induced norm on l_2^q by $\|\cdot\|$.

Proposition 2.2 (Singular Value Decomposition in l_2) Every $u \in l_2^q$ can be decomposed as $u = \sum_{i=1}^q \lambda_i u_i v_i^T$ with

- 1) $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_q > 0$ called the singular values of u .
- 2) $u_i \in \mathbb{R}^{1 \times 1}$ with $\|u_i\| = 1$ and $u_i^T u_j = 0$ for $i \neq j$ called the left singular vectors of u .
- 3) $v_i \in l_2^m$ with $\|v_i\| = 1$ and $v_i \perp v_j$ for $i \neq j$ called the right singular vectors of u .

The singular values are uniquely determined and if they are distinct then the singular vectors are also uniquely determined up to a sign.

Proof. The existence and properties of the SVD for finite matrices are discussed in e.g. [3]. Let Π denote the empirical covariance matrix of u i.e. $\Pi = \sum_{t=1}^n u(t)u(t)^T$. As Π is symmetric the left singular vectors are equal to the right ones so let its SVD be given by $\Pi = \sum_{i=1}^q \mu_i u_i u_i^T$. Let $U = [u_1 \dots u_q]$ then the empirical covariance matrix of $U^T u$ is given by $\text{diag}(\mu_1 \dots \mu_q)$ so $U^T u$ consists of q orthogonal components of norm $\sqrt{\mu_i}$. It is easily verified that for $v_i = (1/\sqrt{\mu_i})u_i^T u$ and $\lambda_i = \sqrt{\mu_i}$ $u = \sum_{i=1}^q \lambda_i u_i v_i^T$ is an SVD of u . \square

The SVD solves the static total least squares problem as follows.

Proposition 2.3 (Optimal Static Approximation) Let $u = \sum_{i=1}^q \lambda_i u_i v_i^T$ be the SVD of $u \in l_2^q$. Then $w = \sum_{i=1}^m \lambda_i u_i v_i^T$ is the optimal approximation of u in $\mathcal{B}^{q \times m \times 0}$ satisfying the static equations $u^T w = 0$ for $i = m+1, \dots, q$.

Proof. This result follows immediately from a corresponding property of the SVD for finite matrices cf. [3]. \square

Example. One of the essential features of total least squares is that all variables are treated in a similar way. For simplicity we consider simulated data from a model with this type of symmetry, namely an errors in variables model. This also gives us the opportunity to relate total least squares to other well-known identification methods and to discuss the role of stochastic assumptions. We consider the model

$$u(t) = \alpha(t) + \eta(t) \quad y(t) = \alpha(t) + \epsilon(t) \quad (3)$$

The observed variables consist of $u = (u \ y)$ and α is an unobserved latent variable and ϵ and η are unobserved disturbances. Three of the possible methods for the estimation of the parameter α are regression of y on u , regression of u

on y , and total least squares. These methods can be interpreted as maximum likelihood methods, in the case that ε and η are independent white noise processes with variances σ_ε^2 and σ_η^2 and if in addition respectively $\sigma_\eta^2 = 0$, $\sigma_\varepsilon^2 = 0$, or $\sigma_\varepsilon^2 = \sigma_\eta^2$.

As an example, we consider data generated by the model (3) with $\alpha = 1$ and $\sigma_\varepsilon^2 = \sigma_\eta^2 = 0.5$ and where z is a sample of 20 observations of a white noise process with variance one and independent of η and ε . The SVD of the resulting observation is

$$w = 5.64 \begin{pmatrix} 0.72 \\ 0.69 \end{pmatrix} v_1 + 2.31 \begin{pmatrix} -0.69 \\ 0.72 \end{pmatrix} v_2 \quad (4)$$

where v_1 and v_2 are two orthogonal vectors of unit length. According to Proposition 2.3, the optimal static approximation \hat{w} of w of rank 1 is given by the first term in (4), and this satisfies $[-0.69, 0.72]\hat{w} = 0$. This corresponds to an estimated value $0.69/0.72 = 0.96$, which is close to $\alpha = 1$. The corresponding approximation error is $\|w - \hat{w}\| = 2.31$. Regression of y on u yields an estimate of 0.69, and regression of u on y gives 1.36. These results are depicted in Fig. 1.

This example illustrates the fact that the static total least squares (TLS) scheme is in between both regressions. The method is easily adapted for the case $\sigma_\varepsilon^2 \neq \sigma_\eta^2$, by using a weighted l_2 -norm for $\tilde{w} = (\tilde{u}, \tilde{y})$, defined by $\|\tilde{w}\|_\alpha^2 := \alpha^2 \|\tilde{u}\|^2 + \|\tilde{y}\|^2$ with $\alpha = \sigma_\varepsilon/\sigma_\eta$. The regressions correspond to the extremal cases with infinite weight on one of the components. To choose an appropriate weighted l_2 -norm we need information on the relative errors involved in the measured system variables, c.q., the relative weight one attaches to deviations in the different variables. In this paper we will not further address these problems. \diamond

III. GLOBAL TOTAL LEAST SQUARES

In the rest of this paper we are concerned with total least squares in dynamical systems. For this purpose we describe in this section our systems concept and corresponding notions of complexity and misfit.

As stated in the introduction, we consider systems described by difference equations. From the formulation of the global total least squares problem (2), it is obvious that sets of equations with the same solution set are equivalent as they yield the same approximation error for every observation. Hence not the equations themselves, but their solution set is the essential object in our modeling procedure. This is a strong motivation for adopting the behavioral approach to systems, as introduced in [10] and [11], in which a system is defined by the set of time series that are compatible with the system laws. This set is called the behavior of a system. The system laws themselves are considered as a description or representation of the behavior. The properties we impose on difference equations are reflected by the set-theoretic properties of the corresponding behavior. Linear, time-invariant difference equations correspond to linear, shift-invariant behaviors. If in addition the equations have finite lag, it can be decided if a time series belongs to the behavior by scanning it through a finite window. This property is called completeness, which is further explained in Appendix A, (see Definition A.1). We will further restrict the attention

Fig. 1. Scatter diagram of the data w : the solid line denotes the TLS model and the dashed lines the two regression models; the dotted lines indicate which distance is minimized in the three different models.

to behaviors in l_2 . The resulting class of systems is defined as follows.

Definition 3.1 (l_2 -Systems): l_2 -systems are linear, shift-invariant, complete subspaces of l_2^q .

As a measure of the restrictiveness of a set of difference equations we take into account the number of independent equations and their total lag, as described in the introduction. We call the equations independent if the number of equations cannot be reduced without changing the solution set, i.e., if there exists no equivalent smaller set of equations describing the same system. On the set theoretic level of l_2 -systems, we define the complexity of a system in terms of its rank and its degree. The rank of a system is defined as the number of the degrees of freedom at each time instant, which is equal to the number of inputs, and the degree of a system corresponds to the dimension of the state space (see Definition A.3).

Definition 3.2 (Complexity): The complexity of an l_2 -system \mathcal{B} is defined as $c(\mathcal{B}) := (m, n)$, where m denotes the rank of \mathcal{B} and n its degree.

Let $\mathcal{B}^{q,m,n}$ denote the class of l_2 -systems with rank at most m and degree at most n . Then $\mathcal{B}^{q,m,n}$ consists of the solution sets of at least $q-m$ independent linear time-invariant difference equations with the sum of their lags at most n , i.e., $w \in \mathcal{B}^{q,m,n}$ if and only if there exists a system $\mathcal{B} \in \mathcal{B}^{q,m,n}$ with $w \in \mathcal{B}$.

We summarize this in Table I. For further clarification we also relate these concepts to the classical characterization of systems in terms of input-output mappings.

We define the following concept of the misfit of a system.

Definition 3.3 (Misfit): The misfit of an l_2 -system \mathcal{B} with respect to an l_2 -time series w is defined as $d(w, \mathcal{B}) := \inf_{\tilde{w} \in \mathcal{B}} \|w - \tilde{w}\|$.

This leads to the following reformulation of the global total least squares problem (GTLS) as described in the introduction (see (2)).

TABLE I
COMPARISON OF SYSTEM CONCEPTS

Difference Equations	l_2 -behaviours	I/O-mapping
linear	linear subspace	linear
time-invariant	shift-invariant	time-invariant
finite order	l_2 -complete	rational transfer function
$q-m$ indep. equations	rank m	m inputs, $q-m$ outputs
minimal sum of lags is n	degree n	McMillan degree n

Definition 3.4 (GTLS): For an observation $w \in l_2^q$ and given tolerated complexity (m, n) , determine an l_2^q -system $B^* \in \mathcal{B}^{q,m,n}$ such that $d(w, B^*) = \min_{B \in \mathcal{B}^{q,m,n}} d(w, B)$.

This involves a double minimization. The inner minimization, evaluating the misfit $d(w, B)$, amounts to optimization over a linear space. Secondly, we have to determine a system for which the misfit is minimal. This is a nonlinear optimization problem over a nonconvex set.

Leading Example: We describe a simple example, which will be used in the following sections to clarify the introduced general framework. We consider a time series in $B^{2,1,1}$, that is corrupted by white noise. The regular part w_r consists of two components, u_r and y_r , where u_r is the realization of a white noise process with unit variance, and y_r satisfies

$$y_r(t) = 2/3 y_r(t-1) + 2u_r(t) - 2u_r(t-1). \quad (5)$$

The observation w consists of two components u and y , with

$$u(t) = u_r(t) + \eta(t); \quad y(t) = y_r(t) + \varepsilon(t) \quad (6)$$

where η and ε are independent white noise processes with variance 0.25, both independent of u_r . The data consists of a time series of length 100 which is generated by system (6). To obtain a time series in l_2 , the observation (u, y) is taken to be zero outside the observation interval.

Of course, this simple example could be solved by brute force as a nonlinear parameter optimization problem, disregarding any system theoretic interpretation of the problem. In more complicated cases, however, this becomes hardly feasible. Therefore we will follow a system theoretic approach, that also gives more insight in the problem.

The GTLS results in the following sections will be compared with those obtained by three other methods, namely regression, the "output error" method, and the "local total least squares" method. Here we mention that the procedures for GTLS and local total least squares have been implemented in Matlab and that for the regression and output error method we used, respectively, the procedures ARX and OE of the System Identification Toolbox. The regression model B_{regr} is obtained by regressing $y(t)$ on $y(t-1)$, $u(t)$ and $u(t-1)$. For the observation w this gives

$$B_{\text{regr}} = \{(u, y) \in l_2^2; y(t) = 0.10y(t-1) + 1.42u(t) - 0.78u(t-1)\}. \quad (7)$$

This equation yields optimal one-step ahead predictions for $y(t)$, given $y(t-1)$, $u(t)$, and $u(t-1)$. According to our terminology, we would call this method "local ordinary least squares." By ordinary we mean that only one of the components of w is approximated and by local that only

the first step ahead predictions of difference equations are taken into account. In the GTLS scheme we approximate both components and take full account of the global, higher order forward and backward implications of difference equations.

The output error model B_{oe} is the system with the property that for the given input u , the corresponding system output y is as close as possible to the observed output y . In fact, this method has some similarity to GTLS, the difference being that the input is kept fixed and only the output is approximated. In our terminology it is a "global ordinary least squares" method. The estimated output error model is

$$B_{\text{oe}} = \{(u, y) \in l_2^2; y(t) = 0.68y(t-1) + 1.15u(t) - 1.51u(t-1)\}. \quad (8)$$

Finally we use a simple modification of the static total least squares method of Section II to determine a first-order model, as follows. Define the block Hankel matrix $H \in l_2^4$ by $H(t) = \begin{bmatrix} w(t-1) \\ w(t) \end{bmatrix}$, then static equations for H correspond to first-order equations for the observation w . The optimal static equation for H is obtained by applying Proposition 2.2 with $q = 4$ and $m = 3$. Clearly, the quality of the corresponding first-order model for w is evaluated only locally. By this we mean that, for example, the second-order restrictions on $(w(t-2), w(t-1), w(t))^T$ implied by the model are not taken into account, and the same holds true for higher order restrictions. Therefore we call this the "local total least squares" model. For the data of this example this gives

$$B_{\text{lls}} = \{(u, y) \in l_2^2; y(t) = 0.54y(t-1) + 1.87u(t) - 1.82u(t-1)\}. \quad (9)$$

This example will be continued in the next sections. \diamond

IV. STATE REPRESENTATIONS

One of the crucial questions in our modeling theory is how to calculate the misfit of a system with respect to a given observation, cf. Definition 3.3. Obviously this requires a numerical representation of the system. In Section V we develop a representation that is extremely useful for this purpose, namely the isometric state representations. They also play a central role in the construction of optimal models, as discussed in Section VII. We now first introduce general state representations, which will be abbreviated as SR. Let σ denote the shift operator, defined as $\sigma x(t) = x(t+1)$.

Definition 4.1 (State Representation). A state representation (A, B, C, D) of an l_2 -system B is a description of the form

$$B = \{w \in l_2^q; \exists x \in l_2^n, v \in l_2^m \text{ such that } \sigma x = Ax + Bv \text{ and } w = Cx + Dv\}$$

with $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{q \times n}$, $D \in \mathbb{R}^{q \times m}$ and $n, m \in \mathbb{N}$.

Here v is an auxiliary input, x is a state trajectory and w a system trajectory, m denotes the number of auxiliary inputs and n the number of state variables. The system defined by

this representation is denoted as $\mathcal{B}(A, B, C, D)$. We mention that the condition that x and v are square summable involves no loss of generality, as it can be shown that for every $(x, v): \mathbf{Z} \rightarrow \mathbf{R}^n \times \mathbf{R}^m$ generating $w \in l_2^q$ there also exists $(x', v') \in l_2^n \times l_2^m$ generating the same time series w . Systems in $\mathbf{B}^{q,m,n}$, i.e., with rank at most m and degree at most n , are precisely those systems that admit an SR with m auxiliary inputs and n states, cf. Proposition A.4.

Representations are called equivalent if they describe the same system. They are called minimal if the number of state variables and the number of auxiliary inputs are both minimal. These two quantities can be minimized simultaneously, so for every system there indeed exists a minimal SR. From a given SR we obtain equivalent ones as follows.

Proposition 4.2 (Equivalent State Representations): Let be given a state representation (A, B, C, D) of an l_2 -system \mathcal{B} . Then for all invertible $S \in \mathbf{R}^{n \times n}$, invertible $R \in \mathbf{R}^{m \times m}$, and $F \in \mathbf{R}^{m \times n}$, $(S(A + BF)S^{-1}, SBR, (C + DF)S^{-1}, DR)$ is also a state representation of \mathcal{B} . Moreover, if (A, B, C, D) is minimal, then all minimal state representations for \mathcal{B} are obtained in this way.

Proof: By definition, $w \in l_2^q$ is contained in $\mathcal{B}(A, B, C, D)$ if and only if there exist an v and x such that $\sigma x = Ax + Bv$ and $w = Cx + Dv$. These equations are equivalent to $\sigma(Sx) = S(A + BF)S^{-1}(Sx) + SBR(R^{-1}(v - Fx))$ and $w = (C + DF)S^{-1}(Sx) + DR(R^{-1}(v - Fx))$, provided that S and R are invertible. This shows the equivalence of the representations. For a proof of the fact that for minimal representations all equivalent representations are obtained in this way we refer to [5, Corollary IV.3-4]. \square

Observe that minimal SR's for a given l_2 -system are highly nonunique. The choice of basis in the state space, corresponding to S , is a well-known nonuniqueness of state-space representations. In our framework the auxiliary input v is merely a tool to describe the system behavior and need not have additional external significance. This allows for a basis transformation for the auxiliary input, corresponding to R . Further the behavior is invariant under a static state feedback F to this auxiliary input. This is in contrast to the common notion of feedback to the actual input of the system, which would affect the set of compatible input-output pairs. As a consequence, in our framework the spectrum of the A -matrix is not an intrinsic property of a system. In the next section we exploit this nonuniqueness to obtain SR's with convenient properties for computing the misfit of a model with respect to data.

Minimality of a representation can be expressed in terms of rank conditions on the matrices (A, B, C, D) , as follows.

Proposition 4.3 (Minimal State Representations for l_2 -Systems): A state representation (A, B, C, D) is minimal if and only if:

- 1) (A, B) is controllable
- 2) $\forall F \in \mathbf{R}^{m \times n}$, $(A + BF, C + DF)$ is observable
- 3) $\ker D = 0$.

Proof: See Appendix B.

By eliminating the state, SR's induce an image representation of l_2 -systems. For the exposition in the sequel,

representations with A asymptotically stable are most relevant. Every l_2 -system allows for such a representation, which follows from Propositions 4.2 and 4.3.1.

Proposition 4.4 (Image Representations): Let \mathcal{B} be an l_2^q -system in $\mathbf{B}^{q,m,n}$, with state representation (A, B, C, D) , where A is asymptotically stable. Let $G: l_2^m \rightarrow l_2^q$ be defined as $G = C(\sigma I - A)^{-1}B + D$, i.e., $(Gv)(t) = Dv(t) + \sum_{k=1}^{\infty} CA^{k-1}Bv(t-k)$. Then $\mathcal{B} = \text{im } G$.

Proof: G is well defined, as A is asymptotically stable. It is easily verified that the equations $\sigma x = Ax + Bv$ and $w = Cx + Dv$ imply that $Gv = w$. \square

Leading Example (Continued): Consider the l_2 -system corresponding to (5), $\mathcal{B}_{\text{ex}} := \{w \in l_2^2; w = (u, y), \text{ with } y(t) = 2/3y(t-1) + 2u(t) - 2u(t-1)\}$. This can be written in input/state/output form as follows

$$x(t+1) = 2/3x(t) + u(t); y(t) = -2/3x(t) + 2u(t). \quad (10)$$

From this it is easy to obtain an SR by taking the auxiliary input v to be equal to u , which gives

$$\mathcal{B}_{\text{ex}} = \mathcal{B}\left(2/3, 1, \begin{bmatrix} 0 \\ -2/3 \end{bmatrix}\right) \quad (11)$$

This representation is minimal. The corresponding image representation $G = \sum_{k=0}^{\infty} G_k \sigma^{-k}$ has coefficients $G_0 = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$, and $G_k = \begin{bmatrix} 0 \\ -(2/3)^k \end{bmatrix}$. An SR equivalent to (11) is given by $\left(1, 1/2, \begin{bmatrix} 1/3 \\ 0 \end{bmatrix}, \begin{bmatrix} 1/2 \\ 1 \end{bmatrix}\right)$, which follows from Proposition 4.2 by taking $S = 1$, $R = 1/2$, and $F = 1/3$. Note that in this representation the auxiliary input is given by y . This also illustrates that the eigenvalues of A are not intrinsic for the system \mathcal{B} . \diamond

V. ISOMETRIC STATE REPRESENTATIONS

In this section we define isometric state representations (ISR's), which are defined by a local isometry property involving the state variable.

Definition 5.1 (Isometric State Representation): A state representation (A, B, C, D) is called isometric if for all $x \in \mathbf{R}^n$, $v \in \mathbf{R}^m$, $w \in \mathbf{R}^q$ and $z \in \mathbf{R}^n$ such that $z = Ax + Bv$ and $w = Cx + Dv$ there holds

$$|v|^2 + |x|^2 = |w|^2 + |z|^2. \quad (12)$$

Equivalently

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix}^T \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} I_n & 0 \\ 0 & I_m \end{pmatrix} \quad (13)$$

Minimal ISR's can be constructed from arbitrary minimal SR's as follows.

Proposition 5.2 (Construction of ISR): Let (A, B, C, D) be a minimal state representation, and let $K \in \mathbf{R}^{n \times n}$ be the unique symmetric positive definite solution of the algebraic Riccati equation

$$K = A^T K A - (B^T K A + D^T C)^T (B^T K B + D^T D)^{-1} \cdot (B^T K A + D^T C) + C^T C. \quad (14)$$

Let the matrices $S \in \mathbf{R}^{n \times n}$, $F \in \mathbf{R}^{m \times n}$ and $R \in \mathbf{R}^{m \times m}$ be solutions of the equations

$$S^T S = K \quad (15)$$

$$RR^T = (B^T K B + D^T D)^{-1} \quad (16)$$

$$F = -(B^T K B + D^T D)^{-1}(B^T K A + D^T C). \quad (17)$$

Then $(S(A + BF)S^{-1}, SBR, (C + DF)S^{-1}, DR)$ is an equivalent isometric minimal state representation.

Proof: See Appendix B.

The following proposition gives a necessary minimality condition for ISR's and states that they are unique modulo unitary transformations.

Proposition 5.3 (Minimal ISR).

- 1) If (A, B, C, D) is an ISR, then A is stable. If the representation is minimal then A is asymptotically stable.
- 2) Two minimal ISR's (A, B, C, D) and (A', B', C', D') are equivalent if and only if there exist unitary matrices U and V such that $(A', B', C', D') = (UAU^T, UBV, C'U^T, DV)$.

Proof: See Appendix B.

ISR's induce a description of l_2 -systems as the image of an isometric operator. This is made explicit in the following proposition.

Proposition 5.4 (Isometric Image Representations): Let (A, B, C, D) be a minimal isometric state representation of an l_2 -system \mathcal{B} . Then the corresponding image operator $G: l_2^m \rightarrow l_2^q$ defined by $G = C(\sigma I - A)^{-1}B + D$ is isometric, i.e., $\|Gv\| = \|v\|$ for all $v \in l_2^m$.

Proof: If $w = Gv$ then $w(t) = Cx(t) + Dv(t)$ for $x = (\sigma I - A)^{-1}Bv$, so that $\sigma x = Ax + Bv$. Summation of (12) over $t \in \mathbf{Z}$ yields $\|v\|^2 + \|w\|^2 + \|\sigma x\|^2$. Clearly $\|\sigma x\| = \|\sigma x\|$, from which the result follows. \square

Summarizing, every l_2 -system can be represented as the image of an isometric $q \times m$ transfer function with an ISR as its realization. In the literature an isometric operator G is sometimes called lossless, and if it is in addition stable it is called inner. So an ISR is a realization of an inner transfer function that displays the isometry in a local way, in terms of the state variables.

Leading Example (Continued): We apply the construction of Proposition 5.2 to the SR (11) of l_2 -system \mathcal{B}_{ex} . This yields $K = 4/9$, $S = 2/3$, $R = 3/7$, and $F = 4/21$, resulting in the isometric representation

$$\sigma x = 6/7x + 2/7v; w = \begin{bmatrix} 2/7 \\ -3/7 \end{bmatrix} x + \begin{bmatrix} 3/7 \\ 6/7 \end{bmatrix} v. \quad (18)$$

According to Proposition 5.3, \mathcal{B}_{ex} has a unique minimal ISR, modulo sign changes for the state and for the auxiliary input. \diamond

VI. OPTIMAL APPROXIMATION WITHIN A SYSTEM

In this and the next section we consider the GTLS problem of Definition 3.4. As stated before, this involves a double minimization. In this section we discuss the computation of

Fig. 2. Projection scheme.

the misfit, and in the next section we treat the problem of selecting an optimal model.

For the computation of the misfit we will use the adjoint G^* of an operator $G: l_2^m \rightarrow l_2^q$. This is defined by the condition $\langle w, Gv \rangle = \langle G^*w, v \rangle$ for all $v \in l_2^m$ and $w \in l_2^q$, where $\langle \cdot, \cdot \rangle$ denotes the inner product on l_2 . It follows that G is isometric if and only if $G^*G = I$. For the image operator $G := C(\sigma I - A)^{-1}B + D$ the adjoint is given by $G^* = B^T(\sigma^{-1}I - A^T)^{-1}C^T + D^T$. This can also be written as $G^* = \mathcal{R}_m G^T \mathcal{R}_q$ where $\mathcal{R}_k: l_2^k \rightarrow l_2^k$ denotes the time reversion operator defined by $\mathcal{R}_k w(t) := w(-t)$ and $G^T := B^T(\sigma I - A^T)^{-1}C^T + D^T$.

Theorem 6.1 (Optimal Approximation Within a System): Let be given an observation $w \in l_2^q$ and an l_2^q -system $\mathcal{B} \in \mathbf{B}^{q,m,n}$. Let $G: l_2^m \rightarrow l_2^q$ be an isometric image representation of \mathcal{B} . Then the optimal approximation $\hat{w} \in \mathcal{B}$ is given by $\hat{w} = GG^*w$, with misfit $d(w, \mathcal{B}) = \|(I_q - GG^*)w\|$.

Proof: This is a well-known result. To be explicit, we should minimize $\|w - Gv\|$ over $v \in l_2^m$. Let $v' = v - G^*w$, then $\|w - Gv\|^2 = \|w - GG^*w - Gv'\|^2 = \|GG^*w\|^2 + \|Gv'\|^2$, as $\langle w - GG^*w, Gv' \rangle = \langle G^*w - G^*w, v' \rangle = 0$ where we use that G is isometric so that $G^*G = I_m$. So the minimum is achieved by taking $v' = 0$, and $w = GG^*w$. \square

The optimal approximation within a system \mathcal{B} gives rise to a decomposition $w = \hat{w} + \tilde{w}$, with $\hat{w} \in \mathcal{B}$ regular and with \tilde{w} the corresponding approximation error. We will now show that \tilde{w} also exhibits regularity. As \hat{w} is obtained as the projection of w on \mathcal{B} , it follows that $\tilde{w} \in \mathcal{B}^\perp = \{w \in l_2; \langle w, w' \rangle = 0 \text{ for all } w' \in \mathcal{B}\}$. This set is clearly linear and shift-invariant. The following theorem states that it is an l_2 -system.

Theorem 6.2 (Orthogonal Complement). Let \mathcal{B} be an l_2 -system with rank m and degree n .

- 1) The orthogonal complement \mathcal{B}^\perp of \mathcal{B} is an l_2 -system.
- 2) $\mathcal{B} \oplus \mathcal{B}^\perp = l_2^q$.
- 3) \mathcal{B}^\perp has rank $q - m$ and degree n .
- 4) Let (A, B, C, D) be a minimal isometric state representation of \mathcal{B} , and let \tilde{B}, \tilde{D} be such that $\begin{pmatrix} A & B & \tilde{B} \\ C & D & \tilde{D} \end{pmatrix}$ is a unitary matrix. Then $(A, \tilde{B}, C, \tilde{D})$ is a minimal isometric state representation of \mathcal{B}^\perp .
- 5) Let \hat{w} be the optimal approximation in \mathcal{B} of $w \in l_2^q$. Then the approximation error $\tilde{w} := w - \hat{w}$ is the optimal approximation in \mathcal{B}^\perp of w .

Proof: See Appendix B.

We summarize this result in the following projection scheme as shown in Fig. 2. Here G and \tilde{G} denote the image representations corresponding to, respectively, (A, B, C, D) and $(A, \tilde{B}, C, \tilde{D})$, and $\bar{G} := [G \ \tilde{G}]$. In the literature \bar{G} is sometimes called a lossless embedding of G . Further \hat{v} and \tilde{v} are

TABLE II
MISFIT OF MODELS

model	\mathcal{B}_{ex}	\mathcal{B}_{oe}	\mathcal{B}_{regt}	\mathcal{B}_{ltls}	\mathcal{B}_{rand}
misfit	5.22	5.62	6.84	5.30	13.53

the auxiliary inputs corresponding to \hat{w} and \tilde{w} , i.e., $\hat{w} = G\hat{v}$ and $\tilde{w} = \tilde{G}\tilde{v}$. According to Theorem 6.1 and 6.2.5, there holds that $\hat{v} = G^*w$ and $\tilde{v} = \tilde{G}^*w$ as shown in Fig. 2.

Leading Example (Continued): We apply the projection algorithm of Theorem 6.1 to determine the optimal approximation $\hat{w} \in \mathcal{B}_{ex}$ of the observation w described in Section III. Let G denote the image operator corresponding to the ISR (18), and let (A, B, C, D) denote the corresponding matrices. First compute $\hat{v} := G^*w$, which is given by the backward state equations $x(t) = A^T x(t+1) + C^T w(t)$; $\hat{v}(t) = B^T x(t+1) + D^T w(t)$. Then $\hat{w} = G\hat{v}$ is given by $\hat{x}(t+1) = A\hat{x}(t) + B\hat{v}(t)$; $\hat{w}(t) = C\hat{x}(t) + D\hat{v}(t)$.

According to Theorem 6.2, \mathcal{B}_{ex}^\perp has ISR $(6/7, 3/7, \begin{bmatrix} 2/7 \\ -3/7 \end{bmatrix}, \begin{bmatrix} -6/7 \\ 2/7 \end{bmatrix})$. This corresponds to the equation

$$y(t) = y(t-1) - 1/3u(t) + 1/2u(t-1). \quad (19)$$

So every time series in l_2^2 that is orthogonal to \mathcal{B}_{ex} satisfies this difference equation, in particular the approximation error $\tilde{w} := w - \hat{w}$. The misfit of \mathcal{B}_{ex} equals $\|\tilde{w}\| = 5.22$, as compared to $\|w\| = 22.72$. This is considerably smaller than the l_2 -norm of the white noise by which the observation was corrupted. Recall that $w = w_r + w_n$, with $w_r \in \mathcal{B}_{ex}$ and w_n white noise. In our example, $\|w_n\| = 7.62$. The optimal approximation is simply obtained by projecting the noise w_n on \mathcal{B}_{ex} , with a resulting decomposition $w_n = \hat{w}_n + \tilde{w}_n$, where $\hat{w}_n \in \mathcal{B}_{ex}$ and $\tilde{w}_n \in \mathcal{B}_{ex}^\perp$. In our case, $\|\hat{w}_n\| = 5.56$ and $\|\tilde{w}_n\| = \|\tilde{w}\| = 5.22$. We also determine projections onto the models \mathcal{B}_{regt} , \mathcal{B}_{oe} , and \mathcal{B}_{ltls} , as defined in Section III, and onto a randomly chosen system $\mathcal{B}_{rand} \in \mathcal{B}^{2,1,1}$. The parameters of an SR of \mathcal{B}_{rand} were obtained by a random sample from the standard normal distribution. The resulting misfits are listed in Table II. It turns out that the local total least squares model is of relatively good quality in this example. This, however, may be completely different in other situations, as we will illustrate by an example in Section IX-B. \diamond

VII. MODEL IMPROVEMENT CONSTRUCTIONS

In this section we discuss the second part of the GTLS problem, namely determining an l_2 -system with minimal misfit with respect to a given observation. Formulated in terms of state representations, this amounts to the following.

Definition 7.1 (GTLS in terms of SR): For given observation $w \in l_2^q$ and tolerated complexity (m, n) , determine a state representation (A, B, C, D) with m auxiliary inputs and n states and an auxiliary input $\hat{v} \in l_2^m$ such that for $\hat{w}(t) := (C(\sigma I - A)^{-1}B + D)\hat{v}$, the error $\|w - \hat{w}\|$ is minimal.

We follow an iterative approach for this nonlinear problem. In each step we keep some parameters fixed, such that the resulting subproblem becomes sufficiently simple. For instance, for fixed (A, B, C, D) the resulting problem in \hat{v} is solved

by the projection scheme discussed in the foregoing section. We consider the following subproblems.

Problem 1—Optimal C and D : For given A, B and \hat{v} , solve the GTLS problem for C and D .

Problem 2—Optimal B and D : For given A, C and \hat{v} , solve the GTLS problem for B and D .

Problem 3—Optimal B, D and \hat{v} in an ISR: For given A and C with $A^T A + C^T C = I_n$, solve the GTLS problem for B, D , and \hat{v} , under the restriction that (A, B, C, D) is isometric.

In the next theorem we give constructive solutions of these problems.

Theorem 7.2 (Model Improvement Constructions):

- 1) Construction 1 (Projection of the Approximation Error): Let \hat{x} be defined by $\sigma\hat{x} = A\hat{x} + B\hat{v}$, and let $\mathcal{E} := \{\hat{w} \in l_2^q; \exists C \in \mathbb{R}^{q \times n}, D \in \mathbb{R}^{q \times m} \text{ such that } \hat{w} = C\hat{x} + D\hat{v}\}$. Let $P\hat{x} + Q\hat{v}$ denote the orthogonal projection of w onto \mathcal{E} , then $\mathcal{B}_1 := \mathcal{B}(A, B, P, Q)$ solves problem 1.
- 2) Construction 2 (Dual version of construction 1): Let $\mathcal{F} := \{\hat{w} \in l_2^q; \exists B \in \mathbb{R}^{n \times m}, D \in \mathbb{R}^{q \times m} \text{ such that } \hat{w} = (C(\sigma I - A)^{-1}B + D)\hat{v}\}$. Let the orthogonal projection of w onto \mathcal{F} be given by $(C(\sigma I - A)^{-1}P + Q)\hat{v}$, then $\mathcal{B}_2 := \mathcal{B}(A, P, C, Q)$ solves problem 2.
- 3) Construction 3 (SVD on auxiliary inputs): Let $\bar{B} \in \mathbb{R}^{n \times q}, \bar{D} \in \mathbb{R}^{q \times q}$ be such that $\begin{pmatrix} A & \bar{B} \\ C & \bar{D} \end{pmatrix}$ is a unitary matrix. Let $\bar{v} := (\bar{B}^T(\sigma^{-1}I - A^T)^{-1}C^T + \bar{D}^T)w$ have SVD $\bar{v} = \sum_{i=1}^q \lambda_i u_i z_i$, and let $U_m := [u_1, \dots, u_m]$. Then $\mathcal{B}_3 := \mathcal{B}(A, \bar{B}U_m, C, \bar{D}U_m)$ solves problem 3.

Proof: Parts 1 and 2 follow immediately from the definitions of \mathcal{E} and \mathcal{F} . For part 3, observe that (A, B, C, D) is an ISR if and only if there exist \bar{B}, \bar{D} , and a unitary V such that $[B \ \bar{B}] = \bar{B}V$ and $[D \ \bar{D}] = \bar{D}V$. For this representation the projection scheme gives $\begin{pmatrix} v \\ \bar{v} \end{pmatrix} = V^T \bar{v}$, with misfit $\|\bar{v}\|$. By taking $V = [u_1, \dots, u_q]$, this misfit is determined by the $q-m$ smallest singular values of \bar{v} , which is minimal. \square

We use these results in an iterative algorithm for the GTLS problem. At each step we use one of the three constructions to improve the model. The resulting model parameters are transformed to ISR, which also involves an update of the A -matrix. The projection scheme is then applied to update v .

Proposition 7.3: The above method leads to a sequence of models with monotonically decreasing misfit.

Proof: This is immediately evident from Theorem 7.2. \square

So the algorithm leads to a convergent sequence of misfits. In the next section we show that, in the limit, the corresponding models are stationary points with respect to the GTLS criterion.

Leading Example (Continued): To illustrate the foregoing, we consider the data $w = (u, y)$ described in Section III (see (5) and (6)). To investigate the effect of the choice of an initial model, we apply the model improvement constructions to the models \mathcal{B}_{ex} , \mathcal{B}_{oe} , \mathcal{B}_{regt} , \mathcal{B}_{ltls} , and \mathcal{B}_{rand} as described in Sections III and VI. The results are in Table III. The first row shows the initial misfits, cf. Table II. The next three rows contain the misfits of the models obtained by applying each of the constructions separately and only once. This shows that

TABLE III
MODEL IMPROVEMENTS

model	B_{ex}	B_{oe}	B_{regr}	B_{ltls}	B_{rand}
misfit	5.22	5.62	6.84	5.30	13.53
construction 1	5.14	5.12	6.10	5.23	6.21
construction 2	5.14	5.13	6.13	5.30	6.26
construction 3	5.21	5.15	6.78	5.30	6.59
limit	5.11	5.11	5.11	5.11	5.11

TABLE IV
ORDER SELECTION

order	$n = 0$	$n = 1$	$n = 2$	$n = 3$	$n = 4$
misfit	6.71	5.11	5.02	4.91	4.91

each individual construction can give a significant decrease of the misfit. The last row shows the misfit resulting from applying these constructions iteratively until convergence.

For each initial model convergence occurred after about 20 iterations. The limiting model is the same in all four cases, which suggests that it is optimal. It is given by

$$B_{\text{GTLs}} = \{(u, y) \in l_2^2; y(t) = 0.67y(t-1) + 1.85u(t) - 1.96u(t-1)\}. \quad (20)$$

The parameters of this system are relatively close to those of the data generating system, cf. (5).

Next, we investigate whether the model order can be deduced from the data. For this purpose we compare in Table IV the optimal misfits for models of various degree. The misfit of the optimal static model is given by the smallest singular value of w . This clearly motivates the choice of a first-order model. It is significantly better than the static model, and an increase of the order gives only small improvements. \diamond

VIII. OPTIMALITY CONDITIONS

From the model improvement constructions in Section VII we can derive necessary conditions for optimality, as for an optimal model the constructions can give no improvement. We express the optimality conditions in terms of empirical covariances. For two sequences $a \in l_2^k$ and $b \in l_2^l$ this is defined as $\text{cov}(a, b) := \sum_{t=-\infty}^{\infty} a(t)b(t)^T \in \mathbb{R}^{k \times l}$. Further, by $\text{cov}([a_1, a_2], [b_1, b_2])$, we denote the covariance matrix of the combined trajectories $[a_1^T \ a_2^T]^T$ and $[b_1^T \ b_2^T]^T$.

Theorem 8.1 (l_2 -optimality Conditions): Let B denote a GTLS model for an observation $w \in l_2^q$. Let $\hat{w} \in B$ denote the optimal approximation of w , and $\tilde{w} \in B^\perp$ the corresponding approximation error. Let \hat{x}, \hat{v} denote, respectively, the state and auxiliary input corresponding to \hat{w} in a minimal state representation of B , and let \tilde{x}, \tilde{v} be defined analogously for \tilde{w} . Then the following equivalent conditions hold:

- 1) $\text{cov}(\hat{v}, \tilde{v}) = 0$, $\text{cov}(\hat{v}, \hat{x}) = 0$ and $\text{cov}(\hat{x}, \tilde{v}) = 0$;
- 2) $\text{cov}([\hat{v}, \hat{x}], [\tilde{v}, \tilde{x}]) = 0$;
- 3) $\text{cov}([\hat{v}, \hat{x}, \hat{w}, \sigma x], [\tilde{v}, \tilde{x}, \tilde{w}, \sigma \tilde{x}]) = 0$.

Proof: See Appendix B.

In practice, to evaluate how far these conditions are satisfied it may be useful to consider the empirical correlations, i.e., the covariances scaled by the magnitude of the variables.

Next we investigate how far these conditions are sufficient for optimality. It is not difficult to check that the number of free parameters in (A, B, C, D) , modulo the equivalence of Proposition 4.2, is given by $nq + m(q - m)$. This is precisely the number of equations in Theorem 8.1.1. In fact, these conditions characterize the stationary points with respect to the GTLS criterion. We call a system B a stationary point for an observation w if all the derivatives of the GTLS misfit $d(w, B(A, B, C, D))$ with respect to the system parameters are zero for a minimal SR of B . As all its minimal SR's are linearly related this is equivalent to the condition that all minimal SR's of B are stationary points.

Theorem 8.2: An l_2 -system B satisfies the optimality conditions of Theorem 8.1 if and only if B is a stationary point of the GTLS criterion.

Proof: See Appendix B.

This shows that the GTLS algorithm can only converge to stationary points. This does not, however, establish convergence of the systems. For what it is worth, we mention that we never encountered convergence problems in any of our simulations. A thorough discussion of the convergence properties of the algorithm falls beyond the scope of this paper.

The foregoing results can also be used to analyze whether a proposed system B is close to optimality. This is, for example, relevant in the formulation of stopping criteria for the iterative algorithm of Section VII. Probably the most convincing way to evaluate optimality is to consider the distance between B and a GTLS model B^* , as defined in Definition 3.4. This is in general not feasible, however, as it would require the knowledge of B^* . Instead of asking how far the system should be changed to become optimal for the observed data w , we will consider the question of how far these data should be changed to make the given system optimal. For pragmatic reasons we consider the distance to the nearest stationary point, defined as

$$\min\{\|\bar{w}\|; B \text{ is stationary for } w - \bar{w}\}. \quad (21)$$

Because it seems difficult to evaluate this distance exactly, we present an upper bound that is relatively easy to compute. This upper bound is obtained by allowing only adjustments of the data that belong to B^\perp , so that the optimal approximation of the data within B is not affected. This leads to the following definition of the optimality margin.

Definition 8.3 (Optimality Margin): The optimality margin of a system B with respect to an observation w is defined as

$$\min\{\|\bar{w}\|; \bar{w} \in B^\perp \text{ and } B \text{ is stationary for } w - \bar{w}\}. \quad (22)$$

The following result shows that the computation of the optimality margin is indeed relatively easy.

Proposition 8.4 (Optimality Margin): Let w denote the optimal approximation of w in B and let $\tilde{w} := w - \hat{w}$ denote the corresponding approximation error. Further define $\mathcal{Z} := \{z \in B^\perp; B \text{ is stationary for } \hat{w} + z\}$. Then \mathcal{Z} is a linear space, and the optimality margin is given by $\|\tilde{w} - \tilde{w}'\|$, where \tilde{w}' is the orthogonal projection of \tilde{w} on \mathcal{Z} .

TABLE V
OPTIMALITY MARGINS

model	B_{gtls}	B_{ex}	B_{oe}	B_{reg}	B_{lts}	B_{rand}
optimality margin	$4.58 \cdot 10^{-6}$	1.00	2.29	3.32	1.23	11.19

Proof: See Appendix B.

These results can also be used to determine a lower bound for the achievable misfit. This indicates the quality of a proposed model relative to the optimal one. For this purpose we will assume that a proposed model B is not only stationary for the adjusted data $w - \bar{w}$, but even globally optimal.

Proposition 8.5 (Bounds for the Minimal Misfit): Let B be given an observation w , and let e^* be the minimally achievable misfit under a certain complexity constraint. Further let B be a GTLS model of tolerated complexity for adjusted data $w - \bar{w}$ with misfit $e := d(w, B)$. Then there holds

$$e - 2\|\bar{w}\| \leq e^* \leq e. \quad (23)$$

Proof: Let B^* denote a GTLS model for the original data w , so that $d(w, B^*) = e^*$. Then the upper bound follows from the optimality of B^* . For the lower bound we use the properties of the misfit that $d(w, B) \leq \|w\|$ and $d(w_1 + w_2, B) \leq d(w_1, B) + d(w_2, B)$, so that $e = d(w, B) \leq d(\bar{w}, B) + d(w - \bar{w}, B) \leq \|\bar{w}\| + d(w - \bar{w}, B^*) \leq \|\bar{w}\| + d(w, B^*) + d(\bar{w}, B^*) \leq 2\|\bar{w}\| + e^*$. Here we have used the optimality of B for $w - \bar{w}$ in the second inequality. \square

This shows that for models with a small optimality margin the corresponding misfit is nearly optimal.

Leading Example (Continued): The covariances of Theorem 8.1 give a first indication of the optimality of a model. To make this scale invariant we consider the correlations in an ISR. For the nominal model B_{ex} they are around 0.3, for the regression model B_{reg} around 0.35, while for the randomly chosen model B_{rand} correlations of 0.8 occur. For the model B_{gtls} in (20) the correlations are approximately zero, below 10^{-5} .

From the optimality margins we obtain more precise information about the optimality of the systems. They are listed in Table V. This shows that it requires only a change of the observation of the order $\|\bar{w}\| \approx 10^{-5}$ to make B_{gtls} a stationary point, cf. (22). Now assume that B_{gtls} is globally optimal for $w - \bar{w}$, which is reasonable assumption. The evaluation of the bounds in Proposition 8.5 for the data in this example with $e = 5.1095$ and $2\|\bar{w}\| \approx 10^{-5}$ shows that the optimal misfit $e^* \approx 5.1095$ is determined within an accuracy of 10^{-5} . This also shows that B_{gtls} is optimal within this accuracy level.

IX. SIMULATION EXPERIMENTS

We illustrate the use of the GTLS algorithm by three simulation experiments. The first example concerns model reduction, i.e., the approximation of a system by one of lower complexity. We use weighted l_2 -norms to determine the l_2 -optimal approximation of a systems impulse response. In the second example we show that the algorithm can handle noncausal systems without any additional difficulty. As a final example we identify a system with multiple outputs, described

TABLE VI
PROPERTIES OF REDUCED MODELS

model	B_{gtls}	B_{bal}	B_{hank}
misfit with respect to w	0.32	0.36	0.38
error in impulse response	0.54	0.46	0.57
Hankel norm distance	0.93	0.80	0.74

TABLE VII
EFFECT OF SCALING

scaling factor	$\alpha = 1$	$\alpha = 10$	$\alpha = 100$
$\ \cdot\ _\alpha$ -misfit with respect to w	0.3204	0.4457	0.4476
error in impulse response	0.5407	0.4477	0.4476

by more than one equation, and we discuss the choice of the model complexity.

A. l_2 -Model Reduction

The algorithm of Section VII can be applied to arbitrary time series in l_2 . Here we analyze its performance for very special data, a system impulse response. The aim is to reduce the dimension of the state space in such a way that the error in the impulse response is as small as possible (cf. [9] and the references therein). We compare the results of our algorithm with those obtained by balanced reduction and optimal Hankel norm approximation that have been developed especially for model reduction (see [2] and [7]). We consider the single-input, single-output system B with poles in $\pm 0.9i$ and $-0.7 \pm 0.6i$, so $B = \{[u \ y]^T \in l_2^2; y(t) = 0.5u(t) - 1.4y(t-1) - 1.66y(t-2) - 1.13y(t-3) - 0.69y(t-4)\}$. This system has complexity (1, 4), and we consider reduction to complexity (1, 2). The observation $w \in B$ consists of two components u and y , where u is a unit pulse at time $t = 0$ and y is the corresponding response.

We apply the GTLS algorithm, starting in a randomly chosen model. When the decrease in the misfit has become sufficiently small, below 10^{-10} , the iterations are stopped. This occurs after a few hundred iterations. The final model B_{gtls} is compared in Table VI with the balanced reduction B_{bal} and the Hankel norm reduction B_{hank} .

The l_2 -error in the impulse response in B_{gtls} is somewhat larger than that in B_{bal} and B_{hank} . If one is interested in this response then one should prevent an approximation of the input, so that an optimal approximation of the output becomes the criterion. This is achieved by taking the norm $\|\tilde{w}\|_\alpha^2 := \alpha^2 \|\tilde{u}\|^2 + \|\tilde{y}\|^2$ with α sufficiently large. The effect of increasing α is given in Table VII. This shows that for large α the method determines better approximations of the impulse response.

This also gives bounds for the minimally achievable l_2 -error, which we denote by e^* . Let B_α be the GTLS model for $\|\cdot\|_\alpha$, and let y_α be the impulse response of B_α ; then it is easily checked that $d(w, B_\alpha) \leq e^* \leq \|y - y_\alpha\|$. By increasing α we can obtain an arbitrarily accurate estimate of e^* . This gives an iterative solution method for the l_2 -optimal impulse response approximation problem. For $\alpha = 100$ we obtain $e^* = 0.4476$; see Table VII. The corresponding model

Fig. 3 The impulse response (solid line) and its l_2 -optimal approximation of second order (dashed line)

is given by the equation $y(t) = -1.35y(t-1) - 0.78y(t-2) + 0.50u(t) + 0.11u(t-1) - 0.21u(t-2)$. The impulse response is depicted in Fig. 3.

B Noncausal Systems

We consider the following noncausal system, the "Mexican hat,"

$$w_2(t) = -\frac{d^2}{dt^2} \left\{ \int_{-\infty}^{\infty} \varphi(x) w_1(t-x) dx \right\} \quad (24)$$

where φ is the standard normal density $\varphi(r) = (2\pi)^{-1/2} e^{-\frac{1}{2}r^2}$. In the simulations we consider a discrete-time version $w_2(t) = \sum_{j=-N}^N G_j w_1(t-j)$ with $N = 40$ and time steps of size 0.2. Note that w_2 is not a causal output, as the transfer function from w_1 to w_2 is not proper.

First we apply our procedure to the impulse response observation, i.e., w_1 is a unit pulse at time $t = 0$ and w_2 is the corresponding response; see Fig. 4. The misfits of the optimal models of orders 2, 4, and 6 are given in Table VIII. They are compared with the optimal Hankel norm approximations of orders 1, 2, and 3 of the causal part of the impulse response and using the symmetry of the Mexican hat to estimate the anticausal part. Analogously we determined approximations by balanced reduction. In Table VIII we also list the error in the impulse response of these models, i.e., the l_2 -distance between the systems impulse response and the Mexican hat w_2 . This error should be compared with the magnitude of the response, given by $\|w_2\| = 0.35$.

Hankel norm reduction and especially balancing give rather good results. They can only be used, however, when a causal impulse response is available. The GTLS method makes no use of the symmetry of the observed signals, but this property is preserved well in the identified models. This is illustrated in Figs. 5 and 6, which contain the optimal approximations of orders 2 and 4.

We also apply the GTLS method to data w_n consisting of two noisy steps for the input and the corresponding system output. These data and the optimal approximation of order 4

Fig. 4 The Mexican hat.

TABLE VIII
MODEL QUALITY

model		B_{gtls}	B_{bal}	B_{hank}
n=2	misfit	0.17	0.18	0.32
	error in impulse response	0.21	0.20	0.34
n=4	misfit	0.046	0.047	0.052
	error in impulse response	0.051	0.050	0.055
n=6	misfit	0.0070	0.0071	0.0078
	error in impulse response	0.0076	0.0075	0.0081

Fig. 5 The pulse w_1 (solid line), the first component of the l_2 -optimal approximation of second order (dashed line) and fourth order (dash-dotted line)

are given in Fig. 7. We should mention that the approximation error in the input is so small that it is nearly invisible in this figure.

The misfit of this model and the error in its impulse response are listed in the first column of Table IX. In view of the results for $n = 4$ in Table VIII, this shows that the identified model is a rather accurate approximation of the Mexican hat. Depending on the choice of an initial model, it typically takes a few hundred iterations to obtain convergence, and sometimes convergence to a local optimum occurred.

Fig. 6. The Mexican hat w_2 (solid line), the second component of the l_2 -optimal approximation of second order (dashed line) and fourth order (dash-dotted line).

Fig. 7. Noisy step measurement w_n (solid lines) and its l_2 -optimal approximation of fourth order (dashed lines).

TABLE IX
LOCAL VS GLOBAL METHOD

method	Global TLS	Local TLS
misfit with respect to w_n	0.11	1.17
error in impulse response	0.066	0.522

Finally, as mentioned at the end of Section VI, we will once more consider the local total least squares method described in Section III. The results for the fourth order model are given in the second column in Table IX. This clearly shows that, perhaps not surprisingly, the local method gives poor results with respect to the global total least squares criterion. For example, the error in the impulse response of the local model is even larger than the Mexican hat itself, which has norm $\|w_2\| = 0.35$.

C. A System with Multiple Outputs

In this experiment we consider a system with multiple outputs, so that a single difference equation does not suffice to describe the system. For simplicity we consider a system

TABLE X
SELECTION OF RANK AND DEGREE

model	$n = 0$	$n = 1$	$n = 2$	$n = 3$	$n = 4$
$m = 1$	3.33	1.45	0.93	0.89	0.88
$m = 2$	1.30	0.61	0.56	0.52	0.46

with one input and two outputs. The data are generated as $w = w' + v$, where $w' \in \mathcal{B}^{3,1,2}$ satisfies the equations

$$\begin{aligned} w'_2(t) &= w'_2(t-1) + w'_1(t) \\ w'_3(t) &= w'_2(t) + w'_1(t-1). \end{aligned} \quad (25)$$

For w_1 we take white noise with unit variance, and for v a three-dimensional white noise process with independent components and variance 0.01. The observation interval has length 50. Outside this interval we define $w(t) = 0$. The GTLS model of rank one and degree two is

$$\begin{aligned} w_2(t) &= 0.95w_2(t-1) - 0.04w_2(t-2) + 1.08w_1(t) \\ &\quad + 0.07w_1(t-1) + 0.15w_1(t-2) \\ w_3(t) &= 0.95w_3(t-1) - 0.04w_3(t-2) + 1.12w_1(t) \\ &\quad + 1.08w_1(t-1) - 0.89w_1(t-2). \end{aligned} \quad (26)$$

Transforming model equation (25) to the form

$$\begin{aligned} w'_2(t) - w'_2(t-1) &= w'_1(t) \\ w'_3(t) - w'_3(t-1) &= w'_1(t) + w'_1(t-1) - w'_1(t-2) \end{aligned} \quad (27)$$

shows that the original model equations are estimated rather accurately. We compare the misfits of GTLS models of various complexity in Table X.

For rank one, the misfit hardly decreases for orders above two. This could be expected, as the regular part of the data belongs to a system of order two. For rank two the results suggest to take the order one. Comparing the complexities $(m, n) = (1, 2)$ and $(2, 1)$, the first one of course leads to a larger misfit, as it imposes more restrictions. The misfit is still relatively small, however, when compared to the norm of the data $\|w\| = 6.10$.

X. CONCLUSION

In this paper we investigated the modeling of vector time series by means of difference equations, using the global total least squares criterion. Distinctive features of our approach are that no decomposition into inputs and outputs is required and that the criterion measures the global misfit in a nonparametric way. The misfit of a given system is evaluated by a dynamic projection algorithm formulated in terms of isometric state representations. We developed an iterative algorithm for constructing optimal models and gave a characterization of stationary points of the GTLS criterion. The method was illustrated by some simulation experiments.

The results of this paper can be extended in several directions, e.g., time series on a finite time interval, time varying systems, and time-varying norms for the misfit. Further research will be concerned with statistical properties and the development of faster algorithms and recursive methods.

APPENDIX A l₂-SYSTEMS

By l_2^q we denote the set of q -dimensional square summable time series over time axis \mathbf{Z} , i.e., $l_2^q := \{w: \mathbf{Z} \rightarrow \mathbf{R}^q; \sum_{t=-\infty}^{\infty} w(t)^T w(t) < \infty\}$. We define l_2 -systems as follows. By σ we denote the time shift defined by $(\sigma w)(t) := w(t+1)$, $t \in \mathbf{Z}$.

Definition A.1 (l_2 -systems): An l_2 -system is a subset \mathcal{B} of l_2^q that is:

- 1) linear, i.e., for $w, w' \in \mathcal{B}$ and $\alpha, \beta \in \mathbf{R}$ there holds $\alpha w + \beta w' \in \mathcal{B}$;
- 2) shift-invariant, i.e., $\sigma \mathcal{B} = \mathcal{B}$;
- 3) complete, i.e., if $w \in l_2^q$ satisfies $w|_T \in \mathcal{B}|_T$ for all finite $T \subset \mathbf{Z}$, then $w \in \mathcal{B}$.

This class of systems can be represented by linear, time-invariant difference equations of finite lag. Let $\mathbf{R}^{p \times q}[s]$ denote the set of $p \times q$ matrices with polynomial entries. A set of p difference equations corresponds to a polynomial matrix in the shift σ , i.e., $R(\sigma) \in \mathbf{R}^{p \times q}[\sigma]$.

Proposition A.2: A set $\mathcal{B} \in l_2^q$ is an l_2 -system if and only if $\mathcal{B} = \{w \in l_2^q; R(\sigma)w = 0\}$ for some $R \in \mathbf{R}^{p \times q}[s]$ and $p \in \mathbf{N}$.

Proof: The if-part is trivial, and the other part is proved by construction; see [10, Theorem 5]. \square

The complexity of a system is measured in terms of its dimension. Considered as a linear space, every nonzero l_2 -system has infinite dimension. Therefore we consider its dimension on finite time intervals.

Definition A.3: For a given system \mathcal{B} let $\mathcal{B}^0 := \{w \in \mathcal{B}; w(t) = 0 \text{ for } t < 0\}$, and let \mathcal{B}_0^0 be the restriction of \mathcal{B}^0 to time $t = 0$.

- 1) The rank of \mathcal{B} is defined as $m(\mathcal{B}) := \dim(\mathcal{B}_0^0)$.
- 2) The degree of \mathcal{B} is defined as $n(\mathcal{B}) := \dim(\mathcal{B}|_{[0, \infty)} \bmod \mathcal{B}_0^0|_{[0, \infty)})$.

The rank and degree determine the dimension of an l_2 -systems on finite intervals. To be specific, if \mathcal{B} is a system with rank m and degree n , then $\dim(\mathcal{B}|_T) = mN + n$ for intervals $T \subset \mathbf{Z}$ of length $N \geq n$. The rank and degree have the following interpretation. The rank is the number of degrees of freedom for a system at each time instant, given the past. This is equal to the number of inputs in the system. The degree measures the remaining freedom due to initial conditions. This is equal to the number of states. This is made precise in the following result.

Proposition A.4: The rank and degree of a system equal, respectively, the number of auxiliary inputs and the number of states in a minimal state representation.

Proof: For a proof we refer to [10, Theorem 9]. \square

APPENDIX B PROOFS

Proof of Proposition 4.3:

Necessity of 1: Let $\mathcal{R} := \text{im}[B \ AB \ \dots \ A^{n-1}B]$, then $A\mathcal{R} \subset \mathcal{R}$ and $\text{im } B \subset \mathcal{R}$. If (A, B) is not controllable there is a choice of basis for the state space such that with respect to this basis A and B take the form $\begin{bmatrix} A_1 & A_2 \\ 0 & 0 \end{bmatrix}$ and $\begin{bmatrix} B_1 \\ 0 \end{bmatrix}$.

So in a corresponding partition $\begin{pmatrix} x_1 \\ x_2 \end{pmatrix}$ of the state space, it holds that $\sigma x_2 = A_2 x_2$. As this admits only the zero solution in l_2 , x_2 can be removed.

Necessity of 2: Suppose there exists an f such that $(A + BF, C + DF)$ is not observable. Then the unobservable components of the state can be removed, as in the previous part.

Necessity of 3: An obvious condition is that $\begin{bmatrix} B \\ D \end{bmatrix}$ has full column rank, so it suffices to prove that $\ker D \subset \ker B$. Suppose $\ker D \setminus \ker B \neq \{0\}$, then there exists an invertible $R \in \mathbf{R}^{m \times m}$ such that $\begin{bmatrix} BR \\ DR \end{bmatrix} = \begin{bmatrix} B' & b \\ D' & 0 \end{bmatrix}$ with $0 \neq b \in \mathbf{R}^n$. Then \mathcal{B} is represented by $\sigma x = Ax + B'u' + bz$ and $w = Cx + D'u'$. As z influences w only with a delay, we remove its direct influence on σx by defining $\sigma x' := \sigma x - bz$. This gives $\sigma x' = Ax' + B'u' + Ab\sigma^{-1}z$ and $w = Cx' + D'u' + C'b\sigma^{-1}z$. Hence (A, B, C', D) is equivalent to $(A, [B' \ Ab], C', [D' \ C'b])$. From Proposition 4.2 it follows that this is equivalent to $(A + Abf, [B' \ Ab], C' + C'bf, [D' \ C'b])$, for all $f \in \mathbf{R}^{1 \times n}$. As $b \neq 0$, f can be chosen such that $I_n + bf$ is singular, by taking $f = -b^T / \|b\|^2$. It is easily verified that then $(A + Abf, C' + C'bf) = (A(I_n + bf), C'(I_n + bf))$ is not observable. From the Necessity of 2 it follows that the state dimension can be reduced.

Sufficiency of the Conditions: Let (A, B, C', D) be an SR with m auxiliary inputs and n states that satisfies Conditions 1), 2), and 3). From controllability and Proposition 4.2 it follows that without loss of generality we may assume that A is asymptotically stable. We prove that the rank of \mathcal{B} equals m , and its degree equals n . Then the result follows from Proposition A.4.

Concerning the rank, consider \mathcal{B}^0 as introduced in Definition A.3. Observability implies that trajectories $w \in \mathcal{B}^0$ have state zero at time $t = 0$. So $\mathcal{B}_0^0 = \text{im } D$, and from Condition 3) it follows that $\dim \mathcal{B}_0^0 = \text{rank } D = m$. Concerning the degree, we consider the space $\mathcal{B}|_{[0, \infty)} \bmod \mathcal{B}_0^0|_{[0, \infty)}$; cf. Definition A.3-2). This space can be parameterized by the initial state x_0 . Observability implies that this parameterization is injective, from which the result follows. \square

Proof of Proposition 5.2: Write $(A', B', C', D') := (S(A + BF)S^{-1}, SBR, (C + DF)S^{-1}, DR)$. Then

$$\begin{pmatrix} A' & B' \\ C' & D' \end{pmatrix} = \begin{pmatrix} S & 0 \\ 0 & I_m \end{pmatrix} \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} S^{-1} & 0 \\ FS^{-1} & R \end{pmatrix}.$$

Equation (13) for (A', B', C', D') gives, with $K = S^T S$

$$\begin{aligned} & \begin{pmatrix} A'^T & C'^T \\ B'^T & D'^T \end{pmatrix} \begin{pmatrix} K & 0 \\ 0 & I_m \end{pmatrix} \begin{pmatrix} A & B \\ C & D \end{pmatrix} \\ &= \begin{pmatrix} S^{-1} & 0 \\ FS^{-1} & R \end{pmatrix}^{-T} \begin{pmatrix} S^{-1} & 0 \\ FS^{-1} & R \end{pmatrix}^{-1} \\ &= \begin{pmatrix} S^T & -F^T R^{-T} \\ 0 & R^{-T} \end{pmatrix} \begin{pmatrix} S & 0 \\ -R^{-1}F & R^{-1} \end{pmatrix} \\ &= \begin{pmatrix} K + F^T(RR^T)^{-1}F & -F^T(RR^T)^{-1} \\ -(RR^T)^{-1}F & (RR^T)^{-1} \end{pmatrix}. \end{aligned}$$

Now verification of (16), (17), and (14) is straightforward. For a proof of the uniqueness of K we refer to [8]. \square

Proof of Proposition 5.3: From (13) it follows that $A^T A = I_n - C^T C$, hence $|Ax|^2 = |x|^2 - |Cx|^2 \leq |x|^2$. So A is stable. We prove that the representation is not minimal if A is not asymptotically stable. In that case A has an eigenvalue λ with $|\lambda| = 1$. Let x denote a corresponding eigenvector, and x^* its complex conjugate. Then $|Cx|^2 = x^* C^T C x = x^* x - x^* A^T A x = |x|^2 - |Ax|^2 = 0$. This implies that $CA^k x = 0$, $k \geq 0$, so that (A, C) is not observable and hence not minimal.

From the proof of Proposition 5.2 it follows that (15)–(17) are necessary conditions. Equation (15) determines S modulo a left unitary factor, corresponding to U . Equation (16) determines R modulo a right unitary factor, corresponding to V . \square

Proof of Theorem 6.2: From Definition 5.1 it follows that (A, \bar{B}, C, \bar{D}) as defined in part 4) is an ISR. As A is asymptotically stable [see Proposition 5.3-1)] the corresponding image representation $\bar{G}: l_2^{q-m} \rightarrow l_2^q$ is well defined. We first prove that

$$GG^* + \bar{G}\bar{G}^* = I_q \quad (28)$$

Define $\bar{B} = [B \ \bar{B}]$ and $\bar{D} = [D \ \bar{D}]$. Then (A, \bar{B}, C, \bar{D}) is also an isometric state representation. Let $\bar{G}(\sigma): l_2^q \rightarrow l_2^q$ denote the corresponding image representation. Then $\bar{G} = [G \ \bar{G}]$, so $GG^* + \bar{G}\bar{G}^* = \bar{G}\bar{G}^*$. It remains to prove that $\bar{G}\bar{G}^* = I_q$, or equivalently, that $\bar{G}^* = \mathcal{R}_q \bar{G}^T \mathcal{R}_q$ is isometric. The operator \mathcal{R}_q is clearly isometric, and because \bar{G}^T is the image representation induced by the ISR $(A^T, C^T, \bar{B}^T, \bar{D}^T)$, it is also isometric. This proves (28).

- 1) From Theorem 6.1 it follows that $\bar{G}\bar{G}^* w$ is the optimal approximation of w in $\mathcal{B}(A, \bar{B}, C, \bar{D})$. From (28) we obtain $\{w \in \mathcal{B}(A, \bar{B}, C, \bar{D})\} \Leftrightarrow \{\bar{G}\bar{G}^* w = w\} \Leftrightarrow \{GG^* w = 0\} \Leftrightarrow \{w \in \mathcal{B}^\perp\}$. So $\text{im } \bar{G} = \mathcal{B}^\perp$, which proves 1).
- 2) Equation (28) shows that every $w \in l_2^q$ can be decomposed into a part contained in \mathcal{B} and one in \mathcal{B}^\perp .
- 3) As (A, \bar{B}, C, \bar{D}) is a state representation of \mathcal{B}^\perp , it follows that $m(\mathcal{B}^\perp) \leq q - m$ and $n(\mathcal{B}^\perp) \leq n$. From part 2) it follows that $m(\mathcal{B}^\perp) \geq q - m$, so $m(\mathcal{B}^\perp) = q - m$. As $(\mathcal{B}^\perp)^\perp = \mathcal{B}$, there holds that $n = n((\mathcal{B}^\perp)^\perp) \leq n(\mathcal{B}^\perp)$, so that $n(\mathcal{B}^\perp) = n$. This proves 3).
- 4) That (A, \bar{B}, C, \bar{D}) is an ISR of \mathcal{B}^\perp was proved in 1), and minimality follows from 3) and Proposition A.4.
- 5) Equation (28) implies that $\hat{w} = w - \bar{w} = w - GG^* w = \bar{G}\bar{G}^* w$, and the result follows from Theorem 6.1. \square

Proof of Theorem 8.1: It suffices to prove the theorem for a minimal isometric SR. This can be seen as follows. If condition 2) holds for an arbitrary minimal SR, then it holds for all equivalent minimal SR's, as in the transformation $(S(A + BF)S^{-1}, SBR, (C + DF)S^{-1}, DR)$, the auxiliary input and state are linearly transformed to $R^{-1}(\hat{v} - F\hat{x})$ and Sx ; see the proof of Proposition 4.2.

So let (A, B, C, D) be a minimal ISR of \mathcal{B} , and let \bar{B}, \bar{D} , be defined as in Theorem 6.2-4). In the proof we will make use of the following relations, which follow from the projection

scheme in Section VI; see Fig. 2.

$$\text{for } \hat{v}: x = A^T \sigma x + C^T w, \quad \hat{v} = B^T \sigma x + D^T w \quad (29)$$

$$\text{for } \tilde{v}: x = A^T \sigma x + C^T w, \quad \tilde{v} = \bar{B}^T \sigma x + \bar{D}^T w \quad (30)$$

$$\text{for } \hat{w}: \sigma \hat{x} = A \hat{x} + B \hat{v}, \quad \hat{w} = C \hat{x} + D \hat{v} \quad (31)$$

$$\text{for } \tilde{w}: \sigma \tilde{x} = A \tilde{x} + \bar{B} \tilde{v}, \quad \tilde{w} = C \tilde{x} + \bar{D} \tilde{v}. \quad (32)$$

Further, from (13) we obtain

$$\begin{aligned} \hat{x} &= A^T \sigma \hat{x} + C^T \hat{w}, & \hat{v} &= B^T \sigma \hat{x} + D^T \hat{w}, \\ 0 &= \bar{B}^T \sigma \hat{x} + \bar{D}^T \hat{w} \end{aligned} \quad (33)$$

$$\begin{aligned} \tilde{x} &= A^T \sigma \tilde{x} + C^T \tilde{w}, & 0 &= B^T \sigma \tilde{x} + D^T \tilde{w}, \\ \tilde{v} &= \bar{B}^T \sigma \tilde{x} + \bar{D}^T \tilde{w}. \end{aligned} \quad (34)$$

We first describe those optimality conditions that can be derived straightforwardly from the model improvement constructions in Theorem 7.2.

Lemma B.1:

- 1) Construction 1 gives no improvement if and only if $\text{cov}([\hat{x}, \hat{v}], \hat{w}) = 0$.
- 2) Construction 2 gives no improvement if and only if $\text{cov}(\hat{v}, [\sigma \tilde{x}, \tilde{w}]) = 0$.
- 3) If Construction 3 gives no improvement, then $\text{cov}(\hat{v}, \tilde{v}) = 0$.

Proof of the Lemma: We use the notation of Theorem 7.2.

- 1) As $\hat{w} = C\hat{x} + D\hat{v}$, clearly $\hat{w} \in \mathcal{E}$. Construction 1 does not yield an improvement iff the projection of \hat{w} onto \mathcal{E} is zero, from which the result follows.
- 2) Construction 2 gives no improvement iff the projection of \hat{w} onto F is zero, cf. part 1). This is equivalent to $\langle \hat{w}, (C(\sigma I - A)^{-1} B' + D')v \rangle = 0$ for all B', D' . From (34) this is equivalent to $\langle \hat{w}, \sum_{k=0}^{\infty} C^k A^{k-1} B' \sigma^{-k} \hat{v} + D' \hat{v} \rangle = \langle \sum_{k=1}^{\infty} B'^T (A^T)^{k-1} C^T \sigma^k \hat{w} + D'^T w, v \rangle = \langle B'^T \sigma \tilde{x} + D'^T \tilde{w}, v \rangle = 0$, from which the result follows.
- 3) If $\text{cov}(\hat{v}, \tilde{v}) \neq 0$, then construction 3 decreases $\|\hat{v}\| = \|\tilde{v}\|$. \square

Returning to Theorem 8.1, we first prove part 2. From the lemma it follows that $\text{cov}(\hat{v}, \tilde{v}) = 0$, and $\text{cov}(\hat{v}, \hat{x}) = \text{cov}(\hat{v}, A^T \sigma \hat{x} + C^T \hat{w}) = 0$. As \bar{D} is injective, $\text{cov}(\hat{x}, \tilde{v}) = 0$ if and only if $\text{cov}(\hat{x}, \bar{D}\tilde{v}) = 0$, which is equivalent to $\text{cov}(\hat{x}, \tilde{w} - C\tilde{x}) = -\text{cov}(\hat{x}, C\tilde{x}) = 0$. So to prove 2 it remains to show that $\text{cov}(\hat{x}, \hat{x}) = 0$. As (A^T, B^T) is observable, this is equivalent to $\text{cov}(\sigma \hat{x}, B^T A^T \sigma \hat{x}) = 0$ for all $k \geq 0$. We prove this by induction. For $k = 0$, the lemma shows that $\text{cov}(\sigma \hat{x}, B^T \sigma \hat{x}) = \text{cov}(\sigma \hat{x}, -D^T \hat{w}) = 0$. Now suppose that $\text{cov}(\sigma \hat{x}, B^T A^T \sigma \hat{x}) = 0$ for $k \leq N$. Then $\text{cov}(\sigma \hat{x}, B^T A^T \sigma \hat{x}) = \text{cov}(A\hat{x} + B\hat{v}, B^T A^T \sigma \hat{x}) = \text{cov}(A\hat{x}, B^T A^T \sigma \hat{x}) = \text{cov}(A\hat{x}, B^T A^T \sigma (\hat{x} - C^T \hat{w})) = A \text{cov}(\hat{x}, B^T A^T \sigma \hat{x}) = 0$. This proves Theorem 8.1.2. Concerning the equivalence of 1, 2, and 3, the implications $3 \Rightarrow 2 \Rightarrow 1$ are trivial. Further, if 1 holds then $\text{cov}(\hat{x}, \hat{x}) = \text{cov}(\sigma \hat{x}, \sigma \hat{x}) = \text{cov}(A\hat{x} + B\hat{v}, A\hat{x} + B\hat{v}) = \text{cov}(A\hat{x}, A\hat{x}) = A \text{cov}(\hat{x}, \hat{x}) A^T$. As A is asymptotically stable, it follows that $\text{cov}(\hat{x}, \hat{x}) = 0$, so 1 implies 2. Finally, 3 is easily derived from 2 by using (31) and (32). \square

Proof of Theorem 8.2: Let w be a given observation and let \hat{w} be its optimal approximation in \mathcal{B} . Further let

(A, B, C, D) be a minimal SR of B with A asymptotically stable, and write the approximation error as $\tilde{w} := w - \hat{w} = w - (C(\sigma I - A)^{-1}B + D)\hat{v}$. We have to prove that B satisfies the optimality conditions if and only if the derivative of $\|\tilde{w}\|$ with respect to the parameters in A, B, C, D , and \hat{v} is zero. First we analyze the tangent space of \tilde{w} with respect to these parameters. Let \mathcal{E} and \mathcal{F} be defined as in Theorem 7.2, and let $\mathcal{G} := \{\bar{w} \in l_2^q; \exists H \in \mathbb{R}^{n \times n} \text{ such that } \bar{w} = C(\sigma I - A)^{-1}H\hat{x}\}$ with \hat{x} the state corresponding to \hat{w} .

Lemma B.2: The tangent space \mathcal{T} of $\tilde{w} = w - (C(\sigma I - A)^{-1}B + D)\hat{v}$ is given by $\mathcal{T} = \mathcal{B} + \mathcal{E} + \mathcal{F} + \mathcal{G}$.

Proof of the Lemma: The tangent space is defined as the smallest closed subspace of l_2 containing all partial derivatives. Note that \tilde{w} is linear in \hat{v} , in B , in C and in D . A change of \hat{v} corresponds to adding $\bar{w} \in \mathcal{B}$ to \tilde{w} , a change of C and D to adding $\bar{w} \in \mathcal{E}$ to \tilde{w} and a change of B and D to adding $\bar{w} \in \mathcal{F}$ to \tilde{w} . It remains to prove that the derivatives of \tilde{w} with respect to the parameters in A span the space \mathcal{G} . For $H \in \mathbb{R}^{n \times n}$ let x' be defined by $\sigma x' = (A - H)x' + B\hat{v}$ and let $w' := Cx' + D\hat{v}$. The corresponding error is $\tilde{w}' := w - w'$, so that the change in \tilde{w} is given by $\bar{w} = \tilde{w}' - \tilde{w} = \hat{w} - w' = C(\hat{x} - x') = C\bar{x}$ for $\bar{x} := \hat{x} - x'$. As $\sigma \bar{x} = A\hat{x} - (A - H)x' = A\bar{x} + Hx' = A\bar{x} + H\hat{x} - H\bar{x}$, ignoring the second-order term $H\bar{x}$ for small H gives the result. \square

We will next prove the theorem by showing that the optimality conditions and the stationarity condition are both equivalent to $\tilde{w} \perp \mathcal{T}$.

Stationarity is equivalent to the condition that $\lim_{\delta \rightarrow 0} \delta^{-1} \{\|\tilde{w} + \delta \bar{w}\| - \|\tilde{w}\|\} = 0$ for all $\bar{w} \in \mathcal{T}$. It is easily verified that this limit equals $\langle \tilde{w}, \bar{w} \rangle / \|\bar{w}\|$, so stationarity is equivalent to $\tilde{w} \perp \mathcal{T}$.

Finally we show that $\tilde{w} \perp \mathcal{T}$ is equivalent to the optimality conditions. First, suppose that the optimality conditions hold. As \tilde{w} is an optimal approximation within \mathcal{B} this holds that $\tilde{w} \perp \mathcal{B}$. Further, Theorem 8.1-3) states that $\text{cov}([\hat{v}, \hat{x}], \tilde{w}) = 0$, so that $\tilde{w} \perp \mathcal{E}$, and $\text{cov}(\hat{v}, [\sigma \bar{x}, \tilde{w}]) = 0$, so that the proof of Lemma B.1-2) shows that $\tilde{w} \perp \mathcal{F}$. Finally, for $\bar{w} \in \mathcal{G}$ given by $\bar{w} = \sum_{k=1}^{\infty} CA^{k-1}H\sigma^{-k}\hat{x}$ we obtain by using (34) that $\langle \bar{w}, \tilde{w} \rangle = \langle \sum_{k=1}^{\infty} CA^{k-1}H\sigma^{-k}\hat{x}, \tilde{w} \rangle = \langle \hat{x}, \sum_{k=1}^{\infty} H^T A^{T(k-1)} C^T \sigma^k \tilde{w} \rangle = \langle \hat{x}, H^T \sigma \tilde{x} \rangle = 0$, so $\tilde{w} \perp \mathcal{G}$. From Lemma B.2 it follows that $\tilde{w} \perp \mathcal{T}$.

Second, supposing that $\tilde{w} \perp \mathcal{T}$ we prove the optimality conditions. The fact that $\tilde{w} \perp \mathcal{E} + \mathcal{F}$ implies the conditions in Lemma B.1-2) and B.1-2), cf. the proof of that lemma. The condition in Lemma B.1-3) follows from that in B.1-2) by using (34). Further, the optimality conditions were derived from these conditions in the proof of Theorem 8.1. \square

Proof of Proposition 8.4: First we prove that \mathcal{Z} is a linear space. Observe that for every $z \in \mathcal{B}^\perp$ the optimal approximation of $\hat{w} + z$ within \mathcal{B} is given by \hat{w} . Let (\hat{v}, \hat{x}) be the auxiliary input and state for \hat{w} in a minimal SR of B , and let (\hat{v}_z, \hat{x}_z) be defined analogously for z in \mathcal{B}^\perp . As (\hat{v}, \hat{x}) is fixed, the condition in Theorem 8.1-2) for stationarity of B with respect to $\hat{w} + z$ consists of linear restrictions on (\hat{v}_z, \hat{x}_z) . As \hat{x}_z is a linear function of \hat{v}_z , these conditions can be expressed as linear restrictions on \hat{v}_z alone. This shows that B is a stationary point for $\hat{w} + z$ if and only if the

auxiliary input \hat{v}_z is restricted to a linear subspace of l_2 , from which the linearity of \mathcal{Z} follows. Next we show that the minimum in (22) is achieved by taking $w_0 = w - \bar{w}_0 = \hat{w} + \tilde{w} - (\tilde{w} - \tilde{w}') = \hat{w} + \tilde{w}'$ and $w' \in \mathcal{Z}$. By definition of \mathcal{Z} it follows that B is stationary for $w - \bar{w}_0$, by definition of \mathcal{Z} . Further, $\bar{w} \in \mathcal{B}^\perp$ is such that B is stationary for $w - \bar{w} = w - \bar{w}_0$ if and only if $z := \tilde{w} - \bar{w} \in \mathcal{Z}$. Now the norm of $w - w_0$ is minimized by taking $z = \tilde{w}'$, the orthogonal projection on \tilde{w} on \mathcal{Z} , hence $\bar{w}_0 = \tilde{w} - \tilde{w}'$. \square

He was researcher at the PTT Research Telecommunications Laboratory in Groningen in 1989. Since 1990 he has been working as a Research Assistant at the Tinbergen Institute and the Econometric Institute of the Erasmus University Rotterdam.

Control of Chained Systems

Application to Path Following and Time-Varying Point-Stabilization of Mobile Robots

Claude Samson

Abstract—Chain form systems have recently been introduced to model the kinematics of a class of nonholonomic mechanical systems. The first part of the study is centered on control design and analysis for nonlinear systems which can be converted to the chain form. Solutions to various control problems (open-loop steering, partial or complete state feedback stabilization) are either recalled, generalized, or developed. In particular, globally stabilizing time-varying feedbacks are derived, and a discussion of their convergence properties is provided. Application to the control of nonholonomic wheeled mobile robots is described in the second part of the study by considering the case of a car-pulling trailers.

1. INTRODUCTION

FROM a theorem due to Brockett [5], it is known that nonholonomic wheeled mobile robots with restricted mobility (such as unicycle-type and car-like vehicles) cannot be stabilized to a desired configuration (or posture) via differentiable, or even continuous, pure-state feedback [3], [24], [1]. Nonsmooth feedback has been proposed as an alternative solution (see [4], [6], [32], for example). Another alternative, first pointed out by the author in [25], consists of using smooth time-varying feedbacks, i.e., feedbacks which explicitly depend on the time variable. Such feedbacks had previously been very little studied in Control Theory. The result given in [25], for a unicycle-type vehicle, has subsequently motivated research work to explore the potentialities of time-varying feedbacks [8], [9], [11], derive explicit design methods [19], [34], and extend their use in robotics applications [26], [29].

The possibility of modeling the kinematic equations of wheeled mobile robots by so-called canonical chain form equations (a particular class of nonlinear nilpotent systems) has been pointed out in [17] when treating the case of car-like vehicles. It was known before that the equations of unicycle-type vehicles (a simpler case) could be written in this form, but this had not been used explicitly at the control design level. More recently, it has been shown [31] that the equations of vehicles with trailers could also be locally converted into a chain form.

In [17], the authors aimed essentially at exploring methods for open-loop steering of nonholonomic systems by using sinusoidal inputs. More recently, the authors of [34] have realized that chained systems could also be put under another canonical form, called "power form," and that power form systems belonged to the class of systems considered in [19] for which explicit smooth time-varying stabilizing feedbacks can be derived. The method proposed in [34], for deriving such controls, is applied to the problem of locally stabilizing a car-like system to a desired posture. A global solution to this problem had previously been given by the author in [26], [27] by using another approach.

Since the power form is mathematically equivalent to the chain form, one may question the interest of using one form rather than the other one when dealing with practical applications and mobile robot control in particular. To the author's knowledge, no single and definitive answer can be brought to this question because the two forms present complementary advantages and drawbacks. For example, it seems that model equations of nonholonomic vehicles using physical coordinates, such as Cartesian coordinates and angles between articulated bodies, are naturally closer to the chain form than to the power form. In this respect, the logic of using the chain form when addressing the problem of path following should be evident from the present paper. Concerning the theoretically more difficult problem of point stabilization, the answer is not as clear. As shown in this paper, a rather simple solution to smooth feedback stabilization can be obtained by complementing path following solutions, thus making the chain form intuitively attractive in this case. Smooth time-varying stabilization, however, does not seem to be compatible with fast convergence [11]. For this reason, recent studies on point stabilization have focused on the possibility of achieving faster (exponential) convergence by using nonsmooth feedback: M'Closkey and Murray have been working with the power form (see [14] for example), with the probable reason that their approach based on the use of homogeneous system coordinates does not apply well to the chain form, while Sordalen has proposed an original solution, mixing open-loop and feedback control strategies, by using the chain form [32]. The question is therefore far from being settled at the time being and will certainly motivate future developments.

This paper is organized as follows. Section II focuses on the control of chain form systems. After pointing out some

Manuscript received July 22, 1993; revised January 27, 1994 and April 10, 1994. Recommended by Associate Editor, A. M. Bloch. This work was supported by the European ESPRIT Program, PROMotion Project 6546.

facts about these systems and recalling some results about the open-loop steering problem, it is shown that chain form systems can themselves be converted into a slightly different form, named here skew-symmetric chain form, particularly well adapted to subsequent Lyapunov design and analysis of globally stabilizing time-varying feedbacks. Whenever this is possible, as it is the case here, finding adequate Lyapunov functions at an early stage of the analysis presents some advantages in terms of simplicity of the control design and stability proofs. A comparison with Center Manifold techniques, as used in [34] for example, is in this respect illustrative. In the process of deriving smooth feedback control laws for chained systems, useful connections with more classical linear control techniques are carried out. Several solutions to the point-stabilization problem are then tentatively compared by analyzing the type of stability associated with each of them. This motivates a short discussion about the practical relevance of the notion of asymptotical rate of convergence.

In Section III, the results of Section II are applied to a car pulling n -trailers, seen as an extension of the unicycle and car cases. The same approach as in [29], in which stabilization to a desired configuration is treated as an extension of the path following problem, is considered. This approach involves a specific parameterization of the vehicle's posture which facilitates the decoupling of the path following problem from translational velocity control. The interest of this parameterization for solving path planning issues is also pointed out in connection with the approach developed in [21]. Finally, a modification in the modeling of the system's equations is proposed so as to broaden the control stability domain.

II. CONTROL OF CHAIN FORM SYSTEMS

A. About Chained Systems

Let us consider a chain form system which may be written as

$$\begin{aligned}\dot{x}_1 &= u_1 \\ \dot{x}_2 &= u_1 x_3 \\ \dot{x}_3 &= u_1 x_4 \\ &\vdots \\ \dot{x}_{n-1} &= u_1 x_n \\ \dot{x}_n &= u_2\end{aligned}\quad (1)$$

or, equivalently

$$\dot{X} = h_1(X)u_1 + h_2(X)u_2 \quad h_1(X) = \begin{bmatrix} 1 \\ x_3 \\ x_4 \\ \vdots \\ x_n \\ 0 \end{bmatrix} \quad h_2 = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} \quad (2)$$

With respect to the notations used in [17], the components of the state vector have just been ordered differently.

In the second part of the study, where system (1) will be used to model the kinematic equations of wheeled mobile robots, x_1 will represent the distance covered by the vehicle along a path to be followed, and x_2 will represent the lateral distance between the vehicle and the path. Path following will therefore mainly consist in regulating x_2 to zero, independently of the values taken by x_1 (and thus u_1) while stabilization to a desired configuration will further involve the regulation of x_1 to zero by utilizing also the input u_1 . The possibility of directly relating the first state components of the chained form to physical euclidean-type coordinates justifies the preference given here to this form over the theoretically equivalent power form introduced in [34].

It is worth noting that a chained system like (1), although it is nonlinear, has a strong underlying linear structure. This clearly appears when u_1 is taken as a function of time and no longer as a control variable. In this case, the system becomes a single-input time-varying linear system which may be written as

$$\begin{aligned}\dot{x}_1 &= 0 \\ \dot{X}_2 &= \begin{bmatrix} 0 & u_1(t) & 0 & \cdots & 0 \\ 0 & 0 & u_1(t) & \cdots & 0 \\ \vdots & & & & \vdots \\ 0 & \cdots & \cdots & u_1(t) & 0 \\ 0 & \cdots & \cdots & 0 & u_1(t) \\ 0 & 0 & \cdots & \cdots & 0 \end{bmatrix} X_2 + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \\ 1 \end{bmatrix} u_2\end{aligned}\quad (3)$$

with

$$\dot{x}_1 = x_1 - \int_0^t u_1(\tau) d\tau \quad \text{and} \quad X_2^T = [x_2, x_3, \dots, x_n].$$

Putting a two-input nonlinear system in the chain form, when it is possible, is thus equivalent to linearizing this system with respect to one of its inputs. Since the chained system is controllable, controllability of the original system is a necessary condition. A necessary and sufficient condition is given in [18].

When the input u_1 is taken as a function of time, the system is clearly no longer controllable due to the first equation. Under certain conditions upon the choice of $u_1(t)$, however, the second part of the system involving X_2 remains controllable.

This type of property is very useful. It is used further in the study for the derivation of smooth time-varying feedbacks which asymptotically stabilize the point $X = 0$. It can also be utilized to solve the open-loop steering problem, i.e., the problem of determining open-loop control inputs that steer the system to a desired configuration X_{desired} , chosen equal to zero without loss of generality. The method basically consists of two steps: i) choose an integrable function $u_1(t)$ which ensures controllability of the second part of the system, and determine a control $u_2(t)$ which drives $X_2(t)$ to zero in finite time (usually done by integrating the system's equations on some time interval and solving a set of algebraic equations), and ii) once X_2 is at zero, keep u_2 equal to zero so as to leave X_2 unchanged, and determine $u_1(t)$ so as to drive $x_1(t)$ to zero in finite time.

This method has been used in [16], with $u_1(t)$ and $u_2(t)$ chosen as piecewise constant inputs. In this case, the first step corresponds to discretizing the system's equations with u_1 being kept constant (and different from zero) over $n-1$ sampling time intervals Δ and applying a dead-beat control strategy (the poles of the controlled discretized system are set equal to zero) to determine the values of u_2 on the time intervals $[k\Delta, (k+1)\Delta]$ ($0 \leq k \leq n-2$). At time $t = (n-1)\Delta$, X_2 has reached zero and u_1 may then be chosen equal to $-x_1((n-1)\Delta)/\Delta$ so as to have x_1 equal to zero at time $t = n\Delta$. Note that by working more on the choice of u_1 , feedback versions of this technique can be obtained. It may also be shown, as a complement to [16], that multiplying the piecewise constant inputs by $(1 - \cos(\omega t))$, with $\omega = (2\pi/\Delta)$, does not change the values of X at the sampling instants. In this way piecewise constant inputs are transformed into time-continuous inputs that achieve the same result.

The solution proposed in [17], with $u_1(t)$ and $u_2(t)$ being composed of sinusoids at integrally related frequencies, may also be viewed as a variant of this method. Obviously, the same method applies to other inputs. A more geometrical method for open-loop steering of nonholonomic vehicles will also be pointed out further in Section III-B.

When u_1 is constant and different from zero, the above system becomes time-invariant and the second part of the system is clearly controllable. By applying classical linear control techniques, it is then possible to derive linear feedbacks $u_2(X_2)$ which stabilize the origin $X_2 = 0$ exponentially.

In fact, even if $u_1(t)$ is not constant but only piecewise continuous, bounded, and strictly positive (or negative), it is quite simple to derive stabilizing feedbacks $u_2(X_2)$ for the second part of the system. Indeed, since $x_1(t)$ varies monotonically with time, differentiation with respect to time can be replaced by differentiation with respect to x_1 . From now on we will refer to this change of variable as the u_1 -time-scaling procedure. Then, the second part of the system may equivalently be written

$$\begin{aligned} \dot{x}_2^{(1)} &= \text{sign}(u_1)x_3 \\ \dot{x}_3^{(1)} &= \text{sign}(u_1)x_4 \\ &\vdots \\ \dot{x}_{n-1}^{(1)} &= \text{sign}(u_1)x_n \\ \dot{x}_n^{(1)} &= \text{sign}(u_1)v_2 \end{aligned} \quad (4)$$

with

$$x_i^{(1)} = \text{sign}(u_1) \frac{\partial^i x_i}{\partial x_1^i} \quad \text{and} \quad v_2 = u_2/u_1(t).$$

This is the equation of a linear invariant system, an equivalent input-output representation of which is

$$x_2^{(n-1)} = \text{sign}(u_1)^{n-1} v_2. \quad (5)$$

One falls upon a controllable invariant linear system which admits exponentially stabilizing linear feedbacks in the form

$$v_2(X_2) = -\text{sign}(u_1)^{n-1} \sum_{i=1}^{n-1} g_i x_2^{(i-1)} \quad (g_i > 0, \forall i) \quad (6)$$

the control gains g_i being chosen so as to satisfy the classical Routh-Hurwitz stability criterion (the positivity of g_i is necessary but not sufficient).

Hence, the time-varying control

$$u_2(X_2, t) = u_1(t)v_2(X_2) \quad (7)$$

globally asymptotically stabilizes the origin $X_2 = 0$ in this case. Moreover, the trajectories followed by the system's solutions are invariant with respect to variations of $u_1(t)$.

This "feedback linearization" technique, associated with u_1 -time-scaling, has in fact been used by other authors working on mobile robot control. For example, Sampei *et al.* [22] have applied it to the problem of following a straight line in the case of a car pulling a single trailer. Their solution differs, however, from the one given further in the article in that they took the car's steering wheel angle as a control, instead of the angle's velocity.

In the earlier work of Dickmanns and Zapp [10], on vision-based roadline following, u_1 -time-scaling is also implicitly used together with tangent linearization of the system's equations, instead of exact feedback linearization. In their work, u_1 has the physical meaning of the car's translational velocity.

Extension of the path following problem to the point-stabilization problem to achieve smooth time-varying feedback stabilization of a unicycle-type vehicle to a given posture, based on u_1 -time-scaling, has been first proposed in [29]. The present study may be seen as a generalization of the results described in this paper.

B. Skew-Symmetric Chain Form and Lyapunov Control Design

We show next, by introducing the skew-symmetric chain form evoked before, and via a Lyapunov-like analysis, that control (7) globally stabilizes the origin $X_2 = 0$ for the second part of the chained system, provided that $|u_1(t)|$ and $|\dot{u}_1(t)|$ are bounded, and $u_1(t)$ does not asymptotically tend to zero. An important difference with the result stated previously is that $u_1(t)$ is now allowed to pass through zero.

From there it will be simple to complement the analysis and derive smooth time-varying feedbacks which globally stabilize the origin $X = 0$ of the complete system.

To this purpose, let us consider the following change of coordinates $\phi_1: X \mapsto Z$ in R^n

$$z_1 = x_1$$

$$z_2 = x_2$$

$$z_3 = x_3$$

$$z_{j+3} = k_j z_{j+1} + L_{h,j} z_{j+2} \quad 1 \leq j \leq n-3 \quad (8)$$

where

- k_j ($1 \leq j \leq n-3$) is a real positive number;
- $L_{h_1} z_j = \frac{\partial z_j}{\partial X} h_1(X)$: the Lie derivative of z_j along h_1 ;
- $L_{h_1}^k = L_{h_1}^{k-1} L_{h_1}$: the Lie differentiation operator of order k along h_1 .

One easily verifies that the Jacobian matrix $(\partial \phi_1 / \partial X)$ is a constant lower triangular matrix with ones on the diagonal. It is therefore a regular linear change of coordinates in R^n .

Moreover: $L_{h_2} z_i = 0$ ($1 \leq i \leq n-1$), and $L_{h_2} z_n = 1$.

Taking the time derivative of z_{j+3} and using 2

$$\begin{aligned} \dot{z}_{j+3} &= \frac{\partial z_{j+3}}{\partial X} \dot{X} \\ &= (L_{h_1} z_{j+3})u_1 + (L_{h_2} z_{j+3})u_2. \end{aligned} \quad (9)$$

Also, from 8

$$L_{h_1} z_{j+3} = -k_{j+1} z_{j+2} + z_{j+4}. \quad (10)$$

Hence

$$\dot{z}_{j+3} = -k_{j+1} u_1 z_{j+2} + u_1 z_{j+4} \quad (0 \leq j \leq n-4) \quad (11)$$

and

$$\dot{z}_n = L_{h_1} z_n u_1 + u_2. \quad (12)$$

The original chained system has thus been converted to the following skew-symmetric chained system

$$\begin{aligned} \dot{z}_1 &= u_1 \\ \dot{z}_2 &= u_1 z_3 \\ \dot{z}_3 &= -k_1 u_1 z_2 + u_1 z_4 \\ &\vdots \\ \dot{z}_{j+3} &= -k_{j+1} u_1 z_{j+2} + u_1 z_{j+4} \quad (0 \leq j \leq n-4) \\ \dot{z}_n &= -k_{n-2} u_1 z_{n-1} + u_2 \end{aligned} \quad (13)$$

with

$$u_2 = (k_{n-2} z_{n-1} + L_{h_1} z_n) u_1 + u_2. \quad (14)$$

The interest of this form is that it naturally lends itself to Lyapunov control design and analysis, as illustrated by the following proposition.

Proposition 2.1: Assume that $|u_1(t)|$ and $|\dot{u}_1(t)|$ are bounded, and consider the control

$$w_2 = -k_{w_2}(u_1) z_n \quad (15)$$

where $k_{w_2}(\cdot)$ is a continuous application strictly positive on $R - \{0\}$. If this control is applied to system (13), then the positive function

$$\begin{aligned} V(Z_2) &= 1/2(z_2^2 + (1/k_1)z_3^2 + (1/k_1 k_2)z_4^2 + \dots \\ &\quad + \left(1/\prod_{j=1}^{j=n-2} k_j\right) z_n^2) \end{aligned} \quad (16)$$

is nonincreasing along the closed-loop system's solutions, and asymptotically converges to some limit value V_{\lim} (which *a priori* depends on the initial conditions).

Moreover $u_1(t)V(Z_2(t))$ asymptotically tends to zero.

Therefore, if $u_1(t)$ does not asymptotically tend to zero, $V_{\lim} = 0$ and the manifold $Z_2 = 0$ is globally asymptotically stable.

The proof of this proposition, as of subsequent propositions, uses an extended version of Barbalat's Lemma stating that if a given differentiable function $f(x)$ from R^+ to R converges to some limit value when x tends to infinity, and if the derivative $(df/dx)(x)$ of this function is the sum of two terms, one being uniformly continuous and the other one tending to zero when x tends to infinity, then $(df/dx)(x)$ tends to zero when x tends to infinity.

Proof of Proposition 2.1: Taking the time derivative of V and using the system's $(n-1)$ last equations, one obtains

$$\dot{V} = \left(1/\prod_{j=1}^{j=n-2} k_j\right) z_n w_2. \quad (17)$$

Thus, if control (15) is used

$$\dot{V} = -\left(k_{w_2}(u_1)/\prod_{j=1}^{j=n-2} k_j\right) z_n^2 \quad (\leq 0). \quad (18)$$

The considered Lyapunov-like function is thus non-increasing.

This in turn implies that $\|Z_2(t)\|$ is bounded, uniformly with respect to the initial conditions. Existence and uniqueness of the system's solutions over R^+ also follows.

Now, since V is nonincreasing, $V(t)$ converges to some limit value $V_{\lim} (\geq 0)$. Since $k_{w_2}(\cdot)$ is continuous and since $|u_1(t)|$ and $|\dot{u}_1(t)|$ are bounded, $k_{w_2}(u_1(t))$ is uniformly continuous. Hence, the right-hand side member of equality (18) is uniformly continuous along any system's solution, and, by application of Barbalat's lemma, $V(t)$ tends to zero. Therefore, $k_{w_2}(u_1(t))z_n(t)$ tends to zero. This in turn implies, using the properties of the function $k_{w_2}(\cdot)$ and the boundedness of $|u_1(t)|$ and $|z_n(t)|$, that $u_1(t)z_n(t)$ tends to zero.

From now on, the time index will often be omitted to simplify the notations. Taking the time derivative of $u_1^2 z_n$ and using the convergence of $u_1 z_n$ to zero, gives

$$\frac{d}{dt}(u_1^2 z_n) = -k_{n-2} u_1^3 z_{n-1} + o(t) \quad \text{with} \quad \lim_{t \rightarrow +\infty} o(t) = 0 \quad (19)$$

$u_1^3 z_{n-1}$ is uniformly continuous along a system's solution since its time derivative is bounded. Therefore, in view of (19) and since $u_1^2 z_n$ tends to zero, $(d/dt)(u_1^2 z_n)$ also tends to zero (by application of the aforementioned extended version of Barbalat's lemma). Hence, $u_1^3 z_{n-1}$, and thus $u_1 z_{n-1}$, tend to zero.

Taking the time derivative of $u_1^2 z_j$ and repeating the above procedure iteratively, one obtains that $u_1 z_j$ tends to zero for $2 \leq j \leq n$. In view of the system's equations, we note that this in turn implies the convergence of \dot{Z}_2 to zero.

Summing up the squared values of $u_1(t)z_j(t)$, for $2 \leq j \leq n$, it appears that $u_1(t)^2 V(t)$ tends to zero. And so does $u_1(t)^2 V_{\lim}$ (from the already established convergence of $V(t)$ to V_{\lim}). \diamond

Remarks:

- One can verify that, with the particular choice $k_{w_2}(u_1) = k'_{w_2}|u_1|$, the set of controls u_2 given by (14) and (15) with $k_i > 0$ ($i = 1, \dots, n-2$) and $k'_{w_2} > 0$, coincides with the set of stable linear controls (7) previously associated with the linear invariant system (4). More precisely, there is a one-to-one correspondence between the elements of the two sets. One can thus apply classical linear control design methods to determine adequate values for the parameters k_i ($i = 1, \dots, n-2$) and k'_{w_2} and optimize the control performance near $Z_2 = 0$, as illustrated in [29]. This correspondence also underlies the connection existing between the Routh–Hurwitz criterion and the operation consisting in transforming the original chain form into a skew-symmetric chain form.
- Nonconvergence of $u_1(t)$ to zero, under the assumption that $|\dot{u}_1(t)|$ is bounded, implies that $\int_0^t |u_1(\tau)| d\tau$ tends to infinity with t . Divergence of this integral is in fact necessary to the asymptotical convergence of $\|Z_2(t)\|$ to zero, when using control (15) with $k_{w_2}(u_1) = k'_{w_2}|u_1|$. This appears clearly when interpreting this control as a stabilizing linear control for the linear invariant system (4) obtained by replacing the time variable by the aforementioned integral. This integral may still diverge, however, when $u_1(t)$ tends to zero slowly “enough” (like $t^{-\frac{1}{2}}$, for example). This indicates that $\|Z_2(t)\|$ may still converge to zero when $u_1(t)$ does.

Proposition 2.1 is not only of interest in solving the path following problem for mobile robots, it also suggests a way of determining smooth time-varying feedbacks which globally asymptotically stabilize the origin $Z = 0$ (or $X = 0$) of the whole system. In this case, u_1 is used as a control the role of which is to complement the action of the control u_2 (or w_2) in order to also obtain asymptotical convergence of z_1 (or x_1) to zero. Since chained systems like (1) cannot be asymptotically stabilized by using smooth pure state feedbacks (by application of a Brockett’s theorem [5]), smooth feedback stabilization can only be achieved by using another type of control. A time-varying control law will be considered in the present case.

Proposition 2.2: Consider the same control as in Proposition 2.1

$$w_2 = -k_{w_2}(u_1)z_n \quad (20)$$

complemented with the following time-varying control

$$u_1 = -k_{u_1}z_1 + h(Z_2, t) \quad (21)$$

where

- k_{u_1} is a positive number;
- $h(Z_2, t)$ is a function of class C^{p+1} ($p \geq 1$), uniformly bounded with respect to t , with all successive partial derivatives also uniformly bounded with respect to t , and such that $C_1: h(0, t) = 0, \forall t$ C_2 : There is a time-

diverging sequence $\{t_i\}_{i \in \mathbb{N}}$, and a positive continuous function $\alpha(\cdot)$ such that

$$\|Z_2\| \geq l > 0 \Rightarrow \sum_{j=1}^{p+1} \left(\frac{\partial^j h}{\partial t^j}(Z_2, t_i) \right)^2 \geq \alpha(l) > 0, \forall i.$$

Controls (20) and (21) globally asymptotically stabilize the origin $Z = 0$.

Proof of Proposition 2.2: It has already been shown that the positive function $V(Z_2)$ used in Proposition 2.1 is non-increasing along the closed-loop system’s solutions, implying that $\|Z_2(t)\|$ is bounded uniformly with respect to initial conditions. Note that the boundedness of $|u_1(t)|$ and $|\dot{u}_1(t)|$ is not needed to prove this fact.

The first equation of the controlled system is

$$\dot{z}_1 = -k_{u_1}z_1 + h(Z_2, t). \quad (22)$$

This is the equation of a stable linear system subjected to the bounded additive perturbation $h(Z_2(t), t)$. Therefore, $|z_1(t)|$ is also bounded uniformly with respect to the initial conditions.

Existence and uniqueness of the solutions over R^+ is thus ensured.

From the expression of u_1 , it is then found that $u_1(t)$ (taken as a function of time along a system’s solution) is bounded. And so is its first derivative [by using the regularity properties imposed upon $h(Z_2, t)$].

Proposition 2.1 thus applies. In particular, $V(Z_2(t))$ tends to some limit value $V_{\lim} (\geq 0)$, $\|\dot{Z}_2(t)\|$ tends to zero, and $Z_2(t)$ tends to zero if $u_1(t)$ does not.

We now proceed by contradiction.

Assume that $u_1(t)$ does not tend to zero. Then, $\|Z_2(t)\|$ tends to zero. By uniform continuity and since $h(0, t) = 0$ (condition C_1), $h(Z_2(t), t)$ also tends to zero. Equation (22) then becomes the equation of a stable linear system subjected to an additive perturbation which asymptotically vanishes. As a consequence, $z_1(t)$ tends to zero. From the expression of u_1 , this in turn implies that $u_1(t)$ tends to zero, yielding a contradiction.

Therefore, $u_1(t)$ must asymptotically tend to zero.

Differentiating the expression of u_1 with respect to time and using the convergence of $u_1(t)$ and $\|\dot{Z}_2(t)\|$ to zero, we get

$$\dot{u}_1(t) = \frac{\partial h}{\partial t}(Z_2(t), t) + o(t) \quad \text{with} \quad \lim_{t \rightarrow +\infty} o(t) = 0. \quad (23)$$

Since $(\partial h / \partial t)(Z_2(t), t)$ is uniformly continuous (its time derivative is bounded), $\dot{u}_1(t)$, and thus $(\partial h / \partial t)(Z_2(t), t)$, tend to zero (Barbalat’s Lemma).

By using similar arguments, one obtains that the time-derivative of $(\partial h / \partial t)(Z_2(t), t)$ and $(\partial^2 h / \partial t^2)(Z_2(t), t)$ tend to zero.

By repeating the same procedure as many times as necessary, we show that $(\partial^j h / \partial t^j)(Z_2(t), t)$ tends to zero, ($1 \leq j \leq p$). Therefore

$$\lim_{t \rightarrow \infty} \sum_{j=1}^{p+1} \left(\frac{\partial^j h}{\partial t^j}(Z_2(t), t) \right)^2 = 0. \quad (24)$$

Assume now that V_{lim} is different from zero. This implies that $\|Z_2(t)\|$ remains larger than some positive real number l (which can be calculated from V_{lim}). The previous convergence result is then not compatible with the condition C_2 imposed on the function $h(Z_2, t)$.

Therefore, V_{lim} is equal to zero, and $Z_2(t)$ asymptotically converges to zero. Then, by uniform continuity and using condition C_1 , $h(Z_2(t), t)$ tends to zero.

In view of the expression of u_1 , asymptotical convergence of $z_1(t)$ to zero readily follows. \diamond

Remark: Dependence of the function $h(Z_2, t)$ upon the last state variable z_n is not required when the function $k_{w_2}(\cdot)$ is strictly positive on R . The reason is that $z_n(t)$ unconditionally converges to zero in this case, due to the convergence of $\dot{V}(Z_2(t))$ to zero (cf. proof of Proposition 2.1).

It can be noted that only the control input u_1 depends on time explicitly via the function $h(Z_2, t)$. We will refer to this function as the heat-function, to establish a parallel with well-known probabilistic global minimization methods and underline the primary role of this term in the control, i.e., forcing “motion” as long as the system has not reached the desired equilibrium point, thus preventing the system’s state from converging to other equilibrium points.

According to Proposition 2.1, when one is only interested in the regulation of Z_2 (as in the case of mobile robot path following), any sufficiently regular input $u_1(t)$, which does not asymptotically tend to zero, can be used. This leaves the user with some freedom concerning the choice of this input. For instance, uniform exponential convergence of $\|Z_2(t)\|$ to zero is obtained when $|u_1(t)|$ remains larger than some positive number. Other sufficient conditions for exponential convergence of $\|Z_2(t)\|$ to zero, which do not require $u_1(t)$ to have always the same sign, may also be derived. For example, if $|\dot{u}_1(t)|$ is bounded, it is sufficient to have $|u_1(t)|$ periodically larger than some positive number.

If the application further requires the regulation of z_1 (stabilization of a mobile robot about a fixed desired configuration, for example), then Proposition 2.2 suggests implementing a time-varying feedback u_1 . In both cases, the same control law u_2 (or w_2) based on u_1 -time-scaling can be used.

The conditions imposed by Theorem 2.2 upon the heat-function are not severe and can easily be met. For example, the following three functions

$$h(Z_2, t) = \|Z_2\|^2 \sin(t) \quad (25)$$

$$h(Z_2, t) = \sum_{j=0}^{n-2} a_j \sin(\beta_j t) z_{2+j} \quad (26)$$

$$h(Z_2, t) = \sum_{j=0}^{n-2} a_j \frac{\exp(b_j z_{2+j}) - 1}{\exp(b_j z_{2+j}) + 1} \sin(\beta_j t) \quad (27)$$

(with $a_j \neq 0$, $b_j \neq 0$, $\beta_j \neq 0$, and $\beta_i \neq \beta_j$ when $i \neq j$) satisfy these conditions. For the first function, this is obvious. For the second function, the proof is given in [26]. The same proof basically applies to the third function which presents the additional feature of being uniformly bounded with respect to all its arguments. It can be noted that it is not necessary to use sinusoids at integrally related frequencies, as opposed to the

solution proposed in [34]. In fact, the theorem implies that it is not even necessary to use time-periodic functions, as assumed in most time-varying feedback stabilization results.

For practical purposes, the choice of the heat function is important because the overall control performance (as measured by convergence rate, time needed to enter a small ball centered on zero, sensitivity with respect to perturbations, etc.) critically depends upon this choice. This has been checked by the author in simulation. By performing a complementary analysis in the three-dimensional case, based on Center Manifold techniques, it is also possible to explain why the functions (26) and (27) are better than (25) with respect to the induced asymptotical convergence rate. For the last two functions, the parameters a_j and b_j , which characterize the “slope” of $h(Z_2, t)$ near $Z_2 = 0$ have been found to have much influence on the transient time needed for the system’s solutions to get close to zero. Basically, the larger these parameters are, the shorter the transient time is.

C Stability and Asymptotical Rate of Convergence

From Section II-B, we already know that, when using the smooth time-varying control law (20), (21) with $k_{w_2}(u_1) = k'_{w_2}|u_1|$ ($k'_{w_2} > 0$), the convergence of $\|Z(t)\|$ to zero cannot be exponential. Indeed, $u_1(t)$ would otherwise converge to zero exponentially and the integral $\int_0^t |u_1(\tau)| d\tau$ would not diverge. This would be in contradiction with the fact (pointed out earlier) that divergence of this integral is necessary to the asymptotical convergence of $\|Z_2(t)\|$ to zero.

From the simulation of a smooth time-varying feedback control applied to a unicycle-type vehicle, it has also been observed in [28] that the norm of the state vector did not converge to zero faster than $t^{-\frac{1}{2}}$ for most initial configurations. This is much slower than the uniform exponential rate of convergence that can be obtained in the case of nonlinear systems the linear tangent approximation of which is controllable. It is claimed in [11] that it is not possible to achieve exponential stability for nonholonomic systems by using smooth (differentiable everywhere) time-periodic feedbacks. In mathematical terms, this means that the system’s trajectories cannot satisfy the following inequality

$$\|X(t)\| \leq K \|X(0)\| \exp(-\lambda t) \quad \forall X(0) \text{ in some open ball centered on zero} \quad (28)$$

for some positive real numbers K and λ .

The practical significance of this relation, when it is satisfied, is two-fold: i) the ratio $\|X(t)\|/\|X(0)\|$ between transient and initial errors is uniformly bounded, and ii) all solutions end up converging to zero exponentially.

It is worth noting that these two properties, regrouped under the strong concept of exponential stability, do not necessarily hold together.

For example, the piecewise-continuous time-invariant feedback law proposed by Canudas and Sørvalen in [6], for posture stabilization of a unicycle, only yields the following result

$$\|X(t)\| \leq (K_1 + K_2 \|X(0)\|) \exp(-\lambda t). \quad (29)$$

Each solution converges to zero exponentially, but the slightest initial error, or perturbation, may produce transient deviations the size of which is larger than some constant. Note that this sensitivity to small perturbations, observed for this particular example, is not necessarily indicative of nonsmooth feedbacks as a whole.

In [32], Sørđalen proposes another interesting control which may be seen as a time-varying mix of open-loop and feedback strategies, continuous with respect to time, but nonsmooth in the state vector. He shows that this control, which applies to any chain form system, yields the following property

$$\|X(t)\| \leq g(\|X(0)\|)\exp(-\lambda t) \quad (30)$$

where $g(\cdot)$ is a class \mathcal{K} -function (i.e., strictly increasing and such that $g(0) = 0$) which is not Lipschitz around zero. Precisely, the derivative of $g(x)$ tends to infinity when x tends to zero.

This property has been called \mathcal{K} -exponential stability. It is weaker than the usual exponential stability notion in the sense that the ratio between transient and initial deviations is not uniformly bounded. Nevertheless, it is better than (29) in the sense that the deviations are not lowerbounded by some positive constant. As in the previous case, all solutions tend to zero exponentially in the absence of perturbations acting on the system.

By using the properties of homogeneous systems [12], time-periodic feedbacks which are continuous with respect to both time and state, but not differentiable at the origin, have been proposed in [14], [20], [30] and have been shown to achieve the same type of exponential stability.

Concerning the case of smooth time-varying feedbacks, such as the ones derived in the Section II-B, it is simple to verify that we have

$$\|X(t)\| \leq K\|X(0)\| \quad (31)$$

for some positive constant K the size of which may be taken as close to one as desired via a suitable choice of the control parameters.

Smooth time-varying feedbacks thus are, in some sense, less sensitive to initial errors than the aforementioned nonsmooth feedbacks. The "price" paid for this type of robustness is that the system's solutions do not converge to zero as fast as exponentially. In fact, in view of the above discussion, one can only expect to have

$$\|X(t)\| \leq K\|X(0)\|f(t); \quad f(0) = 1, \quad \lim_{t \rightarrow +\infty} f(t) = 0 \quad (32)$$

where $f(t)$ is a decreasing function which does not tend to zero as fast as exponentially. For example: $f(t) = (1+t)^{-\frac{1}{2}}$, in the case of the control considered in [28], as it may be rigorously established either by applying Center Manifold techniques [7] or by invoking two-time scale techniques, as done in [14].

The purpose of the above discussion was to summarize our actual knowledge concerning the stability properties of

controlled nonholonomic mobile robots (with restricted mobility) in the case of point-stabilization and to point out the difficulty in objectively comparing smooth and nonsmooth feedback solutions. So far, exponential stability, in the usual sense, has not been obtained and is most likely out of reach. Exponential convergence of the solutions to zero, in the absence of perturbations and modeling errors, is possible, however, by using either piecewise-continuous time-invariant feedbacks or continuous time-varying feedbacks which are not differentiable at zero. Smooth time-varying feedbacks are less efficient in terms of asymptotical rate of convergence, but are also potentially not very sensitive to initial conditions and perturbations in the vicinity of zero. A slow asymptotical convergence rate still does not mean that the system's solutions cannot be rapidly steered to an arbitrarily small neighborhood of zero, as pointed out in [34] (for example) and illustrated by simulation results in [29]. Nevertheless, this type of performance has not been obtained for small values of K . This again reflects the apparently unavoidable compromise between performance and robustness. It should also be noted that perturbations acting on nonholonomic systems are not of equal importance depending on the state component which is primarily affected: a deviation in a direction compatible with the vehicle's mobility is clearly not as severe as a deviation which violates one of the system's kinematic constraints (lateral skidding of a car, for example).

Further clarification of these issues is thus needed in relation to a rather fundamental question, seldom addressed in the control literature: Is the asymptotical rate of convergence a good measurement of the overall control performance? Answering this question is not simple, knowing that regulation errors are physically unavoidable and that what often really matters in practice is to keep these errors as small as possible under realistic adverse experimental conditions. While connections between robustness issues and asymptotical rate of convergence of the controlled system have been much studied in the case of linear systems (or nonlinear systems that can be approximated by controllable linear systems), they are still not well understood in other cases.

To illustrate the difficulty with a concrete example, a control law similar to (20)–(21) has been simulated for a three-dimensional unicycle-type vehicle with the following nonsmooth heat-function

$$h(x_2, x_3, t) = \begin{cases} \sin(t) & \text{if } x_2^2 + (1/k_1)x_3^2 \geq \epsilon^2 \\ 0 & \text{if } x_2^2 + (1/k_1)x_3^2 < \epsilon^2. \end{cases} \quad (33)$$

Note that this function does not satisfy the conditions imposed in Proposition 2.2. The corresponding feedback control is time-varying, but not even continuous.

The $(x_1(t), x_2(t))$ Cartesian position of the vehicle is represented in Fig. 1(a).

The time-evolution of $x_1(t)$, $x_2(t)$, and the vehicle's orientation angle $\theta(t)$ ($\approx x_3(t)$) is shown in Fig. 1(b).

After 25 seconds, all variables "seem" to have converged to zero. In reality, it is possible to show that $x_1(t)$ and both control inputs converge to zero exponentially, while

(a)

(b)

Fig. 1.

$2V(X_2(t)) = x_2(t)^2 + (1/k_1)x_3(t)^2$ can only be shown to become smaller than ϵ^2 ($= 10^{-6}$, in the simulation) after a finite time.

This control therefore does not asymptotically stabilize the system to the desired equilibrium, so that the notion of asymptotical rate of convergence does not even apply here. Is this fact sufficient in itself to assert that this is not a good control?

Fig. 2

III. APPLICATION TO THE CONTROL OF A CAR WITH n -TRAILERS

A Modeling Equations and Notations

We consider a car with n -trailers as represented in Fig. 2. The system is assumed to move on flat ground. The wheels are allowed to roll and spin, but not slip.

The vehicle counted first is the last trailer and the following notations are used:

- l_i is the distance between P_i and P_{i+1}
- α_i ($1 \leq i \leq n$) is the angle between $P_{i-1}P_i$ and P_iP_{i+1} which characterizes the orientation of the vehicle $(i+1)$ with respect to the previous vehicle
- α_0 gives the orientation of the first vehicle with respect to a fixed frame. For instance, we may choose: $\alpha_0 = \text{angle}(\vec{v}_0, \vec{P}_0P_1)$
- α_{n+1} is the angle of the car's driving front wheel with respect to the car's body.
- v_i ($0 \leq i \leq n+1$) is the intensity of the velocity of the point P_i . This is the translational velocity of the $(i+1)$ vehicle.
- r is the radius of the car's front steering wheel, and ω the angular velocity of this wheel about its horizontal axis so that $v_{n+1} = r\omega$.

In what follows, only velocity control is considered, and ω and $(d/dt)\alpha_{n+1}$ are chosen as control variables.

Kinematic equations of this system, with respect to a fixed frame, have been derived by various authors. See [13], [22], [35], for example. We will work here with a more general set of equations expressing the system's motion relatively to an arbitrary given path.

A first set of equations is simply obtained by using the classical identity

$$\frac{d}{dt}\vec{P}_{i+1} = \frac{d}{dt}\vec{P}_i + \vec{\omega}_i \wedge \vec{P}_iP_{i+1} \quad \text{for } 0 \leq i \leq n \quad (34)$$

where $\bar{\omega}_i$ is the angular velocity about the vertical axis of the i th vehicle's body.

This yields the following equations

$$\begin{aligned} v_{n+1} &= r\omega \\ v_i &= v_{i+1} \cos(\alpha_{i+1}) \quad (0 \leq i \leq n) \\ \alpha_0 &= v_0^{-1} \frac{\tan(\alpha_1)}{l_1} \\ \dot{\alpha}_i &= v_i \left(\frac{\tan(\alpha_{i+1})}{l_{i+1}} - \frac{\sin(\alpha_i)}{l_i} \right) \quad (1 \leq i \leq n). \end{aligned} \quad (35)$$

We note that the set of variables α_i entirely characterizes the relative positioning of each vehicle with respect to the others.

The remaining equations must describe the motion of one of the vehicles with respect to the path we would like this vehicle to follow. To this purpose, we choose the first vehicle (i.e., the last trailer) and the position coordinates of the point P_0 .

The path to be followed by this point is denoted as (C) . For the sake of simplicity, we consider a smooth simple curve defined by one of its point, the unitary tangent vector at this point, and its curvature $\text{curv}(s)$, with s being the curvilinear coordinate along the curve. Moreover, it is assumed that

- $\text{curv}(s)$ is differentiable $(n+1)$ times. This is necessary for P_0 to be able to remain on (C) without stopping, as it will later appear.
- The radius of any circle tangencing (C) at two or more points and the interior of which does not contain any point of the curve is lowerbounded by some positive real number denoted as r_{\min} . The set of the circles' centers so defined is the Voronoi diagram associated with the curve [33]. This assumption implies in particular that $|\text{curv}(s)| \leq 1/r_{\min}$, $\forall s$. For example, if (C) is a straight line, then $r_{\min} = +\infty$ and $\text{curv}(s) = 0$. If (C) is a circle, then r_{\min} is the circle's radius and $\text{curv}(s) = 1/r_{\min}$.

Under these assumptions, if the distance between P_0 and (C) is smaller than r_{\min} , there is a unique point on (C) , denoted as $P_{0,\text{proj}}$, so that $\|P_0 P_{0,\text{proj}}\|$ is equal to this distance (see Fig. 2).

Let s denote the curvilinear coordinate at the point $P_{0,\text{proj}}$, and $(P_{0,\text{proj}}; \vec{t}, \vec{n})$ the Frenet frame on the curve at this point. The position of P_0 in the plane is completely characterized by the pair of variables (s, y) where y is the intensity of the vector $\vec{P}_{0,\text{proj}} P_0$, i.e.,

$$P_{0,\text{proj}} P_0 = y \vec{n}. \quad (36)$$

Note that in the particular case where (C) is a straight line, s and y coincide with classical Cartesian coordinates. For other curves, one of the control objectives will be to keep the coordinate y smaller than r_{\min} all the time so as to avoid any ambiguity when using the parameterization (s, y) .

This parameterization has previously been proposed in [29] for the control of a unicycle-type vehicle. While it is primarily used here for feedback control purposes, it is also related to the approach developed in [21] for path planning, as shown in the next section.

Let:

- θ_i denote the angle between \vec{v}_0 and $\vec{t}(s)$

- $\theta = \alpha_0 - \theta_i$ the angle between the first vehicle's body and the curve's tangent vector \vec{t} . When the first vehicle follows (C) exactly, with a nonzero translational velocity, θ can only take values equal to $k\pi$ ($k \in \mathbb{Z}$). Without loss of generality one may assume that the desired value for the angle θ is zero.

The following equations for the first vehicle (see also [29]) are then easily derived

$$\begin{aligned} \dot{s} &= v_0 \frac{\cos(\theta)}{1 - \text{curv}(s)y} \\ \dot{y} &= v_0 \sin(\theta) \\ \dot{\theta}_i &= \text{curv}(s) \dot{s} \\ &= v_0 \frac{\text{curv}(s) \cos(\theta)}{1 - \text{curv}(s)y}. \end{aligned} \quad (37)$$

By regrouping (35) and (37) one obtains the following control system

$$\dot{X} = g_1(X) v_0 + g_2 v_2 \quad (38)$$

with

$$X = \begin{bmatrix} s \\ y \\ \theta \\ \alpha_1 \\ \vdots \\ \alpha_{n+1} \end{bmatrix} \quad \dim(X) = n+1$$

$$\begin{aligned} v_0 &= r\omega \prod_{i=4}^{i=n+4} \cos(x_i) \\ v_2 &= \dot{x}_{n+4} \end{aligned}$$

$$g_{1,1}(X) = \frac{\cos(x_4)}{1 - \text{curv}(x_1)x_2}$$

$$g_{1,2}(X) = \sin(x_4)$$

$$g_{1,3}(X) = \frac{\tan(x_4)}{l_1} - \frac{\text{curv}(x_1)\cos(x_3)}{1 - \text{curv}(x_1)x_2}$$

$$g_{1,4}(X) = \frac{1}{\cos(x_4)} \left(\frac{\tan(x_5)}{l_2} - \frac{\sin(x_4)}{l_1} \right)$$

\vdots

$$g_{1,j}(X) = \frac{1}{\prod_{l=4}^{l=j} \cos(x_l)} \left(\frac{\tan(x_{j+1})}{l_{j-2}} - \frac{\sin(x_j)}{l_{j-3}} \right)$$

\vdots

$$g_{1,n+4}(X) = 0$$

$$g_2 = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}.$$

This control system characterizes our mechanical system, as long as X belongs to the set

$$\Omega = R \times]-r_{\min}, +r_{\min}[\times R \times \left(]-\frac{\pi}{2}, +\frac{\pi}{2}[\right)^{n+1}. \quad (39)$$

Although controllability of the mechanical system in $R^3 \times SO_1^{n+1}$ (i.e., the possibility of steering the system between any two configurations in finite time) has been theoretically established (see [13]), for example, the control design and analysis is hereafter limited to the set Ω . In particular, the angles α_i ($1 \leq i \leq n+1$) are bound to stay in the interval $]-\pi/2, +\pi/2[$. For most practical purposes, this is not restrictive. Moreover, undesirable "jack-knife" effects will systematically be avoided in this way.

B. About Path Planning

As already mentioned, the angle θ must be equal to zero (or π) when P_0 moves along the desired path. This also means that the time-derivative of this angle must be equal to zero. Thus, according to the third equation of the above system, and since y is also equal to zero along the path, one must have

$$\tan(\alpha_1) = \begin{cases} +l_1 \text{curv}(s) & \text{if } \theta = 0 \\ -l_1 \text{curv}(s) & \text{if } \theta = \pi \end{cases} \quad (40)$$

By taking the time derivative of this last equation and comparing the result with the fourth system's equation, one obtains after simple calculations

$$\tan(\alpha_2) = \begin{cases} \frac{l_2}{l_1^2 \text{curv}(s)^2 + 1} \left(\text{curv}(s) + \frac{l_1 \text{curv}^{(1)}(s)}{l_1^2 \text{curv}(s)^2 + 1} \right) & \text{if } \theta = 0 \\ \frac{l_2}{l_1^2 \text{curv}(s)^2 + 1} \left(\text{curv}(s) - \frac{l_1 \text{curv}^{(1)}(s)}{l_1^2 \text{curv}(s)^2 + 1} \right) & \text{if } \theta = \pi \end{cases} \quad (41)$$

where $\text{curv}^{(1)}(s)$ is the first derivative (with respect to the curvilinear coordinate) of the path's curvature.

Repeating the above procedure ($n-1$) times, one would obtain that, along the desired path and for each of the two possible values of θ , the angles α_i ($1 \leq i \leq n+1$) are functions of the path's curvature and its successive derivatives up to the order $(i-1)$. Moreover, one may verify that the correspondence from $]-\pi/2, +\pi/2[^{n+1}$ onto R^{n+1} between the set of angles $\{\alpha_i\}_{1 \leq i \leq n+1}$ and the set $\{\text{curv}^{(i)}(s)\}_{0 \leq i \leq n}$ is one-to-one.

A direct consequence of this fact is that the problem of steering the system between any two configurations (satisfying the aforementioned condition imposed on the range of the angles α_i) can be addressed as a purely geometrical problem consisting of finding a planar path of class C^{n+3} which connects two given points (corresponding to the initial and final position of the point P_0), with given tangents at these points (corresponding to initial and final values of α_0), and conditions imposed on the curvature and its n successive derivatives at both extremities of the path (corresponding to initial and final values of angles α_i ($1 \leq i \leq n+1$)). Since such a path obviously exists, one finds again in this way that the system is controllable in Ω .

The possibility of parameterizing the vehicle's motion by the curvature, and its derivatives, of the path drawn by the first vehicle has been here derived from the system's error equation (38). In [21], this possibility, which yields the above formulation of the path planning problem, is presented as a more general consequence of the system's flatness.

It may also be noted that there is an abundance of methods dealing with this type of geometrical problem. Solution methods proposed in this domain, such as widely used Bezier's polynomial curves (splines) for example [2], could thus be of interest for people working on mobile robot path planning problems and yield methods complementary to those already explored.

C. Smooth Feedback Controls for Path Following and Stabilization about a Fixed Desired Configuration

To apply the results of Section II, system (38) should first be converted into the chain form (1), or, equivalently, to the skew-symmetric chain form (13).

We first rewrite the original system as follows

$$\dot{X} = f_1(X)u_1 + g_2\dot{x}_{n+4} \quad (42)$$

with

$$u_1 = v_0 \frac{\cos(x_3)}{1 - \text{curv}(x_1)x_2}$$

$$\begin{aligned} f_{1,1} &= 1 \\ f_{1,2}(X) &= \frac{1 - \text{curv}(x_1)x_2}{\cos(x_3)} g_{1,2}(x_3) \\ f_{1,3}(X) &= \frac{1 - \text{curv}(x_1)x_2}{\cos(x_3)} g_{1,3}(x_1, x_2, x_3, x_4) \\ f_{1,4}(X) &= \frac{1 - \text{curv}(x_1)x_2}{\cos(x_3)} g_{1,4}(x_1, x_5) \end{aligned}$$

$$\begin{aligned} f_{1,n+3}(X) &= \frac{1 - \text{curv}(x_1)x_2}{\cos(x_3)} g_{1,n+3}(x_4, \dots, x_{n+4}) \\ f_{1,n+4} &= 0. \end{aligned}$$

This control system is equivalent to the original one within the reduced set

$$\Omega_{\text{reduced}} = R \times]-r_{\min}, +r_{\min}[\times \left(]-\frac{\pi}{2}, +\frac{\pi}{2}[\right)^{n+2} \subset \Omega.$$

In particular, due to the choice of the input u_1 , the variable x_3 (i.e., the orientation error θ) has to be kept in the interval $]-\frac{\pi}{2}, +\frac{\pi}{2}[$.

This control system is directly converted into a skew-symmetric chain form via the change of coordinates $\phi_2: X \mapsto Z$, with

$$\begin{aligned} z_1 &= x_1 \\ z_2 &= h_y(x_2) \\ z_3 &= f_{1,2}(x_1, x_2, x_3) \frac{\partial h_y}{\partial x_2} \\ z_4 &= k_1 z_2 + L_{f_1} z_3 \end{aligned}$$

$$z_{j+3} = k_j z_{j+1} + L_{f_1} z_{j+2} \quad (j \leq 2 \leq n+1)$$

(43)

where $h_y(x_2)$ is a smooth monotonic function which maps $]-r_{\min}, +r_{\min}[$ onto R , with first derivative strictly larger than a positive real number, and such that $h_y(0) = 0$. For

example, $h_y(x_2) = (2r_{\min}/\pi)\tan(\pi y/2r_{\min})$ is a possible candidate when $r_{\min} < +\infty$. If $r_{\min} = +\infty$, the simplest choice is $h_y(x_2) = x_2$. This function is introduced here to force $|y(t)| = |x_2(t)|$ to remain smaller than r_{\min} in the subsequent control analysis.

One can verify that the Jacobian matrix $(\partial\phi_2/\partial X)$ is a lower triangular matrix with nonzero components d_i on the diagonal given by

$$D_1 = 1$$

$$d_2 = \frac{\partial h_y}{\partial x_2}$$

$$d_3 = \frac{1 - \text{curv}(x_1)x_2}{\cos(x_3)^2} \frac{\partial h_y}{\partial x_2}$$

$$d_4 = \frac{(1 - \text{curv}(x_1)x_2)^2}{l_1 \cos(x_3)^3 \cos(x_4)^2} \frac{\partial h_y}{\partial x_2}$$

$$d_{n+4} = \frac{(1 - \text{curv}(x_1)x_2)^{n+2}}{(\prod_{i=1}^{i=n+1} l_i)(\prod_{j=3}^{j=n+4} \cos(x_j)^{n+6-j})} \frac{\partial h_y}{\partial x_2}$$

All other components are well defined in Ω_{reduced} . This matrix is thus defined and nonsingular on Ω_{reduced} . Moreover, $\phi_2(\Omega_{\text{reduced}}) = R^{n+4}$. Thus, according to the theorem 0.5 in [23, p. 13], ϕ_2 induces a diffeomorphism of class C^{n+1} ($n+1$ being the degree of differentiability of $\text{curv}(x_1)$) between Ω_{reduced} and R^{n+4} .

Then, by using

$$L_{g_2} L_{f_1}^j z_{i+3} = 0 \quad (0 \leq i \leq n, 0 \leq j \leq n-i) \quad (44)$$

and

$$L_a L_{f_1}^{n+1} z_3 = \frac{(1 - \text{curv}(x_1)x_2)^{n+2}}{(\prod_{i=1}^{i=n+1} l_i)(\prod_{j=3}^{j=n+4} \cos(x_j)^{n+6-j})} \frac{\partial h_y}{\partial x_2}(x_2) \quad (45)$$

it is easy to verify that the control system, with Z as state vector, has the form (13), with the auxiliary control input w_2 defined by

$$w_2 = (k_{n+2}z_{n+3} + L_{f_1} z_{n+4})u_1 + (L_{g_2} L_{f_1}^{n+1} z_3)u_2. \quad (46)$$

Once the system has been put into the skew-symmetric chain form, there only remains to apply Proposition 2.1 to determine a control input w_2 which stabilizes the point $Z_2 = 0$ and thus make the mechanical system follow the path (C) . One can also apply Proposition 2.2 to determine smooth time-varying feedbacks which make the system converge to a given configuration on the path.

Note that stability is only local in this case since the state vector X must belong to Ω_{reduced} . This implies that the angles θ and α_i ($1 \leq n+1$) must have initial values in $]-\frac{\pi}{2}, +\frac{\pi}{2}[$, and that the initial distance $|y(0)|$ must be smaller than r_{\min} .

Remark: The method described above allows asymptotically stabilizing the mechanical system to any configuration so that $|\alpha_i| < (\pi/2)$ ($1 \leq n+1$). In other studies ([22],

[32]), for example, only configurations with zero angles α_i (all trailers aligned) have been considered.

D. A Modification to Broaden the Stability Domain

A practical shortcoming of the above control design method is the necessity of starting with an orientation error $|\theta|$ smaller than $\pi/2$.

This limitation can be removed by considering a more global change of coordinates which converts the initial control system to a modified chain form.

This modification was implicitly used in [29] in the particular case of a unicycle-type vehicle, and simulation results can be found in the same reference.

The new transformation $\phi_3: X \mapsto Z$ that is considered is the following

$$z_1 = x_1$$

$$z_2 = h_y(x_2)$$

$$z_3 = x_3$$

$$z_4 = k_1 \frac{\sin(x_3)}{x_3} \frac{\partial h_y}{\partial x_2}(x_2)z_2 + g_{1,3}(x_1, x_2, x_3, x_4)$$

$$z_j = k_2 z_3 + L_{q_1} z_4$$

$$z_{j+4} = k_{j+1} z_{j+2} + L_{q_1} z_{j+3} \quad (2 \leq j \leq n)$$

(47)

where

- $g_1(X)$ is the vector field involved in the system's representation (38)
- k_j ($1 \leq j \leq n+1$) are positive real numbers
- $h_y(x_2)$ is the monotonic function introduced before.

Remark: Instead of $z_3 = x_3$, one may also take $z_3 = h_\theta(x_3)$, with $h_\theta(x_3)$ being a smooth monotonic function, alike $h_y(x_2)$, which maps an open interval containing $]-\pi, +\pi[$ into R . For example, $h_\theta(x_3) = \tan(kx_3)$ with $k < (1/2)$ can be used. In this case the coordinate z_4 becomes $z_4 = k_1(\sin(x_3)/h_\theta(x_3))(\partial h_y/\partial x_2)(x_2)z_2 + g_{1,3}(x_1, x_2, x_3, x_4)$, and all subsequent coordinates are modified accordingly.

One can verify that $\phi_3(\Omega) = R^{n+4}$ and that the Jacobian matrix $(\partial\phi_3/\partial X)$ is a lower-triangular matrix with nonzero components on the diagonal equal to 1, $(\partial h_y/\partial x_2)(x_2)$, 1, $1/(l_1 \cos(x_4)^2)$, $1/(l_1 l_2 \cos(x_4)^3 \cos(x_5)^2), \dots, 1/((\prod_{i=1}^{i=n+1} l_i)(\prod_{j=4}^{j=n+4} \cos(x_j)^{n+6-j}))$.

The change of coordinates ϕ_3 thus induces a diffeomorphism of class C^{n+1} between Ω and R^{n+4} .

Then, by using

$$L_{g_2} L_{q_1}^j z_{i+3} = 0 \quad (0 \leq i \leq n, 0 \leq j \leq n-i) \quad (48)$$

$$L_{g_2} L_{q_1}^n z_4 = \frac{1}{(\prod_{i=1}^{i=n+1} l_i)(\prod_{j=4}^{j=n+4} \cos(x_j)^{n+6-j})} \quad (49)$$

with the following auxiliary control input w_2

$$w_2 = (k_{n+2}z_{n+3} + L_{g_1} z_{n+4})v_0 + (L_{g_2} L_{q_1}^n z_4)v_2 \quad (50)$$

it is simple to verify that the control system, expressed in terms of the new coordinates, has the following skew-symmetric chain form

$$\begin{aligned} \dot{z}_1 &= v_0 \frac{\cos(z_3)}{1 - \text{curv}(z_1)x_2} \\ \dot{z}_2 &= v_0 \frac{\sin(z_3)}{z_3} \frac{\partial h_y}{\partial x_2}(x_2)z_3 \\ \dot{z}_3 &= -k_1 v_0 \frac{\sin(z_3)}{z_3} \frac{\partial h_y}{\partial x_2}(x_2)z_2 + v_0 z_4 \\ \dot{z}_4 &= -k_2 v_0 z_3 + v_0 z_5 \end{aligned}$$

$$\dot{z}_{j+4} = -k_{j+2} v_0 z_{j+3} + v_0 z_{j+5} \quad (1 \leq j \leq n-1)$$

$$\dot{z}_{n+4} = -k_{n+2} v_0 z_{n+3} + w_2 \quad (51)$$

with $x_2 = h_y^{-1}(z_2)$, and $v_0 = r\omega \prod_{i=1}^{n+4} \cos(x_i)$.

Although this system is not exactly the same as the skew-symmetric chained system (13), a result very similar to Proposition 2.1 can be derived for path following.

Proposition 3.1: If $|v_0(t)|$ and $|\dot{v}_0(t)|$ are bounded, and if the control

$$\begin{aligned} w_2 &= -k_{w_2}(v_0)z_{n+4} \\ (k_{w_2}(\cdot)) &: \text{continuous application strictly positive on } R \setminus \{0\} \end{aligned} \quad (52)$$

is applied to system (51), then the positive function

$$\begin{aligned} V(Z_2) &= 1/2(z_2^2 + (1/k_1)z_3^2 + (1/k_1 k_2)z_4^2 \\ &\quad + \cdots + \left(1/\prod_{j=n+2}^{j=n+4} k_j\right)z_{n+4}^2) \end{aligned} \quad (53)$$

is nonincreasing along the system's solutions, and thus asymptotically converges to some limit value V_{\lim} (which *a priori* depends on the initial conditions).

Moreover, $v_0(t)V(Z_2(t))$ asymptotically converges to zero.

Therefore, if $v_0(t)$ does not converge to zero, then $V_{\lim} = 0$. The submanifold $Z_2 = 0$ is thus globally asymptotically stabilized in this case.

Proof of Proposition 3.1: The proof is quite similar to the proof of Proposition 2.1 except that one has to show at some point that the convergence of $v_0(\sin(z_3)/z_3)(\partial h_y/\partial x_2)(x_2)z_2$ and $v_0 z_3$ to zero yields the convergence of $v_0 z_2$ to zero.

Since $|z_2(t)|$ is bounded (from the boundedness of the Lyapunov function), $(\partial h_y/\partial x_2)(x_2(t))$ is also upperbounded, and $v_0 z_3(\partial h_y/\partial x_2)(x_2)z_2$ thus tends to zero. Therefore, $v_0^2(((\sin(z_3)/z_3))^2 + z_3^2)((\partial h_y/\partial x_2)(x_2))^2 z_2^2)$ also tends to zero.

By assumption, $(\partial h_y/\partial x_2)(x_2)$ is bounded from below by a positive real number. Moreover, the function $((\sin(z_3)/z_3))^2 + z_3^2$ is itself larger than some positive real number. Along a system's solution, it is also bounded from above, since $|z_3(t)|$ is bounded. Using these bounds in the previous convergence result, it is found that $v_0^2 z_2^2$ tends to zero. \diamond

The remarks made after Proposition 2.1 also hold in this case. In particular, adequate values for the control "gains"

k_j ($1 \leq j \leq n+2$) can be determined by comparing, in the neighborhood of $Z_2 = 0$, the control u_2 provided by the proposition and relation (50), with the linearizing feedback (7). Since these gains do not *a priori* depend on the path's shape one may also use, for this comparison, a simpler linear control calculated from the system's tangent linear approximation about the equilibrium ($Z_2 = 0, u_2 = 0$), assuming that the path to be followed is a straight line and that the velocity v_0 is constant.

The problem of stabilizing the system to a fixed desired configuration requires asymptotical convergence of the full state vector Z to zero. A smooth time-varying feedback solution is given in the next complementary proposition.

Proposition 3.2. Consider the same control as in Proposition 3.1

$$w_2 = -k_{w_2}(v_0)z_{n+4} \quad (54)$$

complemented with the following time-varying control

$$v_0 = -k_{v_0} h_s(z_1) + h(Z_2, t) \quad (55)$$

where:

- k_{v_0} is a positive real number.
- $h_s(\cdot)$ is a function of class C^2 which maps R into a bounded interval of R , and such that: i) $h_s(0) = 0$, ii) $0 < h_s^{(1)}(x) < +\infty, \forall x$, and iii) $|h_s^{(2)}(x)| < +\infty, \forall x$. Take for example, the sigmoid function: $h_s(x) = (\exp(ax) - 1/\exp(ax) + 1)$ ($a > 0$).
- $h(Z_2, t)$ is a function with the same properties as in Proposition 2.2.

This control globally asymptotically stabilizes the origin $Z = 0$ of the system (51).

Proof of Theorem 3.2: The first part of the proof consists in showing that $v_0(t)$, and its time derivative are bounded along any system's solution.

Since $\|Z_2(t)\|$ is bounded (due to the boundedness of the Lyapunov function considered in Theorem 3.1), it is clear, from the expression of the control v_0 and the properties of the functions $h_s(z_1)$ and $h(Z_2, t)$, that $|v_0(t)|$ is bounded. As a consequence, $\|\dot{Z}(t)\|$ is also bounded.

Taking the time derivative of the v_0 control law expression

$$\dot{v}_0 = \left[-k_{v_0} h_s^{(1)}(z_1), \frac{\partial h}{\partial Z_2} \right] \dot{Z} + \frac{\partial h}{\partial t} \quad (56)$$

which, in view of the boundedness of $\|Z_2(t)\|$ and $\|\dot{Z}(t)\|$, implies that $|\dot{v}_0(t)|$ is bounded.

Although v_0 is not, strictly speaking, a function of time only (since it is a feedback control), it can be viewed as such along any system's solution, and the results of Proposition 3.1 do apply.

In particular, if $v_0(t)$ does not tend to zero, then $\|Z_2(t)\|$ tends to zero. In this case, $h(Z_2(t), t)$ tends to zero (from condition C_1 and by uniform continuity). From the first system's equation, we also have

$$\dot{z}_1(t) = -k_{v_0} h_s(z_1(t)) + o(t) \quad \text{with } \lim_{t \rightarrow \infty} o(t) = 0. \quad (57)$$

Using the properties of the function $h_s(\cdot)$, the equation implies that the following proposition is true

$$\forall \epsilon > 0, \exists \eta > 0, \exists t_0 : (t > t_0 \text{ and } |z_1(t)| \geq \epsilon) \\ \Rightarrow (z_1(t)\dot{z}_1(t) < -\eta). \quad (58)$$

Since $z_1^2(t)$ cannot remain larger than ϵ^2 with a negative derivative smaller than $-\eta$, there is a time $t_1 (\geq t_0)$ such that $|z_1(t_1)| < \epsilon$. Moreover, after the time t_1 , $|z_1(t)|$ remains smaller than ϵ (since ϵ^2 cannot be reached from below by $z_1^2(t)$ with a negative derivative). The above proposition thus implies

$$\forall \epsilon > 0, \exists t_1 : (t > t_1) \Rightarrow (|z_1(t)| < \epsilon). \quad (59)$$

This is a characterization of the convergence of $z_1(t)$ to zero. In view of the expression of v_0 , this in turn implies that $v_0(t)$ tends to zero (contradiction).

Therefore $v_0(t)$ must tend to zero, implying in turn that $w_2(t)$ and $\dot{z}(t)$ tend to zero. Now, in view of (56)

$$\dot{v}_0(t) = \frac{\partial h}{\partial t}(Z_2(t), t) + o(t).$$

Since $(\partial h / \partial t)(Z_2(t), t)$ is uniformly continuous (its time derivative is bounded), $\dot{v}_0(t)$ tends to zero (Barbalat's lemma). Therefore, $(\partial h / \partial t)(Z_2(t), t)$ also tends to zero. From there, the proof goes on like the proof of Proposition 2.2. \diamond

IV. CONCLUSION

New results about feedback control of chained systems and their application to path following and point stabilization of nonholonomic mobile robots have been presented.

Throughout the paper, feedback control design and analysis have been performed via explicit Lyapunov techniques which apply naturally once the original chain form has been transformed into an equivalent form termed here skew-symmetric chain form. Asymptotical stabilization of the origin of a n -dimensional chained system has been achieved via a two-step approach which allows path following and point stabilization of mobile robots to be treated within the same framework. This approach yields a simple way of determining globally stabilizing smooth time-varying feedbacks the underlying structure of which is easily interpreted. It also applies to the determination of Hölder continuous time-periodic feedbacks which ensure K -exponential stabilization of the origin, as illustrated in [30] in the three-dimensional case. Several smooth and nonsmooth solutions to the point stabilization problem have then been tentatively compared by recalling and commenting upon the type of stability associated with each of them.

Application to path following and point stabilization of a car pulling trailers has been addressed in the second part of the study, based on a specific parameterization of the system's configuration which facilitates the decoupling of the path following problem from translational velocity control and yields general model equations in the chain form. Finally, it has been shown how, by an adequate choice of the system's state coordinates and a slight modification of the original chain form, it is possible to derive feedback control laws endowed with a larger stability domain.

ACKNOWLEDGMENT

The author is grateful to his colleague J.-B. Pomet for his insightful remarks and suggestions.

Input-Output Robust Tracking Control Design for Flexible Joint Robots

Zhihua Qu

Abstract—This paper presents the first input-output robust control design for the trajectory following problem of a flexible-joint robot manipulator. The proposed design provides a class of controllers which only require position and velocity feedback and ensure global stability. The resulting stability is that the tracking error can be made to be smaller than a design parameter arbitrarily chosen by the designer. The proposed control is robust since it guarantees tracking performance in the presence of high-order nonlinear uncertainties including unknown joint elasticity, unknown parameters, load variation, and disturbances. Practically, it is more important that no measurement on acceleration, jerk, or position and velocity deformation is required.

I. INTRODUCTION

Control design for robot manipulators with joint flexibility has attracted much attention from control researchers in recent years. The main reason is that, as shown by experimental study in [24], joint flexibility must be taken into account in both modeling and control design to achieve high tracking performance. Common sources of joint flexibility are gear elasticity (for example, harmonic drives), shaft windup, etc. One of the models of flexible joint robots was presented in [20] in which some energy terms are neglected. Nevertheless, most researchers have adopted this approximate model, and we choose to use this model as well in this paper.

Several methods, such as feedback linearization, observer design, adaptive control, singular perturbation, and robust control, have been investigated to design effective control for flexible joint robots. A list of references on these results can be found in the survey paper [22]; we shall only give a brief synopsis of the most recent developments and provide a comparison of different approaches. In feedback linearization method [20, 10], control is designed based on feedback linearization transformation which requires the knowledge of the dynamics and acceleration and jerk measurements. Under the assumption that joint flexibility is "small," there are two time scales in system dynamics, and a control can be designed using singular perturbation technique. Adaptive version of this slow/fast control was studied in [5]–[7]. The resulting control is intuitively simple since it usually contains two parts: a control for rigid body and a corrective control; the control, however, does not guarantee global stability. The most recent adaptive control scheme proposed in [11] guarantees global stability under the standard assumption that dynamics can be fully parameterized. On the front of robust control design, local stability was shown [19] which can be viewed as an extension of robust control results for rigid robots [14], [16]. Later, a robust control guaranteeing global stability was presented in [3]; this full state feedback robust control design is

an application of the result in [18] and an extension of the robust control law [2] for rigid robots. Hybrid control, or combined robust and adaptive control, of flexible joint robots has also been studied [15], [4].

So far all existing control laws for elastic robots require full state feedback. There are some results [12], [25] on designing state observer for flexible joint robots and on the subject of how to close the control loop, that is, how to design a control based on the estimates of the states [13]. The result in [13] combines high-gain observer with high-gain controller to guarantee local stability. Since the separation principle does not hold, in general, for nonlinear systems, it appears unlikely that full state feedback control can be changed to an estimate-based control to guarantee global stability.

In the present paper we consider for the first time the input-output (I/O) control problem of flexible joint manipulators. The control objective is to design a robust control which guarantees global stability and good tracking performance but requires only feedback of link position and velocity. The proposed design method is inspired by the recent result [17] on robust input-output design of mainly linear systems. The proposed control design is not only more attractive in practice since it requires less feedback information, but also allows the presence of significant but bounded nonlinear uncertainties including fast time varying parameters, modeling errors, load change, and unknown flexibility.

The paper is organized as follows. In Section II, dynamics of flexible joint robots and its properties are presented, and necessary assumptions are introduced. In Section III, input-output robust control design is proceeded. Simulation results are presented in Section IV. Finally, some conclusions are made in Section V.

II. PROBLEM FORMULATION

We shall consider the dynamics of a robot with flexible joints to be described by the following nonlinear differential equations

$$0 = M(q_1)\ddot{q}_1 + N(q_1, \dot{q}_1) + K(q_1 - q_2), \quad (1)$$

$$J\ddot{q}_2 = K(q_1 - q_2) - D\dot{q}_2 + \tau + P(q_1, \dot{q}_1) \quad (2)$$

where q_1 and q_2 represent $n \times 1$ vectors of joint angles and motor angles, respectively, τ is $n \times 1$ the control vector of motor output torques, $M(q_1)$ is an $n \times n$ inertia matrix (symmetric and positive definite) for the rigid links, and K is a diagonal matrix representing the joint stiffness. In (1), $N(q_1, \dot{q}_1) = V_m(q_1, \dot{q}_1)\dot{q}_1 + G(q_1) + F_d\dot{q}_1 + F_s(q_1) + T_d$, $V_m(q_1, \dot{q}_1)$ is an $n \times n$ matrix of centripetal and Coriolis terms, $G(q_1)$ is an $n \times 1$ vector of gravity terms, F_d is an $n \times n$ diagonal matrix of dynamic friction coefficients, $F_s(q_1)$ stands for static friction, and T_d denotes the lumped sum of all bounded disturbances and is in general a unknown nonlinear functional of q_1, \dot{q}_1 . In (2), J is a diagonal matrix of actuator inertias reflected to the link side of the gears, D is also a diagonal matrix of torsional damping coefficients, and $P(q_1, \dot{q}_1)$ denotes any possible nonlinearity whose bounding function depends only on q_1 and \dot{q}_1 .

Let q_1^d characterize the desired, smooth trajectory that the robot should track. The assumption of q_1^d being smooth implies that \dot{q}_1^d and

derivatives up to the second order are continuous and bounded sections of time. The following are the other important properties and assumptions on robot dynamics that will be used in this paper.

- P.1) As shown in [1], the inertia matrix satisfies that, for all $q_1 \in \mathcal{R}^n$, $M I_n \leq M(q_1) \leq \bar{m}(q_1) I_n$ some for known constant \underline{m} and nonnegative function $\bar{m}(q_1)$, where $I_n \in \mathcal{R}^{n \times n}$ is the identity matrix. Function $\bar{m}(q_1)$ reduces to a constant for robots with only revolute joints.
- P.2) It has been shown in [1] that $V_m(q_1, \dot{q}_1)$ is a function of at most of first order in q_1 and \dot{q}_1 . Therefore, there exist constants β_1 and β_2 such that $\|V_m(q_1, \dot{q}_1)\| \leq \beta_1 + \beta_2 \|x_1\| \triangleq \rho_1(x_1)$, where $\|\cdot\|$ denotes Euclidean norm, x_1 is the output vector defined by $x_1 = [e^T \dot{e}^T]^T$, and e is an $n \times 1$ vector representing the trajectory error, i.e., $e = q_1^d - q_1$.
- A.1) Unknown functionals in dynamics equations (1) and (2) include dynamic and static friction, bounded disturbances, etc. It is assumed that they be bounded by known functions as $\|G(q_1) + F_d \dot{q}_1 + F_v(\dot{q}_1)\| \leq \beta_3 + \beta_4 \|x_1\| \triangleq \rho_2(x_1)$, $\|T_d\| \leq \rho_3(x_1, t)$, $\|P(q_1, \dot{q}_1)\| \leq \rho_4(x_1)$, and $\|\dot{M}(q_1)\| \leq \rho_5(x_1)$.
- A.2) The feedback information for control design are only the measurements of joint position and velocity, i.e., q_1 and \dot{q}_1 . The position and velocity deformations $q_2 - q_1$ and $\dot{q}_2 - \dot{q}_1$ are unknown, but initial deformations are bounded, that is, $\|x_2(t_0) - x_1(t_0)\| \leq \rho_6$ or $\|x_2(t_0)\| \leq \rho_7$ for some constant ρ_6 or ρ_7 , where x_2 is the internal state defined by $x_2 = [q_2^T \dot{q}_2^T]^T$.
- A.3) It is physically guaranteed by the property of matrices J , D , $K > 0$ that the fictitious system

$$J\ddot{v} + D\dot{v} + Kv = \ddot{f} + 2\dot{f} + f \quad (3)$$

is uniformly asymptotically stable [23], [8] under zero fictitious input $f(t) = 0$. That is, there exist constants γ_0 , γ_1 , and γ_2 such that the state transition matrix $\Phi(t, t_0)$ associated with (3) satisfies the inequality $\|\Phi(t, t_0)\| \leq \gamma_0 \delta(t) + \gamma_1 e^{-\gamma_2(t-t_0)}$ for all $t \geq t_0$, where $\delta(t)$ is the standard impulse function.

The parameter matrices K , J , and D are unknown and time varying, their values are limited within compact sets as $0 < \underline{K} \leq K \leq \bar{K}$, $0 < \underline{J} \leq J \leq \bar{J}$, $0 < \underline{D} \leq D \leq \bar{D}$, and their derivatives up to the third order are assumed to be bounded.

It is worth making several remarks here about the properties and assumptions listed above. First, for notational simplicity, we consider here the worst situation that no information on dynamics except their bounding functions is known. In many applications in which part of the dynamics are known, only the unknown dynamics need to be bounded since known dynamics can be compensated directly by some nominal (or standard) control law and since only the unknown dynamics have to be bounded and consequently compensated by robust control. The second remark is about Assumption A.3). If the matrices J , D , and K are constants, a lower bound on convergence rate, γ_2 , can be determined from their upper and lower bounds. If the matrices are slowly time varying (that is, time varying parts belong to some space such as L_1 or L_2), γ_2 can also be found by invoking the results in [9]. Only in the case that the matrices are fast time varying, γ_2 has to be assumed since there is no closed-form solution. γ_2 can be estimated in this case, however, because system (3) is always stable. In the event that matrices J , D , and K are known and that there is no uncertainty in (2), the motor angle q_2 can be estimated using linear observer, and I/O control problem reduces to state feedback control problem. The assumption $D > 0$ may always be ensured

physically; although this assumption is needed to show stability under I/O control, the control to be proposed damping and in turn achieves stability of output tracking. This stability imposes no restriction on the value of D . Finally, it will be shown later that Assumption A.2) can be removed so that, in speaking, I/O control becomes globally stabilizing for the system.

The control problem addressed in this paper is to develop an input-output robust control design procedure for flexible joint robots. The main difference between this work and previous work on robust control in [3], [4] is that the control to be designed require only the input and output feedback information, i.e., τ and τ . Measurement of acceleration, or jerk, or deformation is not required. The control is called to be robust since it requires no exact knowledge of the systems, that is, nothing beyond the properties listed above. The control objective is to make the robot track any given trajectory with arbitrarily selected accuracy despite of unknown but bounded nonlinear dynamics.

We can rewrite system dynamics (2) into the following state-space representation

$$\dot{x}_2 = A_2 x_2 + B_2 [\tau + K q_1 + P(q_1, \dot{q}_1)], \quad q_2 = C_2 x_2 \quad (4)$$

where

$$A_2 = \begin{bmatrix} 0 & I_n \\ -J^{-1}K & -J^{-1}D \end{bmatrix}, \quad B_2 = \begin{bmatrix} 0 \\ J^{-1} \end{bmatrix},$$

$$C_2 = [I_n \quad 0], \quad x_2 = [q_2^T \dot{q}_2^T]^T.$$

In the general case that the matrices A_2 and B_2 are time varying, the solution to system (4) can be expressed in terms of transition matrix $\Phi(t, t_0)$ defined in Assumption A.3) as

$$q_2(t) = \Phi(t, t_0) * e^{-(t-t_0)} * [\tau + q_1 + P(q_1, \dot{q}_1)] \quad (5)$$

where initial conditions are assumed to be zero, and $*$ denotes the convolution operation.

III. ROBUST I/O CONTROL

To design control without feedback of motor angle q_2 , consider the following linear time-varying system

$$F(s, t)y = v + d \quad (6)$$

where y , v , and d are column vectors of n dimension, y is the output, v is the corresponding input, d is disturbance, and $F(s, t) = Js^2 + Ds + K$ is the so-called time-varying differential operator [23], [28]. That is, system (6) can be rewritten in terms of differential equation as $J\ddot{y} + D\dot{y} + Ky = v + d$.

The intermediate problem to be studied is under what input v the closed-loop system becomes

$$F_o(s)J_o^{-1}J_y y = v + d' \quad (7)$$

where J_o , D_o , and K_o represent any choice of nominal values of J , D , and K respectively, v is any reference input, d' is the equivalent disturbance, and differential operator $F_o(s)$ is given by $F_o(s) = J_o s^2 + D_o s + K_o$. A solution to this problem is provided by the following lemma. Its proof can be found in the Appendix.

Lemma 1: Choose the input v to be

$$v = G_3 y + r + \eta_1 + \eta_2 \quad (8)$$

where G_1 , G_2 , and G_3 are diagonal matrices, and η_1 and η_2 are auxiliary signals defined by

$$\dot{\eta}_1 = -\eta_1 + G_1 v, \quad \dot{\eta}_2 = -\eta_2 + G_2 y. \quad (9)$$

Then, there are unique choices for matrices G_i such that, under the input (8), system (6) is translated to (7) with $d' = (s+1)^{-1}(sI_n + I_n - G_1)d$.

The above lemma provides us a mean of designing I/O robust control. Now, reconsider dynamic equation (2) by rewriting it as

$$\begin{aligned} J\ddot{q}_2 + D\dot{q}_2 + Kq_2 &= \tau + Kq_1 + P(q_1, \dot{q}_1) \\ &= [G_3 q_2 + \tau + \eta_1 + \eta_2] + [Kq_1 + P(q_1, \dot{q}_1) \\ &\quad - G_3 q_2 - \eta_1 - \eta_2] \triangleq v + d \end{aligned}$$

where η_1 and η_2 are given by (9) with $r = \tau$ and $y = q_2$, and G_i are given by the solutions in the proof of Lemma 1 [i.e., (18)]. It follows from the discussion from Lemma 1 that dynamics (2) becomes

$$\ddot{q}_2' + J_o^{-1} D_o \dot{q}_2' + J_o^{-1} K_o q_2' = \tau + P'(q_1, \dot{q}_1, \zeta) \quad (10)$$

where $q_2' = Jq_2$, $\zeta_1 = e^{-t} * \tau$, $\zeta_2 = e^{-t} * \zeta_1$, $\zeta_3 = e^{-t} * \zeta_2$, $\zeta = [\zeta_1^T \zeta_2^T \zeta_3^T]^T$, and

$$\begin{aligned} P'(q_1, \dot{q}_1, \zeta) &= (s+1)^{-1}(sI_n + I_n - G_1) \\ &\quad \cdot [Kq_1 + P(q_1, \dot{q}_1) - G_3 q_2 - \eta_1 - \eta_2]. \end{aligned}$$

For now, the equivalent uncertainty $P'(q_1, \dot{q}_1, \zeta)$ contains the unmeasured state variable q_2 . Later, q_2 will be eliminated using solution (5), and then $P'(q_1, \dot{q}_1, \zeta)$ will be bounded by a known bounding function only of q_1 , \dot{q}_1 , ζ_3 for designing robust control.

It follows from (10) that the solution for q_2 is given by

$$\begin{aligned} q_2(t) &= J^{-1} C_2 e^{A_{2o} t} J_o' x_2'(t_0) + J^{-1} \bar{\tau} \\ &\quad + J^{-1} C_2 e^{A_{2o} t} B_{2o} J_o P'(q_1, \dot{q}_1, \zeta) \quad (11) \end{aligned}$$

where $x_2'(t_0) = [q_2^T(t_0)J(t_0) \dot{q}_2^T J(t_0) + q_2^T(t_0)\dot{J}(t_0)]^T$, A_{2o} and B_{2o} are the matrices A_2 and B_2 , respectively, with $J = J_o$, $K = K_o$, and $D = D_o$, and $\bar{\tau}$, a filtered version of τ , is defined and can be calculated by

$$\bar{\tau} = C_2 z, \quad z = [z_1^T \ z_2^T]^T, \quad \dot{z} = A_{2o} z + B_{2o} J_o \tau. \quad (12)$$

Substituting solution (11) into (1) yields the output error system

$$\dot{x}_1 = A_1 x_1 + B_1 (\Delta A - J^{-1} \bar{\tau} + q_1) \quad (13)$$

where

$$A_1 = \begin{bmatrix} 0 & I_n \\ -M^{-1}(q_1)K_p & 0 \end{bmatrix}, \quad B_1 = \begin{bmatrix} 0 \\ M^{-1}(q_1)K \end{bmatrix}$$

$\Delta A = K^{-1}K_p e_1 + K^{-1}M(q_1)\ddot{q}_1^T + K^{-1}N(q_1, \dot{q}_1) - J^{-1}C_2 e^{A_{2o} t} x_2'(t_0) - J^{-1}C_2 e^{A_{2o} t} B_{2o} J_o P'(q_1, \dot{q}_1, \zeta)$, and $K_p > 0$ is a diagonal gain matrix chosen by the designer.

Stability analysis and control design will be done using Lyapunov's direct method. To apply the Lyapunov technique, let us choose

Lyapunov function candidate, a positive definite function with respect to x_1 and $z = u$, to be

$$V = V_1 + V_2, \quad V_1 = \frac{1}{2} e_1^T K_p e_1 + \frac{1}{2} (\alpha e_1 + \dot{e}_1)^T M(q_1) (\alpha e_1 + \dot{e}_1),$$

$$V_2 = \frac{1}{2} (z - u)^T (z - u) \quad (14)$$

where u is the vector to be chosen later, and $\alpha > 0$ is a constant scalar. The following lemma illustrates the property of sub-Lyapunov function $V_1(x_1)$ along the trajectory of subsystem (13), and its proof is included in Appendix.

Lemma 2: Consider systems (1) and (2) under Properties P.1) and P.2) and Assumptions A.1), A.2), and A.3). The time derivative of the sub-Lyapunov function $V_1(x_1)$ satisfies the following inequality along the trajectory of system (13)

$$\dot{V}_1(x_1) \leq -\lambda_1 \|e_1\|^2 + \|w(x_1)\| \varphi_1(x_1, \zeta_3) - w^T(x_1) K J^{-1} \bar{\tau} \quad (15)$$

where $\lambda_1 = \alpha \lambda_{\min}(K_p)$, $\lambda_{\min}(\cdot)$, and $\lambda_{\max}(\cdot)$ represent the operation of taking the minimum and maximum eigenvalues, respectively, $w(x_1) \triangleq [\alpha I_n \ I_n] x_1 = \alpha e_1 + \dot{e}_1$, and $\varphi_1(x_1, \zeta_3)$ is a well-defined function only of x_1 and ζ_3 .

Note that bounding function $\varphi_1(x_1, \zeta_3)$ does not depend on internal state x_2 and only requires an estimate (or bound) on the initial condition of x_2 . In $\varphi_1(x_1, \zeta_3)$, only one of bounding terms on initial conditions is included and is denoted by that associated with ρ_7 . In the rest of the proofs of Lemmas 1 and 2, we choose to leave the terms of initial conditions out of bounding functions for simplicity, and we can remove the term containing ρ_7 as well. Although the system is highly nonlinear, this treatment is legitimate since nonzero initial conditions obtained in input-output modeling come from exponentially stable linear systems such as (11) and (9). Consequently, nonzero initial conditions contribute in \dot{V} only exponentially decaying time functions multiplied by terms that are linearly proportional in \dot{V} to the norm of the state. Note that Lyapunov function and its time derivative still have quadratic-like expressions. Thus, the terms associated with nonzero initial conditions can be combined with negative definite quadratic terms using the inequality $-a^2 + 2|a||b| \leq b^2$ to conclude the exactly same stability result. That is, Assumption A.2) can be removed, and nonzero initial conditions need not be considered in stability analysis. The trade-off of assuming zero initial conditions is that the terms bounding initial conditions may converge slow and therefore dominate the behavior of the overall system. By compensating nonzero initial conditions, convergence rate is what is designed and found in stability proof.

Upon having Lemma 1, we can proceed input-output robust control design, the proposed I/O controller is generated by the following recursive mapping

$$\begin{aligned} u &= [u_1^T \ u_2^T]^T, \quad u_1 = u_{11} + u_{12}, \quad u_2 = u_{21} + u_{22}, \\ u_{11} &= \alpha \bar{J} \bar{K}^{-1} \bar{m}(q_1) w(z_2), \\ u_{12} &= \bar{J} \bar{K}^{-1} \frac{\mu(x_1, \zeta_3, t) \|\mu_1(x_1, \zeta_3, t)\|^{v_1}}{\|\mu_1(x_1, \zeta_3, t)\|^{v_1+1} + \epsilon_1^{1+v_1}} \varphi_1(x_1, \zeta_3), \\ u_{21} &= \alpha(u_1 - z_1), \\ u_{22} &= \frac{\mu_2(x_1, z_1, \zeta_2, \zeta_3, t) \|\mu_2(x_1, z_1, \zeta_2, \zeta_3, t)\|^{v_2}}{\|\mu_2(x_1, z_1, \zeta_2, \zeta_3, t)\|^{v_2+1} + \epsilon_2^{1+v_2}} \\ &\quad \cdot g_2(x_1, z_1, \zeta_2, \zeta_3, t), \\ \tau &= \tau_1 + \tau_2, \quad \tau_1 = \alpha u_2 + u_1 + (J_o^{-1} K_o - I_n) z_1 \\ &\quad + (J_o^{-1} D_o - \alpha I_n) z_2, \\ \tau_2 &= \frac{\mu_3(x_1, z, \zeta, t)}{\|\mu_3(x_1, z, \zeta, t)\| + \epsilon_3} g_3(x_1, z, \zeta, t) \quad (16) \end{aligned}$$

here $\epsilon_k > 0$ and $\nu_j \geq 0$, $k = 1, 2, 3$ and $j = 1, 2$, are constants, the constants ν_j are chosen such that the first-order partial derivatives of u_{j2} with respect to their variables are well defined, and $\mu_1(x_1, \zeta_1, t) = w(x_1)\varphi_1(x_1, \zeta_1)$, $g_2(x_1, z_1, \zeta_2, \zeta_3, t) = \|\dot{u}_1\| + \|\bar{J}\|^{-1}\|\bar{K}\|$, $\mu_2(x_1, z_1, \zeta_2, \zeta_3, t) = (u_1 - z_1)g_2(x_1, z_1, \zeta_2, \zeta_3, t)$, $g_3(x_1, z_1, \zeta, t) = \|\dot{u}_2\|$, $\mu_3(x_1, z_1, \zeta, t) = (u_2 - z_2)g_3(x_1, z_1, \zeta, t)$.

The recursive mapping basically involves finding bounding functions of $\|\dot{u}_1\|$ and $\|\dot{u}_2\|$ for obtaining u_2 and τ , respectively. These bounding functions should not be functions of the state derivatives but only of the system state. To this end, the terms $\|\dot{u}_1\|$ and $\|\dot{u}_2\|$ can be bounded by first developing bounds for the first-order partial derivatives of u_i with respect to its variables and then by determining the bounds for the first-order time derivatives of its variables using dynamic equations (12) and (13). The bounding functions are usually obtained by taking the Euclidean norm. This design process yields that, since u_1 is a function of x_1 and ζ_1 , $g_2(\cdot)$ and therefore u_2 are functions of x_1 , ζ_2 , ζ_3 and z_1 , and that $g_3(\cdot)$ and therefore τ are functions of x_1 , ζ and z . As a result, the control design procedure is well defined. There have been several ways to guarantee differentiability of robust control [17]. In the case where there are known dynamics in the system, u_{11} should be modified to compensate. Similarly, u_{21} and τ_1 can be redesigned since not every term in \dot{u}_1 and \dot{u}_2 is uncertain. For simplicity, we leave the details to the reader.

We are now in a position to state the following theorem on control (16) which requires only input-output measurements and is robust with respect to any bounded parameters and uncertainties for manipulators with flexible joints. Its proof can be found in the Appendix.

Theorem: Consider system (1) and (2) under Properties P.1) and P.2) and Assumptions A.1), A.2), and A.3). If I/O robust controller τ is chosen to be the outcome of the mapping procedure (16), then, while all internal state variables are uniformly bounded, the trajectory tracking error x_1 (both e and \dot{e}) is globally and uniformly ultimately bounded. That is, as time approaches infinity, the magnitude of the tracking error characterized by $V_1(e, \dot{e})$ becomes no larger than the design parameter ϵ^* where

$$\epsilon^* = \frac{1}{2\alpha \min \left\{ \frac{\lambda_{\min}(K_p)}{\lambda_{\max}(K_p)}, 1 \right\}} \sum_{i=1}^l \epsilon_i.$$

Furthermore, the robust control τ is continuous and globally, uniformly bounded.

It should be noted that, for good transient performance under nonzero initial conditions, ϵ_i should be chosen to be proportional to the initial condition of measurable sub-state, $x_1(t_0)$. In this case, the stability of uniform ultimate boundedness becomes Lyapunov stability, and the stability is global since $x_1(t_0)$ is available as part of state feedback information. Under zero conditions, ϵ_i should be chosen to be any small constant.

IV. SIMULATION

To illustrate the effectiveness of the proposed input-output robust control scheme, consider a two-link flexible joint robot. An I/O robust controller will be designed for the robot using the nonlinear mapping (16). Each step in mapping (16) requires to find a bounding function for the time derivative of the previous fictitious controller and, if necessary, this derivation procedure can be automated using symbolic manipulation package. Note that a sophisticated nonlinear function of some variables can always be bounded by a simpler but

Fig. 1. Simulation with stiffness $K(t) = 100 + 90 \sin(0.5t)$

higher order polynomial functions of the same variables. Since the proposed control has complete robustness, even a control with oversimplified expressions works very well. Based on this observation, we choose robust controllers u_1 , u_2 , and τ in the form of (16) as follows: $\varphi_1 = (1 + \|x_1\|^2)/10$, $\bar{m}(q_1) = 2$, $\epsilon_1 = \epsilon_2 = \epsilon_3 = 1.0$, $\alpha = 35$, $K_p = I$, $\bar{J}K^{-1} = 5I$, $\nu_1 = \nu_2 = 2$, $D_o = 0.5I$, $K_o = 90I$, $J_o = I$, $g_2 = [1 + (\varphi_1)^2 + \|u_1 - z_1\|^2 + \|w\|^2]/10$, $g_3 = [1 + g_2^2 + \|u_2 - z_2\|^2]/10$. The auxiliary state z is defined by (12) using the nominal parameters J_o , D_o , and K_o .

For a two-link flexible joint robot, the expressions of $M(q)$ and $N(q, \dot{q})$ in the dynamic equation (1) can be found in [1]. For the simulation purpose, we made the following choices: $m_1 = m_2 = 1$, $I_1 = I_2 = 1$, $F_{d1} = F_{d2} = 0$, $J = I$, $D = I$, $K(t) = 100 + 90 \sin(0.5t)$, $T_d(j) = \sin(0.2q_1(j)) + 0.1 \cos(t)$, and $P(q_1, \dot{q}_1)(j) = \cos(\|\dot{q}_1\|^2 + \dot{q}_2^2(j))$, where $j = 1, 2$. The desired trajectory for joint angle to track is $q^d = [1 - \cos(t)]I$.

The robust control was simulated using SIMNON[®], and the simulation results are shown in the figures. Further research is needed to determine bounding functions such that robust control requires less control magnitude.

V. CONCLUSION

A robust control design method was presented in this paper for robot manipulators with flexible joints. In contrast to existing robust control results and to other design techniques such as adaptive control and singular perturbation, the proposed control guarantees global stability while using only measurement of joint position and velocity. Because acceleration and jerk measurement is no longer required, the proposed control is more practical and attractive. Furthermore, the proposed control works robustly to compensate any unknown but bounded uncertainties including unknown flexibility, (time-varying) parameters, load variation, and disturbances. Regardless of uncertainties, position and velocity tracking errors have been shown to satisfy any arbitrarily small tracking accuracy requirement. In return of achieving such a complete robustness, the designer is required off-line to perform differentiation and to determine bounding functions in order to find robust controller through the proposed nonlinear mapping. The off-line calculation can be automated using a software package with the capability of symbolic manipulations.

APPENDIX

Proof of Lemma 1: Utilizing differential operator, we can rewrite the input v as

$$\begin{aligned} v &= G_3 y + r + (s+1)^{-1} [G_1 v + G_2 y] \\ &= (sI_n + I_n - G_1)^{-1} \{[(s+1)G_3 + G_2]y + (s+1)r\}. \end{aligned}$$

Substituting the above equation into (6) yields

$$\begin{aligned} [(sI_n + I_n - G_1)(Js^2 + Ds + K) - (s+1)G_3 - G_2]y \\ = (s+1)r + (sI_n + I_n - G_1)d. \end{aligned}$$

It then follows that the closed-loop system is given by (7) with $d' = (s+1)^{-1}(sI_n + I_n - G_1)d$ iff the following identity holds

$$\begin{aligned} [(sI_n + I_n - G_1)(Js^2 + Ds + K) - (s+1)G_3 - G_2] \\ = (s+1)(J_o s^2 + D_o s + K_o)J_o^{-1}J. \quad (17) \end{aligned}$$

Since all matrices are diagonal, the above equality can be rewritten as

$$\begin{aligned} [(s+1-G_{1i})(J_i s^2 + D_i s + K_i) - (s+1)G_{3i} - G_{2i}] \\ = (s+1)(J_{oi} s^2 + D_{oi} s + K_{oi}) \frac{J_i}{J_o} \end{aligned}$$

where subscript i denotes the i th element on the diagonal. It is easy to verify that the above equality holds if G_1 , G_2 , and G_3 are chosen such that

$$\begin{aligned} G_{1i} &= \frac{D_i}{J_i} - 2\frac{\dot{J}_i}{J_i} - \frac{D_{oi}}{J_{oi}}, \\ G_{3i} &= \dot{D}_i + K_i + (1-G_{1i})D_i - 3\dot{J}_i - 2\ddot{J}_i \\ &\quad - 2\frac{D_{oi}}{J_{oi}}\dot{J}_i - \frac{K_{oi}}{J_{oi}}J_i - \frac{D_{oi}}{J_{oi}}J_i, \\ G_{2i} &= \dot{K}_i + (1-G_{1i})\dot{K}_i - \dot{G}_{1i} - \frac{d^3 J_i}{dt^3} \\ &\quad - \left(1 + \frac{D_{oi}}{J_{oi}}\right)\ddot{J}_i - \frac{K_{oi} + D_{oi}}{J_{oi}}\dot{J}_i - \frac{K_{oi}}{J_{oi}}J_i. \quad (18) \end{aligned}$$

Solution (18) guarantees identity (17) which in turn guarantees that the closed-loop system is internally stable. The above relations will be used to determine known bounds on G_1 , G_2 , and G_3 . These bounds are required in designing robust control. \square

Proof of Lemma 2. It follows from (13) and (14) that

$$\begin{aligned} \dot{V}_1(x_1) &= e_1^T K_p \dot{e}_1 + \frac{1}{2} w^T(x_1) \dot{M}(q_1) w(x_1) \\ &\quad + w^T(x_1) \dot{M}(q_1) (\alpha \dot{e}_1 + \dot{e}_1) \\ &= -\alpha e_1^T K_p e_1 - w^T(x_1) K J^{-1} \bar{\tau} + u^T(x_1) \{0.5 \dot{M}(q_1) u(x_1) \\ &\quad + \alpha \dot{M}(q_1) \dot{e}_1 + K \Delta A + K q_1\}. \end{aligned}$$

Thus, the proof can be completed if the uncertainty $0.5 \dot{M}(q_1) w(x_1) + \alpha \dot{M}(q_1) \dot{e}_1 + K \Delta A + K q_1$ can be bounded in euclidean norm by a well-defined function $\varphi_1(q_1, \dot{q}_1, \zeta_1)$.

It follows from (9) and (8) that $(sI_n + I_n - G_1)\eta_1 = G_1 G_3 q_2 + G_1 \tau + G_1 \eta_2$ and $(s+1)\eta_2 = G_2 q_2$. Hence, we have

$$\begin{aligned} P'(q_1, \dot{q}_1, \zeta_1) &= K q_1 + P(q_1, \dot{q}_1) - G_3 q_2 - (s+1)^{-1} \\ &\quad \cdot [G_1 K q_1 + G_1 P(q_1, \dot{q}_1) + G_2 q_2] - (s+1)^{-1} G_1 \tau \\ &= K q_1 + P(q_1, \dot{q}_1) - (s+1) G_3 \frac{1}{s+1} q_2 + \dot{G}_3 \frac{1}{s+1} q_2 \\ &\quad - (s+1)^{-1} [G_1 K q_1 + G_1 P(q_1, \dot{q}_1)] - G_2 \frac{1}{s+1} q_2 \\ &\quad + \frac{1}{s+1} \dot{G}_2 \frac{1}{s+1} q_2 - G_1 \zeta_1 + (s+1)^{-1} \dot{G}_1 \zeta_1 \\ &= K q_1 + P(q_1, \dot{q}_1) - (s+1) G_3 \frac{1}{s+1} q_2 + \dot{G}_3 \frac{1}{s+1} q_2 \end{aligned}$$

$$\begin{aligned} &- (s+1)^{-1} [G_1 K q_1 + G_1 P(q_1, \dot{q}_1)] - G_2 \frac{1}{s+1} q_2 \\ &+ \frac{1}{s+1} \dot{G}_2 \frac{1}{s+1} q_2 \\ &- (s+1)^{-2} [G_1 \zeta_1 - 3(s+1)^{-1} \dot{G}_1 \zeta_1 + 3(s+1)^{-2} \\ &\quad \cdot \ddot{G}_1 \zeta_1 - (s+1)^{-3} \frac{d^3 G_1}{dt^3} \zeta_1] \end{aligned}$$

in which the last two steps are derived by integration by part. Such steps are necessary to find a well-defined robust control τ by guaranteeing that the second-order time derivative of the bounding function to be determined does not depend on τ explicitly.

The bounding function $\varphi_1(x_1, \zeta_1)$ that bounds uncertainties in \dot{V}_1 can then be chosen to be

$$\begin{aligned} \varphi_1(x_1, \zeta_1) &= \|\bar{K}\| \|q_1\| + \|K_p e_1\| + \overline{m}(q_1) \|\ddot{q}_1\| + \rho_1(x_1) \|\dot{q}_1\| \\ &\quad + \rho_2(x_1) + \rho_3(x_1) + \frac{1}{2} \|w(x_1) \rho_5(x_1) + \alpha \overline{m}(q_1) \|\dot{e}_1\| \\ &\quad + \|\bar{K}\| \|\underline{J}\|^{-1} \|\zeta_2 e^{-\lambda_2(t-t_0)}\| \cdot \|(\bar{J} + \|\bar{J}\|)\| \rho_7 + \|G_1\| \|\cdot\| \|\zeta_1\| \\ &\quad + \int_{t_0}^t \|C_2 e^{-\lambda_2 o(t-s)} B_{2o} J_o\| \|\|\bar{K}\| \|q_1\| + \rho_4(x_1) \\ &\quad + (\|\dot{G}_3\| + \|G_2\|) \\ &\quad \cdot \left| \frac{1}{s+1} q_2 \right| + 3 \|\ddot{G}_1\| \|\cdot\| \|\zeta_1\| \Big] ds \\ &\quad + \int_{t_0}^t \|C_2' e^{-\lambda_2 o(t-s)} B_{2o} J_o\| \|\|\zeta_1\| \\ &\quad \cdot \|\zeta_1\| ds + \int_{t_0}^t \|C_2'' e^{-\lambda_2 o(t-s)} B_{2o} J_o\| (3 \|\dot{G}_1\| \|\cdot\| \|\zeta_1\| \\ &\quad + \|\dot{G}_3\|) \cdot \left| \frac{1}{s+1} q_2 \right| ds \\ &\quad + \int_{t_0}^t \|C_3 e^{-\lambda_3(t-s)} B_1\| (\|\bar{K}\| \|\cdot\| \|G_1\| \|q_1\| + \|\dot{G}_1\| \\ &\quad \cdot \rho_4(x_1) + \|\dot{G}_2\| \|\cdot\| \left| \frac{1}{s+1} q_2 \right| + \left| \frac{d^3 G_1}{dt^3} \right| \|\cdot\| \|\zeta_1\|) ds \Big\} \end{aligned}$$

where $\|\cdot\|$ denotes a known bound or bounding function on the norm of the argument

$$A_1 = \begin{bmatrix} 0 & I_n & 0 \\ 0 & 0 & I_n \\ -J_o^{-1} K_o & -J_o^{-1} (K_o + D_o) & -I_n - J_o^{-1} D_o \end{bmatrix},$$

$$C_2' = [I_n - J_o^{-1} K_o \quad 2I_n - J_o^{-1} D_o],$$

$$C_2'' = [I_n \quad I_n], \quad B_1 = [0 \quad 0 \quad I_n]^T.$$

$$C_3 = [I_n \quad 0 \quad 0]$$

and \bar{J} denotes the upper bound on \dot{J} . Although q_2 is not measured, a bounding function of measured variables can be determined from (5) for $\|(1/s+1)q_2\|$ as

$$\begin{aligned} \left\| \frac{1}{s+1} q_2 \right\| &\leq (\gamma_0 \delta(t) + \gamma_1 e^{-\gamma_2(t-t_0)}) \\ &\quad \cdot \left[\|\zeta_1\| + e^{-(t-t_0)} * e^{-(t-t_0)} * (\|q_1\| + \rho_4(x_1)) \right] \triangleq \left| \frac{1}{s+1} q_2 \right|. \end{aligned}$$

Hence, $\varphi_1(x_1, \zeta_1)$ is a well-defined function only of x_1 and ζ_1 . \square

Proof of Theorem Taking time derivative of V_2 along the trajectory of the system given by (12) yields $\dot{V}_2 = (\bar{\tau} - u_1)^T (\dot{\tau}_1 - \dot{\tau}_2 - u_2)^T (-J^{-1}K_{\tau-1} - J^{-1}D_{\tau-2} + \tau - u_2)$. It follows from $V_1 + V_2$ and from Lemma 2 that

$$\begin{aligned} & \lambda_1 \|e_1\|^2 + \|u(t_1)\| \varphi_1(\tau_1 - \zeta_1) - u^T(t_1) K J^{-1} \bar{\tau} \\ & + (\bar{\tau} - u_1)^T (\dot{\tau}_2 - u_2) \\ & + (\dot{\tau}_2 - u_2)^T (-J^{-1}K_{\tau-1} - J^{-1}D_{\tau-2} + \tau - u_2) \\ & - \lambda_1 \|e_1\|^2 + \|u(t_1)\| \varphi_1(\tau_1 - \zeta_1) - u^T(t_1) K J^{-1} u_1 \\ & + (\tau_1 - u_1)^T [u_2 - u_1 - J^{-1}K u(t_1)] \\ & + (\dot{\tau}_2 - u_2)^T (\tau_1 - u_1 - J^{-1}K_{\tau-1} - J^{-1}D_{\tau-2} + \tau - u_2) \\ & \leq -\lambda_1 \|e_1\|^2 - \alpha \bar{m}(q_1) \|u(t_1)\|^2 - \alpha (\tau_1 - u_1)^2 \\ & - \alpha (\dot{\tau}_2 - u_2)^2 \\ & + \|u(t_1)\| \varphi_1(\tau_1) - u^T(t_1) K J^{-1} u_1 + (\tau_1 - u_1)^T u_2 \\ & + \|\tau_1 - u_1\| \\ & \quad \left[\|u(t_1)\| + \left| K^T u(t_1) \right| \right] + (\dot{\tau}_2 - u_2)^T \tau_1 + \|\dot{\tau}_2 - u_2\| \|u(t_1)\| \\ & \leq -\lambda_1 \|e_1\|^2 - \alpha \bar{m}(q_1) \|u(t_1)\|^2 \\ & - \alpha (\tau_1 - u_1)^2 - \alpha (\dot{\tau}_2 - u_2)^2 + \epsilon_1 + \epsilon_2 + \epsilon_3 \\ & \leq -\lambda^* V + \lambda^* \epsilon^* \end{aligned}$$

where $\lambda^* = \min \{2\lambda_1/\lambda, \lambda_1(K_{\tau-1} - 2\alpha)\}$ and $\epsilon^* = (\epsilon_1 + \epsilon_2 + \epsilon_3)/\lambda^*$. Solving the above first order differential equation yields

$$V(t) \leq e^{-\lambda^*(t-t_1)} V(t_1) + \epsilon^*(1 - e^{-\lambda^*(t-t_1)}) \rightarrow \epsilon^* \quad \text{as } t \rightarrow \infty.$$

Therefore V and the output tracking error e_1 (i.e. τ and ϵ) are uniformly ultimately bounded and their convergence is exponential.

The uniform boundedness of all internal variables can be established as follows. First V_2 being bounded implies that both $\tau_1 - u_1$ and $\dot{\tau}_2 - u_2$ are uniformly bounded. Second it follows from e_1 being bounded that q_1 is bounded and hence u_1 is uniformly bounded. It follows from (16) that $\|u_1\| \leq \bar{K}^{-1} \varphi_1(\tau_1 - \zeta_1)$ which shows that u_1 is uniformly bounded if ζ_1 is bounded. It follows from (92) that

$$\dot{\zeta}_1 = \frac{1}{(\gamma+1)} [Iq_1 + Dq_1 - P(q_1 - q_1)]$$

Note that τ_1 (and therefore q_1 and \dot{q}_1) is bounded. Even if matrices I, D, P are time varying we can show using integration by part (as did in the proof of Lemma 3) that ζ_1 is a function of signal $(1/\gamma+1)q_2$ and its filtered versions through stable transfer functions. On the other hand it follows from (1) that

$$\frac{1}{\gamma+1} \dot{q}_2 = \frac{1}{\gamma+1} \{K^{-1} [M(q_1)q_1 + \lambda(q_1 - q_1) + Kq_1]\}$$

The terms on the right hand side of the above equation can be shown again using integration by part to be functions of q_1, \dot{q}_1 and their filtered versions. Thus we conclude from the above two equations that ζ_1 and u_1 are globally and uniformly bounded. Now one can conclude boundedness of τ_1 since u_1 is bounded. The boundedness of τ_1 then implies boundedness of ζ_1 which in turn shows boundedness of u and therefore τ . Finally boundedness of τ_2 is used to establish in turn boundedness of $\zeta_1, \tau_1, \tau_2, \tau$ and τ_2 . \square

The Use of Symbolic Computation in Nonlinear Control: Is It Viable?

Bram de Jager

Abstract—To help along the analysis and design of nonlinear control systems the NONLINCON package, an acronym for *Nonlinear Control*, was developed. This note addresses the usefulness of symbolic computation, and of the NONLINCON package in particular, for the symbolic analysis and design of nonlinear control systems. The symbolic computation program MAPLE is used as computing substratum. Textbook problems show that the NONLINCON package can be used successfully. A larger scale problem is too complex, however, to be solved with the current versions of NONLINCON and MAPLE. The conclusion is that symbolic computation is a viable approach for textbook problems, but not yet for more complex ones.

I. INTRODUCTION

The use of symbolic computation for control purposes is investigated by several researchers. Zeitz *et al.*, [1] applies the program MACNON, based on MACSYMA, to analyze observability and reachability, and to design observers and controllers for nonlinear systems. Blankenship [2] also used MACSYMA to solve some control problems with his implementation CONDENS. The use of MAPLE for several control problems is reported in [3]. Some problems reported in this note, e.g., with solving partial differential equations, are partly resolved in [4]. They describe a MAPLE package, here called NonCon, that can compute, e.g., the zero dynamics and provide solutions for exact linearization problems. In this note we illustrate the use of this package by applying it to some textbook problems and a more complex one.

The main goals and contributions of this note are

- a proof of the viability of symbolic computation for some problems in the analysis and design of nonlinear control systems
- to show the characteristics of a prototype implementation
- to give some examples and to document some applications
- to discuss directions for future research
- to familiarize a larger audience in the control community with the use of symbolic computation.

The note is structured as follows. First, Section II formulates the control problems and presents the algorithms used. The implementation in NONLINCON of these algorithms is treated in Section III. Section IV presents textbook examples for some problem areas. A more complex example is treated in Section V. Section VI closes with conclusions and gives directions for future research.

II. THE PROBLEMS

Of several areas in nonlinear control, where symbolic computation is likely to be of some profit, we discuss the computation of the normal form, the zero dynamics, and the input-output and state-space exact linearization. In the presentation of these problems, we follow Isidori [5].

A. Preliminaries

We start with a nonlinear model of a plant and assume that it can be described adequately by a set of nonlinear differential equations,

affine in the input u , and without direct feed-through from input to output

$$\dot{x} = f(x) + g(x)u, \quad y = h(x) \quad (1)$$

with state vector $x \in \mathbb{R}^n$, containing all necessary information of the plant, input vector $u \in \mathbb{R}^m$, and output vector $y \in \mathbb{R}^m$. The number of inputs is equal to the number of outputs, i.e., the plant is square. This assumption is for convenience only. Part of the theory can also be derived if the number of inputs is not equal to the number of outputs. The vector field f is smooth, g has m columns g_i of smooth vector fields, and h is a column of m scalar-valued smooth functions h_i .

The type of control law chosen is static state-feedback. Therefore, the value of the input vector $u(t)$ depends on the state $x(t)$ and a new reference input vector $v(t)$ as

$$u = \alpha(x) + \beta(x)v \quad (2)$$

where the components α_i and β_{ij} are smooth functions.

For nonlinear models it is appropriate to allow for a nonlinear change of coordinates

$$z = \Phi(x). \quad (3)$$

It is required that the Jacobian $\partial\Phi/\partial x$ of the transformation Φ is, at least locally, invertible for Φ to qualify as a change of coordinates.

B. Relative Degree

The nonlinear model (1) is said to have a vector relative degree $\{r_1, \dots, r_m\}$ at $x = x''$ if

- 1) $L_{g_j} L_f^{k_j} h_i(x) = 0$ for $k_j = 1, \dots, r_j - 2$ ($i, j = 1, \dots, m$) and all x in a neighborhood of x'' ,
- 2) the following $m \times m$ matrix is nonsingular at x''

$$A(x) = \begin{bmatrix} L_{g_1} L_f^{r_1-1} h_1(x) & \dots & L_{g_m} L_f^{r_m-1} h_1(x) \\ \vdots & & \vdots \\ L_{g_1} L_f^{r_1} h_m(x) & \dots & L_{g_m} L_f^{r_m} h_m(x) \end{bmatrix}$$

Here $L_f^k h_i(x)$ means the k th successive Lie derivative of the scalar function $h_i(x)$ in the direction of the vector field f , e.g., $L_f h_i(x) = (\partial h_i(x)/\partial x)f(x)$. The matrix A is sometimes called the decoupling matrix. The relative degree can also be interpreted as the number of times the outputs have to be differentiated before the input explicitly appears.

The models we consider do not necessarily have a relative degree, either because the first condition cannot be satisfied or because the matrix A is singular at x'' .

C. Normal Form

When the model has a well-defined relative degree we can use a change of coordinates (3), with $z = (\xi, \eta)$, to transform (1) to the normal form

$$\begin{aligned} y_i &= h_i(x) = \xi_i^1 \\ \dot{\xi}_i^1 &= \xi_i^2 \\ &\vdots \\ \dot{\xi}_i^{r_i} &= b_i(\xi, \eta) + \sum_{j=1}^{r_i} a_{ij}(\xi, \eta) u_j \quad \text{for } i = 1, \dots, m \\ \dot{\eta}_i &= q_i(\xi, \eta) + p_i(\xi, \eta) u \quad \text{for } i = r+1, \dots, n \end{aligned} \quad (4)$$

Manuscript received March 26, 1993; revised February 12, 1994.

The author is with the Faculty of Mechanical Engineering, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands. IEEE Log Number 9405674.

with $r = \sum_{j=1}^m r_j$ and

$$a_{ij}(\xi, \eta) = L_{q_j} L_f^{r_j-1} h_i(\Phi^{-1}(\xi, \eta))$$

$$h_i(\xi, \eta) = L_f^{r_i} h_i(\Phi^{-1}(\xi, \eta)) \quad \text{for } i, j = 1, \dots, m.$$

The terms a_{ij} are the entries of A and we can compactly write [with only equations containing the input u in (4)]

$$\dot{\xi}^{(r)} = b(\xi, \eta) + A(\xi, \eta)u \quad (5)$$

$$\dot{\eta} = q(\xi, \eta) + p(\xi, \eta)u$$

where $\xi^{(r)}$ contains $\dot{\xi}_i^{(r)}$, $i = 1, \dots, m$. The equation for $\dot{\eta}$ is called the internal dynamics. Because A is nonsingular if the relative degree is well defined, the control

$$u = A^{-1}(v - b) \quad (6)$$

with the new input v , is properly defined and linearizes the part of model (5) that is visible at the output.

D. Zero Dynamics

The zero dynamics problem is: obtain the dynamics of the model when the output y is required to be zero for all t , by a proper choice of initial state $x(0)$ and control input $u^*(t)$. Here we have to employ an appropriate static state feedback and use proper initial conditions. More specific: we are looking for the locally maximal output zeroing submanifold and its associated dynamics.

When the model has a well-defined relative degree, the zero dynamics follows from the normal form, by substitution of the output nulling input u^* and using the property that the states ξ can be set to zero in the internal dynamics.

For models without a relative degree the zero dynamics can be computed by using the Zero Dynamics Algorithm. The way this algorithm works is by considering a sequence of nested submanifolds M_i , with $M_i \supset M_{i+1}$ and $M_0 = h^{-1}(0)$, i.e., the first submanifold is the inverse image of the point $y = 0$. When some conditions are fulfilled this sequence converges to the locally maximal output zeroing submanifold Z^* in some neighborhood of x'' and there exists a mapping u^* such that $f^*(x) = f(x) + g(x)u^*(x)$ is tangent to Z^* . The pair (Z^*, f^*) is called the zero dynamics of the model. When the mapping $H(x)$ is defined in a neighborhood U of x'' by $Z^* \cap U = \{x \in U; H(x) = 0\}$ the input u^* can be computed as the solution of $L_f H(x) + L_{g_j} H(x)u^* = 0$. For further details of this algorithm and the conditions to be imposed to guarantee convergence of the sequence to Z^* , we refer to [5, Section 6.1].

E. Input-Output Exact Linearization

The input-output exact linearization problem is: find out if it is possible to transform model (1) to a linear one by state feedback (2) and compute this feedback. The linearity property should be established between the new input v and the output y . Formally, we are looking for a neighborhood U of x'' and a static state feedback such that for all $k \geq 0$ and all $1 \leq i, j \leq m$ the expression $L_{(q_j)} L_f^k h_i(x)$ is independent of x on U .

For models with a well-defined relative degree, the input-output exact linearizing feedback follows from the normal form and is given by (6).

For models without a relative degree, the static state feedback that solves the problem can be computed with the Structure Algorithm. This algorithm uses a sequence of Toeplitz matrices

$$M_k(x) = \begin{bmatrix} T_0(x) & \cdots & T_k(x) \\ \vdots & \ddots & \vdots \\ 0 & \cdots & T_0(x) \end{bmatrix}$$

where

$$T_k(x) = \begin{bmatrix} L_{q_1} L_f^k h_1(x) & \cdots & L_{q_m} L_f^k h_m(x) \\ \vdots & \ddots & \vdots \\ L_{q_1} L_f^k h_1(x) & \cdots & L_{q_m} L_f^k h_m(x) \end{bmatrix}$$

for $0 \leq k \leq 2n-1$. The conditions for existence can be cast in rank conditions on $M_k(x)$. Within the Structure Algorithm, feedback functions $\alpha(x)$ and $\beta(x)$ are constructed. For further details of this algorithm we refer to [5, Section 5.4].

F. State-Space Exact Linearization

The state-space exact linearization problem is: under which conditions is it possible to transform the model (1) to a linear and controllable one by state feedback (2) and a change of coordinates (3)? The linearity property should be established between the new input v and the transformed state z .

This problem has been solved. The solution is only valid for models with a well-defined relative degree and requires the existence of (synthetic) outputs for which the model has a full order relative degree, $r = n$. When this cannot be obtained, it is sometimes convenient to strive after a maximal relative degree. Then the corresponding input-output linearizing state feedback realizes a minimal dimension of the internal dynamics.

Using the Lie product

$$[f, g_i] = \frac{\partial g_i}{\partial x} f - \frac{\partial f}{\partial x} g_i$$

define the adjoint $\text{ad}_f^k g_i$ recursively as $\text{ad}_f^k g_i = [f, \text{ad}_f^{k-1} g_i]$ with $\text{ad}_f^0 g_i = g_i$. Then define the distributions

$$G_i = \text{span} \{ \text{ad}_f^k g_j; 0 \leq k \leq i, 1 \leq j \leq m \} \quad \text{for } 0 \leq i \leq n-1.$$

We now state the conditions for a solution [5, Theorem 5.2.4].

Theorem 1. Given the model

$$\dot{x} = f(x) + g(x)u, \quad x \in \mathbb{R}^n, \quad u \in \mathbb{R}^m$$

with $\text{rank } g(x'') = m$. There exists a solution for the state-space exact linearization problem if and only if

- 1) G_i has constant dimension near x'' for each $0 \leq i \leq n-1$
- 2) G_{n-1} has dimension n
- 3) G_i is involutive for each $0 \leq i \leq n-2$.

Here, involutive means that the distribution is closed under the Lie product, i.e., the dimension of the distribution G_i does not change when a vector field, generated by the Lie product of each combination of two of the vector fields in G_i , is added to the distribution.

When the given conditions are fulfilled, there exist solutions $\lambda_i(x)$, $i = 1, \dots, m$, for the following partial differential equations

$$L_{g_j} L_f^k \lambda_i(x) = 0, \quad \text{for } 0 \leq k \leq r_i - 2 \quad \text{and} \quad 1 \leq j \leq m.$$

Also $\sum_{i=1}^m r_i = n$, where the set of integers $\{r_1, \dots, r_m\}$ is the relative degree vector. The m functions λ_i can be computed, based on a constructive proof of Theorem 1. Using the functions λ_i , the change of coordinates Φ and state feedback $u = \alpha(x) + \beta(x)v$ follow.

III. SOLUTION WITH SYMBOLIC COMPUTATION

An analysis of the algorithms shows that symbolic computation programs should be able to compute the Lie derivative and Lie product, the Jacobian, the rank, the Gauss Jordan decomposition, the inverse of a matrix, and the determinant of a matrix; to do matrix-vector and matrix-matrix multiplication; and to test involutiveness. More mundane facilities like symbolic substitution are needed also. The main problems are the computation of solutions for sets of nonlinear equations, e.g., to compute the kernel of a mapping, and

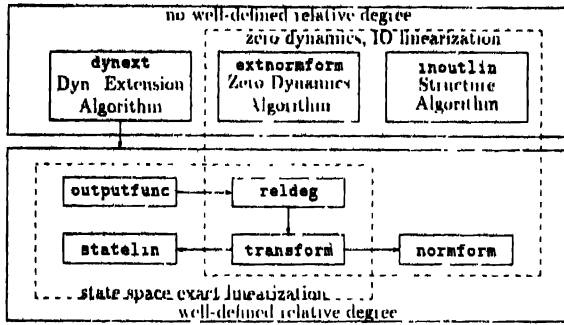

Fig. 1. Structure of NONLINCON.

for sets of partial differential equations. These problems present the major bottlenecks for the symbolic solution of our problems.

Solutions for the problems described in the previous section

- 1) the normal form
- 2) the zero dynamics
- 3) the input-output exact linearization
- 4) the state-space exact linearization

are included in NONLINCON. For problems 1) and 4) the model should have a well-defined relative degree; for 2) and 3) this is not necessary. Implementations of other algorithms, e.g., the Dynamic Extension Algorithm and a method to solve partial differential equations, are included in this package also. The structure of the implementation is sketched in Fig. 1. For a thorough discussion of the implementation, see [6].

Above we noted that a main problem was to compute solutions for sets of nonlinear equations. In MAPLE a facility is available to solve sets of nonlinear equations, namely the `solve` function, but this facility is not always sufficient. We did not try to improve this.

We also noted that another main problem was to solve sets of partial differential equations. In MAPLE almost no facilities are available for their solution. To improve this, the following route was chosen.

The partial differential equations we have to solve are from the "completely integrable" type; in other words, based on Frobenius' Theorem, we know that a solution for the partial differential equations exists. To compute the solutions Frobenius' Theorem itself is of no help. This problem was solved by computing the solutions with an algorithm based on a constructive proof of Frobenius' Theorem. The procedure is as follows. The solution of the partial differential equation can be constructed from the solutions of related sets of ordinary differential equations. Because MAPLE provides some facilities for this type of problems, the `dsolve` command, the problem seems solved. The `dsolve` command is not very powerful, however, and is often unable to present a solution, although this solution is known to exist. Therefore the `dsolve` procedure was extended in an ad hoc way, to handle a larger class of problems, by setting up a recursive procedure to solve sets of differential equations, starting from the "shortest" (assumed to be the simplest) equation, substituting the solution in the remaining equations, and so on. No effort was spent in trying to detect a (block) triangular dependency structure in the set of differential equations, which would be a more rigorous option. Despite this extension the solution of the partial differential equations is often unsuccessful, so NONLINCON cannot complete the computations.

A minor problem was that some standard MAPLE `linalg` functions are only suitable for rational polynomials. This was too limited for our purposes. Therefore, the rank and implicitly the `gausselim` and `gaussjord` procedures were extended, so a larger class of problems could be handled. This resulted in the new functions `extrank`, `extgausselim`, and `extgaussjord`.

Fig. 2. Robot with two revolute joints.

IV. TEXTBOOK PROBLEMS

To illustrate the use of NONLINCON we consider several examples. The first example computes the zero dynamics of a single-input single-output model with a well-defined relative degree. For the second example the zero dynamics is computed with the Zero Dynamics Algorithm. For the last example the input-output linearizing state feedback is computed with the Structure Algorithm. The last two examples are based on models that do not have a well-defined relative degree. All examples are contrived ones. The first example is taken from [7, Example 12.43] and the other two from [5, Examples 6.1.2 and 5.4.1].

Example 1: The model for a robot with two revolute joints (see Fig. 2) can be derived from the kinetic and potential energy T and V

$$2T = m_1 l_1^2 \dot{\theta}_1^2 + m_2 (l_1^2 \dot{\theta}_1^2 + l_2^2 (\dot{\theta}_1 + \dot{\theta}_2)^2 + 2l_1 l_2 (\dot{\theta}_1 + \dot{\theta}_2) \cos \theta_2)$$

$$V = -g \{ (m_1 + m_2) l_1 \cos \theta_1 + m_2 l_2 \cos (\theta_1 + \theta_2) \}.$$

The inputs u_1 and u_2 are the joint torques and the outputs y_1 and y_2 the joint positions. The state x of the model corresponds with the degrees-of-freedom and their derivatives in the following way $x^T = [\theta_1 \ \theta_2 \ \dot{\theta}_1 \ \dot{\theta}_2]$. The aim is to derive the dynamics of the model when it is constrained. There are two cases, the first one with $y = y_1 = \theta_1$ constrained to 0 and $u_2 = 0$, the second one with $y = y_2 = \theta_2$ constrained to 0 and $u_1 = 0$. According to [7] the zero dynamics are given by (with all model parameters set to one)

$$\dot{x}_2 = x_4 \quad \dot{x}_4 = g \sin x_2$$

respectively

$$\dot{x}_1 = x_3 \quad \dot{x}_3 = (3/5)g \sin x_1.$$

The following log of a NONLINCON session shows that these results can be reproduced. Two functions are used: `normform` to compute the zero dynamics and `transform` for the inverse transformation. The log for the first case, where $y = \theta_1$, is found at the bottom of the next page (as marked by (x)). The second case for $y = \theta_2$ is found at the bottom of the next page, as marked by (y). The results coincide with the ones given above.

Example 2: The model of the system is

$$\dot{x} = \begin{bmatrix} x_2 \\ x_4 \\ x_1 x_4 \\ x_5 \\ x_3 \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ x_3 & x_2 \\ 0 & 1 \\ x_5 & x_2 \\ 1 & 1 \end{bmatrix} u, \quad y = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}.$$

This model has no well-defined relative degree at $x'' = 0$ because

$$A = \begin{bmatrix} 1 & 0 \\ x_3 & x_2 \end{bmatrix}$$

singular for $\dot{x}_2 = 0$. The zero dynamics is given in [5] by $\dot{x}_1 = -x_1$ and the zeroing input by

$$\begin{bmatrix} 0 \\ -1 \end{bmatrix}$$

The next edited log of a NonLinCon session shows that the zero dynamics can be computed. From the functions supplied we only needed `extnoimform` that implements the Zero Dynamics Algorithm as shown at the bottom of the page (as indicated by (7)). The term computed last (for \dot{x}_1) represents the zero dynamics. The results coincide with the ones given above.

Example 3 The model of the system is

$$\begin{aligned} \dot{x}_1 + \dot{x}_2 \\ \dot{x}_1 \dot{x}_2 \\ -x_1 + x_2 + u = 0 \\ + x_1^2 \end{aligned}$$

This model has no well defined relative degree because

$$A = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$$

is singular for all t . According to [5] the necessary feedback for input-output linearization is $u = a(t) + b(t)\dot{x}_1$ with

$$a(t) = -x_1 + x_2, \quad b(t) = 2x_1 + 1$$

The following shows that NonLinCon can compute the input-output linearizing state feedback. From the functions supplied we only need `outputlin` that implements the Structure Algorithm which is found at the bottom of the next page. The computed state feedback agrees with the previous result.

Fig. 3 One track model of a vehicle

V. VEHICLE SIMULATION PROBLEM

This more complex problem is derived from an inverse simulation problem in multibody dynamics. A vehicle is required to perform a standardized maneuver. To simulate the maneuver the inputs to the model must be known. Normally the maneuver is such that a suitable selected output of the model can be set to zero. Often this output does not fully determine the behavior of the model and the remaining freedom represents exactly the zero dynamics. If this dynamics is stable then the simulation is also stable; if it is unstable then additional measures are needed for a stable simulation.

As an example we use a simple two dimensional one track model of a vehicle with traction and cornering forces acting on the tires. It looks like the model of a bike because it only considers the center line of a motor vehicle (see Fig. 3).

The required maneuver is steady state turning: the longitudinal speed of the center of mass M is constant and a point P on the

(x)

(y)

(z)

center line should describe a circle of specified radius. The specific problem is for which distances p , from P to M , the zero-dynamics is stable or unstable.

The equations of motion of the model are

$$\begin{aligned} m\ddot{x}_m &= -F_f \sin(\delta + \theta) - F_r \sin \theta + F_{t_r} \cos \theta \\ m\ddot{y}_m &= +F_f \cos(\delta + \theta) + F_r \cos \theta + F_{t_r} \sin \theta \\ J\ddot{\theta} &= aF_f \cos \delta - bF_r \end{aligned}$$

with inputs F_{t_r} (traction force) and δ (steering angle). The three degrees-of-freedom x_m , y_m , and θ , are, respectively, the coordinates of M and the orientation of the vehicle with respect to a fixed reference frame (\vec{e}_x^0 , \vec{e}_y^0), indicated by the superscript 0. The steering angle δ and the drift angles α_f and α_r are given with respect to a body fixed reference frame. The vehicle has mass m and moment of inertia J with respect to M . The forces acting on the vehicle are the traction force F_{t_r} and the lateral tire forces F_f , F_r . The last two forces can be expressed in the drift angle and the normal tire force F_n by the so-called magic formula for pure slip [8]

$$F(F_n, \alpha) = D(F_n) \sin(C \operatorname{atan}(B\xi - E(B\xi - \operatorname{atan}(B\xi)))) \quad (7)$$

with $\xi = \alpha + S_h$. The dependency holds for both front and rear. The parameters in this formula have to be fitted to experimental data. The drift angles can be expressed in the degrees-of-freedom and steering angle by

$$\alpha_f = \delta - \operatorname{atan}(v_{fy}^1/v_{fx}^1), \quad \alpha_r = -\operatorname{atan}(v_{ry}^1/v_{rx}^1)$$

with

$$\dot{v}_j^1 = R^T(\dot{x}_m^0 + \dot{R}\delta_j^1), \quad \dot{v}_i^1 = R^T(\dot{x}_m^0 + \dot{R}\delta_i^1)$$

and

$$R = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}.$$

where the superscript 1 indicates the coordinates with respect to the body fixed reference frame (\vec{e}_x^1 , \vec{e}_y^1). The dependency of the lateral tire forces on the degrees-of-freedom and the steering angle make this model quite nonlinear and difficult to analyze.

By choosing the outputs as

$$\begin{aligned} y_1 &= \dot{x}_m \cos \theta + \dot{y}_m \sin \theta - \dot{V}_d \\ y_2 &= (x_m + p \cos \theta)^2 + (y_m + p \sin \theta)^2 - R_d^2 \end{aligned}$$

with R_d the desired radius of the circle and \dot{V}_d the desired longitudinal speed, the required maneuver corresponds with a zero output. The output y_2 depends on the distance p from P to M . To solve the problem, first compute the zero dynamics and then find out its stability as a function of p .

The first problem encountered in computing the zero dynamics is the nonaffine character of the equations of motion with respect to the steering angle δ . To overcome this problem an integrator can be added to the model and δ can be regarded as a new input. Then the model has a singular decoupling matrix A , however, which makes the analysis more difficult. The `extnormform` function can be used, but this leads to insurmountable problems in the computation due to huge memory needs. Another solution is to add another integrator and use \dot{F}_{t_r} as a new input, making the decoupling matrix regular by "delaying" the input F_{t_r} also. The extension with two integrators allows the use of the standard transformation to the normal form with the function `normform`, although for a larger model. Due to the larger number of states, again problems arise with the memory needed.

To simplify the problem another "saturating" function was used in (7), $\sqrt{\cdot}$ instead of $\sin(\operatorname{atan}(\cdot))$. Now, the transformation can be computed, but the inverse transformation cannot, because of an artificial limit in the size of objects allowed by the software, putting an untimely end to the computation. Results are therefore only available in terms of the old coordinates x , but not in z .

Another attempt to solve the problem of nonaffine input is not to extend the model, but to simplify it so that the input δ appears linear in the equations. To this end, the assumption that δ is small has to be adopted. Then, by using a Taylor series expansion, the system of equations can become linear in δ if the dependency on δ of the front lateral tire force is dropped, so δ should also be small compared with α_f , an unrealistic assumption. This time the transformation to the normal form can be computed, but the set of nonlinear equations, needed to compute the inverse transformation, could not be solved, not due to memory constraints but due to limitations in the `solve` function of MAPLE. Further model simplifications are, of course, possible and may remedy this.

Still another possibility is to use an algorithm that does not require model with affine inputs, see [7]. This has not been implemented.

Including several attempts to completely solve this problem were vain due to

- limits on the maximal object size
- limitations of the solve function
- limits of the available physical (or virtual) memory

The first two problems should be resolved by the MAPLE developers. The last problem is not so easy to solve because the memory requirements are likely to be exponential or double exponential with respect to the problem size [9]. More efficient algorithms are necessary, but some problems will still be computationally intractable.

Numerics can be helpful, e.g., to solve sets of nonlinear (partial differential) equations. For the vehicle problem we resorted to a purely numeric approach to find out the stability of the zero dynamics. We propose to use this problem as a benchmark or yardstick for the viability of symbolic computation programs in nonlinear control.

VI. CONCLUSION AND DISCUSSION

The computation of the normal form of the zero dynamics of the solution of the input-output and the state space exact linearization problems can be automated by using symbolic computation, e.g., by using the NonLinCon package. At the moment, the computations cannot be done for complex models due to the limited capability to solve sets of nonlinear (differential) equations. Therefore the designers of control systems cannot yet routinely compute solutions for these problems using tools based on symbolic computation programs. To remedy this, we recommend extending the capabilities of symbolic computation programs for solving large and intricate sets of nonlinear (differential) equations. It is also necessary to use more efficient algorithms. Future research will therefore aim at

- devising new or modifying existing algorithms to be more efficient in space and time
- implementing the algorithms in a more efficient way, especially with regard to computer memory requirements
- investigating a merge of symbolic with numeric computation for a hybrid solution of the problems
- solving more small and larger scale problems, to further guide in the selection of pressing lines of research

To come back to the title of the note, at the moment we cannot deny nor confirm the unqualified viability of this approach. It is expected that within this decade the capability and efficiency of symbolic computation programs are enhanced and that the increasing computing power/cost ratio of computers will enable the solution of the benchmark and larger problems at reasonable costs.

ACKNOWLEDGMENT

H. van Essen implemented most of the algorithms in MAPLE. I. van de Broek supplied the vehicle simulation problem.

Note on Decentralized Adaptive Controller Design

Joon Lyoo

Abstract—This note extends the decentralized adaptive controller design of Gavel and Siljak [1] to the case when the relative order of each isolated subsystem does not exceed two.

1. INTRODUCTION

Recently Gavel and Siljak [1] presented a stable adaptive decentralized design in the face of unknown interconnection strengths and under some structural conditions placed on the interconnections. As a main result, they suggested a decentralized high gain feedback scheme for model reference adaptive control (MRAC) of an uncertain interconnected system which is composed of single input single output subsystems, and in each subsystem of which either incoming interactions enter through the control channel (Class I) or outgoing interactions pass through the measurement channel (Class II). However, the design technique for the Class I has the disadvantage of disconnecting the interconnection signal from the input of the plant. And moreover, the main result is restricted to the case when the relative order of each subsystem (n^*) is equal to one (Case 1).

This note is concerned with developing a decentralized MRAC design for an uncertain interconnected system which belongs to the Class 0 and allows for the relaxed assumption that n^* is less than and equal to two. Since in case that $n^* = 2$ (Case 2), it is not possible to choose the reference model strictly positive real any longer, the Case 2 needs to be treated in a different way from the Case 1.

Manuscript received July 24, 1992; revised March 23, 1994. This work was supported in part by the Postdoctoral Program of the Korea Science and Engineering Foundation, Republic of Korea.

The author is with the Department of Electronic Engineering, Chungnam National University, Taejeon 305-764, Korea.
IEEE Log Number 9407014.

For later comparison, the main result of [1] for the Class 0 and Case 1 is summarized in the following. Each subsystem controller consists of a precompensator C_i^p and a feedback compensator C_i^f leading to the open-loop subsystem description

$$S_i: \begin{aligned} \dot{x}_i &= A_i x_i + b_i u_i + f_i(t, y) \\ y_i &= c_i^T x_i \end{aligned} \quad (1)$$

$$C_i^p: \dot{z}_{pi} = F_i z_{pi} + g_i u_i \quad (2)$$

$$C_i^f: \dot{z}_{fi} = F_i z_{fi} + g_i y_i, \quad (3)$$

for $i = 1, 2, \dots, N$,

where $x_i \in R^{n_i}$, $z_{pi} \in R^{n_{pi}}$, and $z_{fi} \in R^{n_{fi}}$ are the states of S_i , C_i^p , and C_i^f , u_i and y_i are the scalar input and the scalar output of the subsystem S_i , and $y = [y_1, y_2, \dots, y_N]^T$. Also, f_i is a vector of output-dependent disturbances affecting S_i and satisfies the conic sector bound expressed by

$$\|f_i(t, y)\| \leq \sum_{j=1}^N \xi_{ij} |y_j|, \quad (4)$$

where ξ_{ij} 's are unknown but positive constants.

The local adaptive controllers are given by

$$u_i = \theta_i^T \nu_i, \quad i = 1, 2, \dots, N, \quad (5)$$

where $\nu_i = [\tilde{y}_i, \hat{z}_{pi}^T, \hat{z}_{fi}^T, r_i]^T$ is a vector of available signals, and $\theta_i = [\hat{d}_{fi}, \hat{c}_{pi}^T, \hat{c}_{fi}^T, \hat{k}_{oi}]^T$ is a vector of adaptation gains. Also, r_i is the reference input, and $y_i = y_i - y_{mi}$ is the model output following error with y_{mi} being the model output. $\theta_i(t)$ in (5) is automatically adjusted by the adaptation law to levels that assure stability of the overall system.

$$\dot{\theta}_i = -\Gamma_i(\sigma\theta_i + \nu_i \tilde{y}_i), \quad (6)$$

where Γ_i is a symmetric positive definite weighting matrix and σ is a positive decaying constant.

II. MAIN RESULT

To handle the Case 2, the basic control structure is modified so that the strictly positive realness of the closed-loop isolated subsystem be preserved, and the following local adaptive controllers are devised based on the design concept of [2].

$$u_i = \theta_i^T \nu_i + \hat{\theta}_i^T \Psi_{1i} - \text{sgn}(\tilde{y}_i)(\rho_i |\tilde{y}_i| + \dot{\rho}_i \Psi_{2i}) \quad (7)$$

$$\begin{aligned} \dot{\theta}_i &= -\Gamma_i(\sigma\theta_i + \Psi_{1i} \tilde{y}_i) \\ \dot{\rho}_i &= -\gamma_i(\sigma\rho_i - \Psi_{2i} |\tilde{y}_i|) \end{aligned} \quad (8)$$

$$\begin{aligned} \dot{\Psi}_{1i} &= -h_i \Psi_{1i} + \nu_i \\ \dot{\Psi}_{2i} &= -h_i \Psi_{2i} + |\tilde{y}_i| \end{aligned} \quad (9)$$

where h_i is a positive constant, γ_i is a positive weighting factor, and $\text{sgn}(\cdot)$ means the signum function. In (7), $\rho_i(t)$ is introduced to override some destabilizing effects by the interconnections from other subsystems to the i th subsystem.

Applying (7) to the nonminimal representation (1), (2), and (3), the closed-loop interconnected system becomes

$$\begin{aligned} \dot{S}: \dot{x}_i &= \hat{A}_i(\theta_i^*) \hat{x}_i + \hat{b}_i(\theta_i^T \nu_i + \hat{\theta}_i^T \Psi_{1i} - \theta_i^{*T} \nu_i) \\ &\quad - \text{sgn}(\tilde{y}_i) \hat{b}_i(\rho_i |\tilde{y}_i| + \dot{\rho}_i \Psi_{2i} - \rho_i^* |\tilde{y}_i|) \\ &\quad - \text{sgn}(\tilde{y}_i) \hat{b}_i \rho_i^* |\tilde{y}_i| + \hat{b}_i k_{oi}^* r_i - \hat{b}_i d_{fi}^* y_{mi} + f_i \\ &= \hat{A}_i(\theta_i^*) \hat{x}_i + \hat{b}_{iPR} \phi_{1i}^T \Psi_{1i} - \text{sgn}(\tilde{y}_i) \hat{b}_{iPR} \phi_{2i}^T \Psi_{2i} \\ &\quad - \text{sgn}(\tilde{y}_i) \hat{b}_{iPR} \rho_i^* \Psi_{2i} + \hat{b}_i k_{oi}^* r_i - \hat{b}_i d_{fi}^* y_{mi} + \hat{f}_i \\ y_i &= \hat{c}_i^T \hat{x}_i, \quad i = 1, 2, \dots, N. \end{aligned} \quad (10)$$

where

$$\hat{x}_i = [x_i^T, z_{pi}^T, z_{fi}^T]^T,$$

$$\hat{A}_i(\theta_i^*) = \begin{bmatrix} A_i + b_i d_{fi}^{*T} c_i^T & b_i c_{pi}^{*T} & b_i c_{fi}^{*T} \\ g_i d_{fi}^{*T} c_i^T & F_i + g_i c_{pi}^{*T} & g_i c_{fi}^{*T} \\ g_i c_i^T & 0 & F_i \end{bmatrix}$$

$$\hat{b}_i = [b_i^T, g_i^T, 0]^T, \quad \hat{c}_i^T = [c_i^T, 0, 0]$$

$$\hat{f}_i = [f_i^T, 0, 0]^T, \quad \theta_i^* = [d_{fi}^*, c_{pi}^{*T}, c_{fi}^{*T}, k_{oi}^*]^T$$

$$\phi_{1i} = \theta_i - \theta_i^*, \quad \rho_i^* > 0, \quad \phi_{2i} = \rho_i - \rho_i^*, \quad (11)$$

and \hat{b}_{iPR} is a vector satisfying $\{\hat{c}_i^T(sI_i - \hat{A}_i)^{-1} \hat{b}_i\}(s + h_i) = \{\hat{c}_i^T(sI_i - \hat{A}_i)^{-1} \hat{b}_{iPR}\}$. Note that for $\phi_i = \phi_{1i}$ or ϕ_{2i} , $(s + h_i)\phi_i(s + h_i)^{-1}$ is functionally equivalent to $\{\phi_i + \phi_i(s + h_i)^{-1}\}$ [2]. In (11), θ_i^* and ρ_i^* are unknown parameter vector and unknown positive constant to be defined later for which $\theta_i(t)$ and $\rho_i(t)$ are estimated, respectively.

Corresponding to the plant (10), the reference model chosen to be stable and of minimum phase, and such that $n_i^* = 2$ can be expressed in a nonminimal representation [1]. That is, the model transfer functions $\varphi_{mi}(s)$, $i = 1, 2, \dots, N$ can be realized as

$$\begin{aligned} \hat{M}: \dot{x}_{mi} &= \hat{A}_i(\theta_i^*) \hat{x}_{mi} + \hat{b}_i k_{oi}^* r_i \\ i &= 1, 2, \dots, N. \end{aligned} \quad (12)$$

Defining the tracking error $\hat{e}_i = \hat{x}_i - \hat{x}_{mi}$, the closed-loop error equations are derived by subtracting (12) from (10)

$$\begin{aligned} \dot{S}: \dot{\hat{e}}_i &= \hat{A}_i(\theta_i^*) \hat{e}_i + \hat{b}_{iPR} \phi_{1i}^T \Psi_{1i} - \text{sgn}(\tilde{y}_i) \hat{b}_{iPR} \phi_{2i}^T \Psi_{2i} \\ &\quad - \text{sgn}(\tilde{y}_i) \hat{b}_{iPR} \rho_i^* \Psi_{2i} - \hat{b}_i d_{fi}^* y_{mi} + \hat{f}_i \\ \dot{y}_i &= \hat{c}_i^T \hat{e}_i, \quad i = 1, 2, \dots, N. \end{aligned} \quad (13)$$

where the transfer functions $\{\hat{c}_i^T(sI_i - \hat{A}_i)^{-1} \hat{b}_{iPR}\} = \varphi_{mi}(s + h_i)$ for all i , are strictly positive real. Hence, from the Kalman-Yacubovich Lemma [1], it follows that $(\hat{A}_i, \hat{b}_{iPR}, \hat{c}_i^T)$ satisfies the equations

$$\begin{aligned} \hat{A}_i^T \hat{H}_i + \hat{H}_i \hat{A}_i &= -(N+2)I_i \\ \hat{H}_i \hat{b}_{iPR} &= \hat{c}_i^T \end{aligned} \quad (14)$$

for symmetric positive definite matrix \hat{H}_i and the identity matrix I_i .

The stability of the overall error system (13), $\dot{\phi}_{1i} = \dot{\theta}_i$ and $\dot{\phi}_{2i} = \dot{\rho}_i$ in (8) is then established through the following theorem.

Theorem: The solutions $(\hat{e}_i, \phi_{1i}, \phi_{2i})$, $\{t; t_0, \hat{e}_i(t_0), \phi_{1i}(t_0), \phi_{2i}(t_0)\}$, $i = 1, 2, \dots, N$ of the system \dot{S} , are globally uniformly bounded.

Proof: Let us choose a Lyapunov function candidate as

$$V(\hat{e}, \phi_1, \phi_2) = \sum_{i=1}^N \{\hat{e}_i^T \hat{H}_i \hat{e}_i + \phi_{1i}^T \Gamma_i^{-1} \phi_{1i} + \gamma_i^{-1} (\phi_{2i})^2\}. \quad (15)$$

Evaluating the time derivative of V along (13), (8), and (14), and then taking the norm operation, we use (4) to get

$$\begin{aligned} \dot{V} &\leq \sum_{i=1}^N \left\{ -N \|\hat{e}_i\|^2 - 2 \|\hat{e}_i\|^2 - 2 \rho_i^* |\tilde{y}_i| |\Psi_{2i}| - 2 \sigma \|\phi_{1i}\|^2 \right. \\ &\quad + 2 \sigma \|\phi_{1i}\| \|\theta_i^*\| - 2 \sigma |\phi_{2i}|^2 + 2 \sigma |\phi_{2i}| \rho_i^* \\ &\quad + 2 \|\hat{e}_i\| \|\hat{H}_i \hat{b}_i\| |d_{fi}^*| |y_{mi}| \\ &\quad \left. + 2 \|\hat{e}_i\| \|\hat{H}_i\| \sum_{j=1}^N \xi_{ij} |\tilde{y}_j| + |y_{mj}| \right\}. \end{aligned} \quad (16)$$

Fig. 1. Model output following errors.

Fig. 2. Adapted gains for the subsystem 2.

Note that $\text{sgn}(\hat{y}_i) \hat{c}_i^T \hat{H}_i \hat{b}_{i,K} = \text{sgn}(\hat{y}_i) \hat{y}_i = |\hat{y}_i|$. Completing squares, (16) is modified as

$$\begin{aligned} \dot{V} \leq & \sum_{i=1}^N \left[- \left\{ \sum_{j=1}^N (\|c_i\| - \|\hat{H}_i\| \xi_{ij} |\hat{y}_j|)^2 \right\} \right. \\ & + 2\rho_i^* |\hat{y}_i|^2 - 2\rho_i^* |\hat{y}_i| \Psi_{2i} - \|\hat{c}_i\|^2 - \sigma \|\phi_{1i}\|^2 \\ & - \sigma \|\phi_{2i}\|^2 - (\|c_i\| - \mu_i)^2 + \mu_i^2 - \sigma (\|\phi_{1i}\| - \|\theta_i^*\|)^2 \\ & \left. + \sigma \|\theta_i^*\|^2 - \sigma (\|\phi_{2i}\| - \rho_i^*)^2 + \sigma (\rho_i^*)^2 \right] \end{aligned} \quad (17)$$

where ρ_i^* and μ_i^* are finite positive constants given by

$$\rho_i^* = \frac{1}{2} \sum_{j=1}^N \|\hat{H}_i\|^2 \xi_{ij}^2$$

$$\mu_i = \|\hat{H}_i \hat{b}_i\| |d_{ij}^*| \sup_t |y_{mj}| + \|\hat{H}_i\| \sum_{j=1}^N \xi_{ij} \sup_t |y_{mj}|. \quad (18)$$

In deriving ρ_i^* , $\sum_{i=1}^N \sum_{j=1}^N \|\hat{H}_i\|^2 \xi_{ij}^2 |\hat{y}_j|^2 = \sum_{j=1}^N \sum_{i=1}^N \|\hat{H}_i\|^2 \xi_{ij}^2 |\hat{y}_j|^2$ is used. The term $(-2\rho_i^* |\hat{y}_i| \Psi_{2i})$ in (17) plays the same role as the term $(-2\rho_i \hat{c}_i^T \hat{c}_i \hat{c}_i^T \hat{c}_i = 2\rho_i |\hat{y}_i|^2)$ in (5.27) of [1]. To override the destabilizing term $(2\rho_i^* |\hat{y}_i|^2)$ which arises after aggregation of all the interactions affecting the i th subsystem, Ψ_{2i} must be positive and $\Psi_{2i} \geq |\hat{y}_i|$ for all t . This is the rationale in adopting the signum and absolute functions contrary to [1].

Neglecting the negative term from (17), we obtain

$$\begin{aligned} \dot{V} \leq & \sum_{i=1}^N \{ -\|c_i\|^2 - \sigma \|\phi_{1i}\|^2 - \sigma \|\phi_{2i}\|^2 \\ & + \mu_i^2 + \sigma \|\theta_i^*\|^2 + \sigma (\rho_i^*)^2 \}. \end{aligned} \quad (19)$$

Hence, $\dot{V} < 0$ outside some compact region whose size depend on the strength of the interconnections, local design parameters, and the maximum values of the model outputs. Therefore, all signals are bounded according to Theorem 2.24 of [3].

III. NUMERICAL EXAMPLE

Consider the unstable linear constant interconnected system with unknown system parameters described by

$$\begin{aligned} \dot{x}_1 &= \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} x_1 + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u_1 + \begin{bmatrix} 1 \\ -1 \end{bmatrix} y_2 \\ y_1 &= [4 \quad 2] x_1 \\ \dot{x}_2 &= \begin{bmatrix} 0 & 1 \\ 2 & 0 \end{bmatrix} x_2 + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u_2 + \begin{bmatrix} 0.2 \\ -0.2 \end{bmatrix} y_2 + \begin{bmatrix} -1 \\ 1 \end{bmatrix} y_1 \\ y_2 &= [2 \quad 0] x_2. \end{aligned}$$

Note that $n_1^* = 1$ and $n_2^* = 2$. Let us choose the reference model as

$$\varphi_{m1}(s) = \frac{(s+4)}{(s+2)^2}, \quad \varphi_{m2}(s) = \frac{4}{(s+2)^2},$$

where reference inputs are square waves of height 5 and period 10 s.

Now, using the proposed decentralized adaptive scheme, computer simulations are carried out for MRAC of the example plant. The results with design parameters in (2), (3), (6), (8), and (9)

$$F_i = -4, \quad g_i = 1, \quad \Gamma_i = I_i, \quad i = 1, 2$$

$$\gamma_2 = 2, \quad h_2 = 4, \quad \sigma = 0.01,$$

are presented in Figs. 1 and 2. Due to lack of space, adapted gains are displayed only for the subsystem 2. As can be seen in the figures, the output of each subsystem closely tracks the model output after a finite interval and all the adjustable parameters are bounded for all time.

IV. CONCLUSION

Decentralized adaptive controllers have been developed for a class of interconnected systems with unknown interconnection strengths as well as uncertainties in subsystem dynamics. The local controllers essentially have output error feedback terms to override destabilizing effects by the output-dependent interactions. Specifically when the relative order of each subsystem is equal to two, each subsystem controller is reinforced such that the transfer function of the closed-loop isolated subsystem be strictly positive real.

Characterization of Zeros in Two-Frequency-Scale Systems

Hossein M. Oloomi and Mahmoud E. Sawan

Abstract—We study the asymptotic behavior of the zeros of a two-frequency-scale transfer function in terms of the zeros of its slow and fast transfer functions. By introducing the notion of type index, we will show that all zeros of a two-frequency-scale transfer function with the type index of either $\nu \geq 0$ or $\nu = -1$ can be completely characterized in a manner that is quite similar to the characterization of the poles. We also give a partial characterization for all other zeros in terms of the cardinality of their zero sets.

I. INTRODUCTION

Single parameter standard singularity perturbed systems have been traditionally studied in the time domain [1]. However, an equivalent frequency domain characterization now exists which allows these systems to be studied entirely in the frequency domain [2]–[3]. Using this characterization, many important frequency domain problems including the two-frequency-scale (TFS) compensation design [4], the model matching problem [5]–[6], the H_∞ control theory [7]–[8], and the Hankel norm approximation problem [9] have been solved recently.

Study of the zeros of TFS systems, or equivalently the zeros of singularly perturbed systems, has not been vigorously pursued in the past. The obvious reason for this is that most often a property pertaining to singularly perturbed systems is ascertained in terms of ascertaining the same property for two lower order subsystems. However, when the property is taken to be the asymptotic behavior of the zeros, this deductive technique of proof seems to break down. The discouraging results in the following example demonstrate this point. However, despite the hopeless appearance of the results, we will show that much useful information can be obtained regarding the zeros of $H(s, \epsilon)$ from the knowledge of the zeros of $H_s(s)$ and $H_F(\epsilon s)$.

Example 1: Consider

$$H(s, \epsilon) = \frac{\epsilon s^2 + 1}{(s+1)(\epsilon s+1)}.$$

This is an example of a TFS transfer function with the slow and fast transfer functions $H_s(s) = 1/(s+1)$ and $H_F(\epsilon s) = \epsilon s/(\epsilon s+1)$, respectively. Zeros of $H(s, \epsilon)$ are at $\pm j/\sqrt{\epsilon}$. However, the slow transfer function has a zero at infinity and the fast transfer function has a zero at the origin. In contrast to what one can say about the poles, these zeros do not seem to approximate zeros of $H(s, \epsilon)$ in any meaningful sense.

From the computational point of view, until now the Newton polygon test has been the only available tool for the study of the zeros of TFS transfer functions [10]–[11]. However, this test does not take advantage of the zeros of the slow and fast transfer functions. In contrast, in this paper the behavior of the zeros of $H(s, \epsilon)$ are studied in terms of the behavior of the zeros of $H_s(s)$ and $H_F(\epsilon s)$. Since these two transfer functions have fewer zeros than $H(s, \epsilon)$, one always gains a computational advantage by taking our approach.

IEEE Log Number 9407015.

Additionally, we believe that our results will shed light on the performance analysis of schemes such as TFS LQG/LTR [12] and TFS H_∞ [13]–[14] theories since performance of these schemes as well as many others are ultimately tied to the location of the system zeros in the complex plane [15].

We will use the standard notation N , Z , Q , and R to denote the set of natural, integer, rational, and real numbers, respectively. The superscript “+” will be used to mean “non-negative.” For example, $Z^+ = N \cup \{0\}$. $A \setminus B$ denotes the complement of B in A , and $\text{Card}(A)$ denotes the cardinality of the finite set A . We use $\deg[\cdot]$ and $\delta[\cdot]$ to designate the degree functions for polynomials and rational functions, respectively. The set of all TFS transfer functions is denoted by T . When $H(s, \epsilon) \in T$, we denote its slow part by $H_s(s)$ and its fast part by $H_F(p)$ where $p = \epsilon s$.

We recall from Part 4 of Definition 1 in [2] that poles of a TFS transfer function are separated into two distinct groups. The first group of poles are of type $O(\epsilon^\nu)$ for some $\nu \in Q^+$ and are called the slow poles. The second group are of type $O(1/\epsilon)$ and are called the fast poles. However, as Example 1 shows, zeros of TFS systems can have more general expansions. To further explore this idea, let R_ϵ denote the ring of functions of ϵ that are analytic at $\epsilon = 0$ and let $R_s[s]$ denote the set of all polynomials in s with coefficients in $R_\epsilon[s]$. The following theorem characterizes the roots of a polynomial in $R_s[s]$ [2], [10], [16].

Theorem 1: Let $p(s, \epsilon) \in R_s[s]$. Then

- 1) Each of the n roots of $p(s, \epsilon)$ can be expanded about $\epsilon = 0$ as

$$s_i(\epsilon) = \sum_{j=1}^{\infty} b_{ij} \epsilon^{j/k}, \quad 1 \leq i \leq n, \quad (1)$$

where $b_{ij} \in C$ for each i and j , $k \in N$, $\forall \in Z$, and $\epsilon^{1/k}$ is a branch of $\epsilon^{1/k} = \epsilon$.

- 2) If one root has an expansion as in (1) with $k > 1$, then there will be $k-1$ other roots having expansions with the same coefficients but using different branches of $\epsilon^{1/k} = \epsilon$.

It is important to note that only a finite number of terms with negative exponents appear in the Laurent expansion (1). We will use Theorem 1 to classify the roots of a polynomial in $R_s[s]$ according to their Laurent expansions as given by (1).

Definition 1: A root $s_i(\epsilon)$ of $p(s, \epsilon) \in R_s[s]$ is said to be of type $O(\epsilon^\nu)$ with $\nu = N/k$, if expansion of $s_i(\epsilon)$, as given by (1), has $b_{i,1} \neq 0$ and $b_{i,j} = 0$ for $j < N$. If $b_{i,j} = 0$ for all j , then ν is taken to be zero. ν is called the type index of the root $s_i(\epsilon)$.

Note that, roots that are identically zero are classified as $O(1)$ type roots.

We will also need the concept of lost poles. Lost poles were introduced in [2] in terms of the polynomial system matrix. They were later given a state space interpretation in [3]. The following lemma is a direct consequence of Definition 2.1 in [3].

Lemma 1: Let $H(s, \epsilon) \in T$ have n_1 slow poles and n_2 fast poles. Then $H(s, \epsilon)$ will have l_1 slow lost poles iff $\delta[H_s(s)] = n_1 - l_1$, l_2 fast lost poles iff $\delta[H_F(p)] = n_2 - l_2$, and l lost poles iff it has l_1 slow lost poles and l_2 fast lost poles with $l = l_1 + l_2$.

In the next section we will study the zeros of $H(s, \epsilon) \in T$ under the following two assumptions:

- A1) $H(s, \epsilon)$ has at least one slow pole and one fast pole.
- A2) $H(s, \epsilon)$ has no lost poles.

Note that assumption (A1) excludes the single-frequency-scale case. This is no loss in generality since the single-frequency-scale

case can be treated as a special case of the TFS case. Assumption (A2), on the other hand, is not unique to this paper and in fact it is the standing assumption in the previously published works [3]–[9]. The following lemma is a direct consequence of these assumptions.

Lemma 2: Under assumptions (A1)–(A2), the transfer functions $H_S(s)$ and $H_F(p)$ are nonconstant. In particular, they are nonzero.

Proof: By (A2), $l = 0$. This implies $l_1 = l_2 = 0$. By (A1), $n_1 \geq 1$ and $n_2 \geq 1$. Hence, $\delta[H_S(s)] = n_1 - l_1 = n_1 \geq 1$ and $\delta[H_F(p)] = n_2 - l_2 = n_2 \geq 1$. Q.E.D.

II. ASYMPTOTIC BEHAVIOR OF THE ZEROS

Let $H(s, \epsilon) \in T$. Then $H(s, \epsilon)$ can be written in the fractional form

$$H(s, \epsilon) = \frac{M(s, \epsilon)}{N(s, \epsilon)}, \quad (2)$$

where $M(s, \epsilon), N(s, \epsilon) \in \mathcal{R}_\epsilon[s]$ are relatively prime. We are interested in studying the asymptotic behavior of the zeros of $H(s, \epsilon)$.

Definition 2: Define the following sets.

- The sets of zeros: Let Z_H^0 and Z_H^∞ denote the set of all zeros of $H(s, \epsilon)$ at the origin and at infinity, respectively, and let

$$Z_H := \{s \in \mathbb{C} \mid H(s, \epsilon) = 0\},$$

$$Z_H(\nu_1, \nu_2) := \{s \in Z_H \mid s = O(\epsilon^\nu), \nu_1 < \nu < \nu_2\},$$

$$Z_H(\nu) := \{s \in Z_H \mid s = O(\epsilon^\nu)\},$$

with the multiplicities included in each set.

- The sets of zero indices: Let

$$Q_Z := \{\nu \mid s \in Z_H \text{ \& } s = O(\epsilon^\nu)\},$$

$$Q_Z(\nu_1, \nu_2) := \{\nu \mid s \in Z_H \text{ \& } s = O(\epsilon^\nu), \nu_1 < \nu < \nu_2\}.$$

- The sets of poles: Let P_H^0 denote the set of all poles of $H(s, \epsilon)$ at the origin and $P_H := \{s \in \mathbb{C} \mid N(s, \epsilon) = 0\}$. Let $P_H(\nu_1, \nu_2)$ and $P_H(\nu)$ be defined similar to $Z_H(\nu_1, \nu_2)$ and $Z_H(\nu)$, respectively, but with Z_H replacing P_H . Let multiplicities be included in each of these sets.
- The sets of pole indices: Let Q_P and $Q_P(\nu_1, \nu_2)$ be defined as Q_Z and $Q_Z(\nu_1, \nu_2)$, respectively but with Z_H replacing P_H .
- For the slow and the fast transfer functions, define the set of zeros and the set of poles exactly as above but with H_S and H_F replacing H , respectively.

We are now in a position to present our main theorems. Theorem 2 shows how zeros of the slow transfer function relate to the zeros of the TFS transfer function $H(s, \epsilon)$.

Theorem 2: Let $H(s, \epsilon) \in T$ satisfy assumptions (A1)–(A2). Then

- 1) $Z_{H_S} = Z_{H_S}(0)$.
- 2) $\text{Card}(Z_{H_S}) = \sum_{\nu \in Q_Z^+} \text{Card}(Z_H(\nu))$.
- 3) $\text{Card}(Z_{H_S}^0) = \text{Card}(Z_H^0) + \text{Card}(Z_H(0, \infty))$.
- 4) Every zero $z(\epsilon) \in Z_H(\nu)$ with $\nu \in Q_Z^+$ can be approximated as $z(\epsilon) = z + r(\epsilon)$ where $z \in Z_{H_S}$ and $r(\epsilon) \rightarrow 0$ as $\epsilon \rightarrow 0$.

Proof: We first write $H(s, \epsilon)$ in the fractional form (2). Our immediate goal is to express both $M(s, \epsilon)$ and $N(s, \epsilon)$ in terms of their primitive factors. Since $N(s, \epsilon)$ has only slow and fast roots, its factorization is simpler. So, we proceed with $N(s, \epsilon)$ first. By definition, we have the disjoint union $Q_P = Q_P(0, \infty) \cup \{0\} \cup \{-1\}$. Therefore, we can factor $N(s, \epsilon)$ uniquely as

$$N(s, \epsilon) = g(\epsilon)N_1(s, \epsilon)N_2(s, \epsilon)N_3(s, \epsilon), \quad (3)$$

where $g(\epsilon)$ is analytic at $\epsilon = 0$, and $N_1(s, \epsilon)$, $N_2(s, \epsilon)$ and $N_3(s, \epsilon)$ are monic polynomials (in s) with roots that have type indices in the sets $Q_P(0, \infty)$, $Q_P(0)$, $Q_P(-1)$, respectively. To obtain a more useful representation for $N(s, \epsilon)$, let $\epsilon^\nu \beta_{j,\nu}(\epsilon)$ denote the j th root of $N(s, \epsilon)$ among those roots that have type index ν . Assuming the existence of such roots, we define the following two families of polynomials

$$q_\nu(s, \epsilon) := \prod_{j=1}^{l_\nu} (s - \epsilon^\nu \beta_{j,\nu}(\epsilon)), \quad \nu \in Q_P, \quad (4)$$

$$\tilde{q}_\nu(s, \epsilon) := \epsilon^{-\nu l_\nu} q_\nu(s, \epsilon). \quad (5)$$

We observe that $q_\nu(s, \epsilon) \in \mathcal{R}_\epsilon[s]$ whenever $\nu \in Q_P^+$, and $\tilde{q}_\nu(s, \epsilon) \in \mathcal{R}_\epsilon[s]$ whenever $\nu \in Q_P \setminus Q_P^+$. Use of (4)–(5) allows us to write

$$N_1(s, \epsilon) = \prod_{\nu \in Q_P(0, \infty)} q_\nu(s, \epsilon), \quad (6)$$

$$N_2(s, \epsilon) = q_0(s, \epsilon) = s^{n_{00}} \prod_{j=1}^{l_0 - n_{00}} (s - \beta_{j,0}(\epsilon)), \quad \beta_{j,0}(\epsilon) \neq 0$$

$$:= s^{n_{00}} N_{20}(s, \epsilon), \quad (7)$$

$$N_3(s, \epsilon) = q_{-1}(s, \epsilon) = \epsilon^{-l_{-1}} \tilde{q}_{-1}(s, \epsilon)$$

$$:= \epsilon^{-n_3} \tilde{N}_3(s, \epsilon), \quad n_3 := l_{-1}, \quad (8)$$

where $n_j = \deg[N_j(s, \epsilon)]$ for $j = 1, 2, 4$, and by definition $\beta_{j,-1}(0) \neq 0$ [2]. Thus, $N(s, \epsilon)$ can be factored alternatively as

$$N(s, \epsilon) = \epsilon^{-n_3} g(\epsilon) [N_1(s, \epsilon) s^{n_{00}}] N_{20}(s, \epsilon) \tilde{N}_3(s, \epsilon). \quad (9)$$

Next, we obtain a factorization for $M(s, \epsilon)$. Since each root of $M(s, \epsilon)$ has an expansion of the form (1) given by Theorem 1, we factor $M(s, \epsilon)$ as

$$M(s, \epsilon) = f(\epsilon) \prod_{j=1}^5 M_j(s, \epsilon), \quad (10)$$

where $f(\epsilon)$ is analytic at $\epsilon = 0$, and $M_j(s, \epsilon)$ for $j = 1, \dots, 5$ are monic polynomials (in s) and have roots with type indices in the sets $Q_Z(0, \infty)$, $\{0\}$, $Q_Z(-1, 0)$, $\{-1\}$, and $Q_Z(-\infty, -1)$, respectively. Since these sets are pairwise disjoint and have union equal to Q_Z , this factorization is unique. An alternative representation for $M(s, \epsilon)$ is obtained by introducing the following two families of polynomials

$$p_\nu(s, \epsilon) := \prod_{j=1}^{k_\nu} (s - \epsilon^\nu \alpha_{j,\nu}(\epsilon)), \quad \nu \in Q_Z, \quad (11)$$

$$\hat{p}_\nu(s, \epsilon) := \epsilon^{-\nu k_\nu} p_\nu(s, \epsilon), \quad (12)$$

where $\epsilon^\nu \alpha_{j,\nu}(\epsilon)$ denotes the j th root of $M(s, \epsilon)$ among those that have type index ν , and k_ν denotes the number of such roots. We observe that $p_\nu(s, \epsilon) \in \mathcal{R}_\epsilon[s]$ whenever $\nu \in Q_Z^+$, and $\hat{p}_\nu(s, \epsilon) \in \mathcal{R}_\epsilon[s]$ whenever $\nu \in Q_Z \setminus Q_Z^+$. Use of (11)–(12) allows us to write

$$M_1(s, \epsilon) = \prod_{\nu \in Q_Z(0, \infty)} p_\nu(s, \epsilon), \quad (13)$$

$$M_2(s, \epsilon) = p_0(s, \epsilon) = s^{m_{00}} \prod_{j=1}^{k_0 - m_{00}} (s - \alpha_{j,0}(\epsilon)), \quad \alpha_{j,0}(\epsilon) \neq 0$$

$$:= s^{m_{00}} M_{20}(s, \epsilon), \quad (14)$$

$$M_3(s, \epsilon) = \prod_{\nu \in Q_Z(-1, 0)} p_\nu(s, \epsilon) = \prod_{\nu \in Q_Z(-1, 0)} \epsilon^{\nu k_\nu} \hat{p}_\nu(s, \epsilon)$$

$$:= \epsilon^{-m_3} \prod_{\nu \in Q_Z(-1, 0)} \hat{p}_\nu(s, \epsilon) =: \epsilon^{-m_3} \tilde{M}_3(s, \epsilon), \quad (15)$$

$$M_4(s, \epsilon) = p_{-1}(s, \epsilon) = e^{-k-1} \tilde{p}_{-1}(s, \epsilon) = \epsilon^{-m_4} \tilde{M}_4(s, \epsilon),$$

$$m_4 = k_{-1}, \quad (16)$$

$$M_5(s, \epsilon) = \prod_{\nu \in Q_Z(-\infty, -1)} p_\nu(s, \epsilon) = \prod_{\nu \in Q_Z(-\infty, -1)} \epsilon^{\nu k_\nu} \tilde{p}_\nu(s, \epsilon)$$

$$:= \epsilon^{-\mu_5} \prod_{\nu \in Q_Z(-\infty, -1)} \tilde{p}_\nu(s, \epsilon) = \epsilon^{-\mu_5} \tilde{M}_5(s, \epsilon), \quad (17)$$

where $m_j = \deg[M_j(s, \epsilon)]$ for $j = 1, \dots, 5$, and $\mu_3, \mu_5 \in \mathbb{N}$ by Part 2 of Theorem 1. Hence, $M(s, \epsilon)$ can be factored alternatively as

$$M(s, \epsilon) = \epsilon^{-(\mu_3+m_4+\mu_5)} f(\epsilon) [M_1(s, \epsilon) s^{m_{00}}] \cdot M_{20}(s, \epsilon) \tilde{M}_1(s, \epsilon) \tilde{M}_4(s, \epsilon) \tilde{M}_5(s, \epsilon), \quad (18)$$

and using (9) and (18) we can express $H(s, \epsilon)$ as

$$H(s, \epsilon) = \epsilon^{\gamma_5} \frac{f(\epsilon) M_1(s, \epsilon) s^{m_{00}} M_{20}(s, \epsilon) \tilde{M}_1(s, \epsilon) \tilde{M}_4(s, \epsilon) \tilde{M}_5(s, \epsilon)}{g(\epsilon) N_1(s, \epsilon) s^{n_{00}} N_{20}(s, \epsilon) \tilde{N}_1(s, \epsilon)}, \quad (19)$$

where

$$\gamma_5 = n_4 - (\mu_3 + m_4 + \mu_5). \quad (20)$$

We are now in a position to analyze the limit of $H(s, \epsilon)$ as $\epsilon \rightarrow 0$. We observe that as ϵ approaches zero, each of the polynomials $\tilde{M}_1(s, \epsilon)$, $\tilde{M}_4(s, \epsilon)$, and $\tilde{M}_5(s, \epsilon)$ approaches a finite constant limit, say K_j , $j=3, 4, 5$, respectively. Since $H(s, \epsilon)$ has no lost poles, these constants are nonzero according to Lemma 2. Since $H(s, 0)$ is defined, the polynomial $\tilde{N}_4(s, \epsilon)$ must also approach a finite nonzero limit, say K' . Moreover, $M_1(s, \epsilon) \rightarrow s^{m_1}$, $M_{20}(s, \epsilon) \rightarrow M_{20}(s, 0) = \prod_{j=1}^{m_2-m_{00}} (s - \alpha_{j,0}(0))$ where $\alpha_{j,0}(0) \neq 0$, $N_1(s, \epsilon) \rightarrow s^{n_1}$, and $N_{20}(s, \epsilon) \rightarrow N_{20}(s, 0) = \prod_{j=1}^{n_2-n_{00}} (s - \beta_{j,0}(0))$ where $\beta_{j,0}(0) \neq 0$. Therefore,

$$\frac{M_1(s, \epsilon) s^{m_{00}}}{N_1(s, \epsilon) s^{n_{00}}} \rightarrow s^{\lambda_5}$$

where,

$$\lambda_5 = (m_{00} + m_1) - (n_{00} + n_1). \quad (21)$$

Finally, since $H(s, 0)$ is defined, the quantity $\epsilon^{\gamma_5} f(\epsilon)/g(\epsilon)$ must approach a finite limit, say $K/K'/\prod_{j=1}^5 K_j$, and in the light of Lemma 2, this limit must be nonzero. Hence,

$$H_5(s) := H(s, 0) = K_5 \frac{s^{\lambda_5} M_{20}(s, 0)}{N_{20}(s, 0)}. \quad (22)$$

Since all zeros of $H_5(s)$ are $O(1)$ type zeros, Part 1 of the theorem follows immediately. To prove Part 3, first note from (21) that although the quantities $(m_{00} + m_1)$ and $(n_{00} + n_1)$ are both positive, they cannot be simultaneously strictly positive since otherwise, there would be at least one pole-zero cancellation at the origin and this contradicts (A2). Using this fact we observe that $\lambda_5 < 0$ iff $(n_{00} + n_1) > 0$ and $(m_{00} + m_1) = 0$. Hence, $\text{Card}(Z_{H_5}^0) = m_{00} + m_1 = 0$ and the result holds trivially in this case. On the other hand, $\lambda_5 \geq 0$ iff $(m_{00} + m_1) \geq 0$ and $(n_{00} + n_1) = 0$, and in this case

$$\begin{aligned} \text{Card}(Z_{H_5}^0) &= m_{00} + m_1 \\ &= m_{00} + \deg[M_1(s, \epsilon)] \\ &= \text{Card}(Z_{H_1}^0) + \text{Card}(Z_H(0, \infty)). \end{aligned}$$

This completes the proof of Part 3. To prove Part 2, we note that

$$\begin{aligned} \text{Card}(Z_{H_5}) &= \text{Card}(Z_{H_5}^0) + \deg[M_{20}(s, 0)] \\ &= (m_{00} + m_1) + (m_2 - m_{00}) \\ &= m_1 + m_2 \\ &= \sum_{\nu \in Q_Z^+} \text{Card}(Z_H(\nu)). \end{aligned}$$

Finally, suppose $z(\epsilon) \in Z_H(\nu)$ for some $\nu \in Q_Z^+$. Then $z(\epsilon)$ is a root of the polynomial $M_1(s, \epsilon) M_2(s, \epsilon)$. Since $z(\epsilon)$ has type index $\nu \geq 0$, $z(\epsilon)$ is analytic at $\epsilon = 0$. Hence, $z(\epsilon) = z(0) + r(\epsilon)$ where $r(\epsilon) \rightarrow 0$ as $\epsilon \rightarrow 0$. Our foregoing analysis shows that $M_1(s, \epsilon) M_2(s, \epsilon)$ approaches $s^{m_1+m_{00}} M_{20}(s, 0)$, which is the zero polynomial of $H_5(s)$. Hence, $z := z(0) \in H_5(s)$. This proves the last part of the theorem. Q.E.D.

The next theorem relates the zeros of the fast transfer function to the zeros of the TFS transfer function $H(s, \epsilon)$.

Theorem 3: Let $H(s, \epsilon) \in T$ satisfy assumptions (A1)–(A2). Then

- 1) $Z_{H_5} = Z_{H_5}^0 \cup Z_{H_5}(-1)$.
- 2) $\text{Card}(Z_{H_5}) = \sum_{\nu \in Q_Z(-1, \infty) \cup \{-1\}} \text{Card}(Z_H(\nu)) - \sum_{\nu \in Q_Z(-1, \infty)} \text{Card}(P_H(\nu))$.
- 3) $\text{Card}(Z_{H_5}^0) = \sum_{\nu \in Q_Z(-1, \infty)} \text{Card}(Z_H(\nu)) - \sum_{\nu \in Q_Z(-1, \infty)} \text{Card}(P_H(\nu))$.
- 4) Every zero $z(\epsilon) \in Z_H(-1)$ can be approximated as $z(\epsilon) = z + r(\epsilon)$ where $z \in Z_{H_5}(-1)$ and $r(\epsilon) \rightarrow 0$.

Proof: Due to the space limitation, we only outline the proof. Using the notation and results from the previous theorem, we first express $H(p/\epsilon, \epsilon)$ as shown by (23), found at the bottom of the page, where

$$\gamma_4 = (n_1 + n_2 + n_4) - (m_1 + m_2 + m_3 + m_4 + \mu_5). \quad (24)$$

By the repeated use of Part 2 of Theorem 1, we observe that as $\epsilon \rightarrow 0$, $\epsilon^{m_1} M_j(p/\epsilon, \epsilon) \rightarrow p^{m_j}$ and $\epsilon^{n_j} N_j(p/\epsilon, \epsilon) \rightarrow p^{n_j}$ for $j=1, 2$, $\epsilon^{m_3-\mu_3} \tilde{M}_3(p/\epsilon, \epsilon) \rightarrow p^{m_3}$, $\tilde{M}_4(p/\epsilon, \epsilon) \rightarrow \prod_{j=1}^{m_4} (p - \alpha_{j-1}(0))$ where $\alpha_{j-1}(0) \neq 0$, $\tilde{M}_5(p/\epsilon, \epsilon) \rightarrow K_5$, and $\tilde{N}_4(p/\epsilon, \epsilon) \rightarrow \prod_{j=1}^{n_4} (p - \beta_{j-1}(0))$ where $\beta_{j-1}(0) \neq 0$. Thus, taking the limit in (23) as $\epsilon \rightarrow 0$, we obtain

$$\begin{aligned} H_I(p) &:= H\left(\frac{p}{\epsilon}, \epsilon\right) \Big|_{\epsilon=0} \\ &= \epsilon^{\gamma_4} \frac{f(\epsilon)}{g(\epsilon)} \Big|_{\epsilon=0} \frac{p^{\lambda_4} \tilde{M}_4\left(\frac{p}{\epsilon}, \epsilon\right) \Big|_{\epsilon=0}}{\tilde{N}_4\left(\frac{p}{\epsilon}, \epsilon\right) \Big|_{\epsilon=0}} K_5, \end{aligned} \quad (25)$$

where,

$$\lambda_4 = (m_1 + m_2 + m_3) - (n_1 + n_2). \quad (26)$$

Since $H(s, \epsilon)$ has no lost poles, $K_5 \neq 0$ by Lemma 2. Additionally, since $H_I(p)$ is defined, $\epsilon^{\gamma_4} f(\epsilon)/g(\epsilon)$ must approach a finite nonzero constant, say K_I/K_5 . Hence, we can represent $H_I(p)$ as

$$H_I(p) = K_I \frac{p^{\lambda_4} \tilde{M}_4\left(\frac{p}{\epsilon}, \epsilon\right) \Big|_{\epsilon=0}}{\tilde{N}_4\left(\frac{p}{\epsilon}, \epsilon\right) \Big|_{\epsilon=0}}. \quad (27)$$

$$H\left(\frac{p}{\epsilon}, \epsilon\right) = \epsilon^{\gamma_4} \frac{f(\epsilon)}{g(\epsilon)} \frac{[\epsilon^{m_1} M_1\left(\frac{p}{\epsilon}, \epsilon\right)] [\epsilon^{m_2} M_2\left(\frac{p}{\epsilon}, \epsilon\right)] [\epsilon^{m_3-\mu_3} \tilde{M}_3\left(\frac{p}{\epsilon}, \epsilon\right)] \tilde{M}_4\left(\frac{p}{\epsilon}, \epsilon\right) \tilde{M}_5\left(\frac{p}{\epsilon}, \epsilon\right)}{[\epsilon^{n_1} N_1\left(\frac{p}{\epsilon}, \epsilon\right)] [\epsilon^{n_2} N_2\left(\frac{p}{\epsilon}, \epsilon\right)] \tilde{N}_4\left(\frac{p}{\epsilon}, \epsilon\right)} \quad (23)$$

To prove Part 1 of the theorem, we must first show that $\lambda_L \geq 0$. If not, suppose to the contrary $\lambda_L < 0$. Since $H(s, \epsilon) \in T_c$, by definition $H_I(p)$ cannot have a pole at the origin. Therefore, see from (27) that $M_4(z, \epsilon)|_{z=0}$ must have λ_L roots at the origin to cancel these poles. But this leads to a contradiction since $\lambda_L(0) \neq 0$. Hence, $\lambda_L \geq 0$ i.e. all zeros of $H_I(s, \epsilon)$ are either at the origin or have type the index $\nu = -1$. To prove Part 2, we see that

$$\begin{aligned} \sum_{\epsilon \in Q_H(-1) \cup \{1\}} \text{Card}(Z_H(\nu)) &= \sum_{\epsilon \in Q_H(-1) \cup \{1\}} \text{Card}(P_H(\nu)) \\ &= \sum_1 m_1 - \sum_1 n_1 \\ &= \lambda_L + m_1 \\ &= \lambda_L + \deg M_1(p/\epsilon) \\ &= \text{Card}(Z_{H_I}) \end{aligned}$$

Part 3 follows easily by subtracting $m_1 = \text{Card}(Z_H(-1))$ from both sides of the above equation. Finally let $\epsilon(\epsilon) \in Z_H(-1)$. Then $\epsilon(\epsilon)$ is a root of $M_1(s, \epsilon)$. Since $\epsilon(\epsilon)$ has the type index $\nu = -1$, $\epsilon(\epsilon)$ is analytic at $\epsilon = 0$ and we can write $\epsilon(\epsilon) = \epsilon_1 + \epsilon_2(\epsilon)$ where ϵ_1 is a constant and $\epsilon_2(\epsilon) \rightarrow 0$ as $\epsilon \rightarrow 0$. Part 4 now follows by setting $\epsilon(\epsilon) = \epsilon_2(\epsilon)/\epsilon = \epsilon_2/\epsilon$ and noting that ϵ_1 is a root of $M_1(p/\epsilon) |_{\epsilon=0}$. Q.E.D.

By studying Part 4 of Theorems 2 and 3 we see that the asymptotic behavior of the two polynomials $M_1(s, \epsilon)$, $M(s, \epsilon)$ and $M_4(s, \epsilon)$ are completely characterized in terms of the zeros of the slow and the fast transfer functions respectively. However to completely characterize the asymptotic behavior of all zeros of $H(s, \epsilon)$ the asymptotic behavior of the two polynomials $M_1(s, \epsilon)$ and $M(s, \epsilon)$ in (18) should also be studied in terms of the behavior of the zeros of the slow and fast transfer functions. Although a complete characterization cannot be given due to the vanishing behavior of these two polynomials some partial information can still be obtained as the following two theorems show. To state the first theorem note that $M_1(s, \epsilon)$ in (15) can be written as

$$M_1(s, \epsilon) = \epsilon^l s^{n_1} + \epsilon M(s, \epsilon) \quad \epsilon_1(\epsilon) = M_1(0, \epsilon) \quad (28)$$

where $M(s, \epsilon) \in R[s]$ has degree less than m_1 and $\epsilon_1(0) \neq 0$. Theorem 4 shows that m_1 , μ_1 and $\epsilon_1(0)$ can be determined from the knowledge of the slow and fast transfer functions.

Theorem 4 Under assumptions (A1)–(A2)

- 1) $\mu_1 = \text{Card}(Z_{H_I}^0)$
- 2) $m_1 = \text{Card}(Z_H(-1, 0)) = \text{Card}(Z_{H_I}^*) + \text{Card}(Z_{H_I}^0)$
- 3) If $m_1 \neq 0$ $\epsilon_1(0) = \frac{\lim_{\epsilon \rightarrow 0} \prod_{i=1}^{m_1} \epsilon_i(\epsilon)}{\lim_{\epsilon \rightarrow 0} \prod_{i=1}^{m_1} \epsilon_i(\epsilon)}$ Otherwise $\epsilon_1(0) = \frac{\lim_{\epsilon \rightarrow 0} \prod_{i=1}^{m_1} \epsilon_i(\epsilon)}{\lim_{\epsilon \rightarrow 0} \prod_{i=1}^{m_1} \epsilon_i(\epsilon)}$

Proof In the course of proving Theorems 2 and 3 we proved that $\epsilon = f(\epsilon)/g(\epsilon)$ and $\epsilon^{-1}f(\epsilon)/g(\epsilon)$ approach some finite nonzero constants. This implies that $\epsilon = \epsilon_1$. Thus by equating (20) and (24), we obtain

$$\mu_1 = m_1 + m_2 + m_3 - (n_1 + n_2) \quad (29)$$

On the other hand Part 3 of Theorem 3 shows that

$$\text{Card}(Z_{H_I}^0) = m_1 + m_2 + m_3 - (n_1 + n_2) \quad (30)$$

Comparing (29) and (30) proves Part 1 of the theorem. For Part 2 we rearrange (29) as $m_1 = [(n_1 + n_2) - (m_1 + m_2)] + \mu_1$ and identify the term in the bracket with $\text{Card}(Z_{H_I}^*)$. The last part follows from (22) and (27) noting that $\lambda_L = \epsilon_1(0)$. Q.E.D.

The next theorem shows that $m^* = \deg[M(s, \epsilon)]_{\epsilon=0}$ is determined. Noting that $m^* = \text{Card}(Z_H(-\infty, -1))$ we have

Theorem 5 Let $H(s, \epsilon)$ satisfy assumptions (A1)–(A2). Then

$$\text{Card}(Z_H(-\infty, -1)) = \text{Card}(Z_{H_I}^*) - \text{Card}(H)$$

Proof We have

$$\begin{aligned} \text{Card}(Z_H) &= \sum_{\epsilon \in Q_H} \text{Card}(Z_H(\nu)) \\ &= \sum_{\epsilon \in Q_H^*} \text{Card}(Z_H(\nu)) \\ &\quad + \left[\sum_{\epsilon \in Q_H(-1) \cup \{1\}} \text{Card}(Z_H(\nu)) \right. \\ &\quad \left. - \sum_{\epsilon \in Q_H(-1) \cup \{1\}} \text{Card}(Z_H(\nu)) \right] \\ &\quad + \sum_{\epsilon \in Q_H(-1, 0)} \text{Card}(Z_H(\nu)) \\ &\quad + \sum_{\epsilon \in Q_H(-\infty, -1)} \text{Card}(Z_H(\nu)) \end{aligned}$$

We now replace the first and the fourth summations with the quantities given by Part 2 of Theorem 2 and Part 2 of Theorem 4 respectively. We also replace the summation in the bracket with the quantity obtained after subtracting Part 3 from Part 2 in Theorem 3. After simplifying the result we obtain

$$\begin{aligned} \text{Card}(Z_H) &= \text{Card}(Z_{H_I}^*) + \text{Card}(Z_{H_I}^0) + \text{Card}(Z_{H_I}^*) \\ &\quad + \text{Card}(Z_H(-\infty, -1)) \end{aligned}$$

A further simplification is made upon substituting $\text{Card}(P_H) = \text{Card}(Z_H)$ for the quantity $\text{Card}(Z_{H_I}^0)$ and noting that $\text{Card}(P_H) = \text{Card}(Z_H) - \text{Card}(Z_{H_I}^*)$. This yields

$$\begin{aligned} \text{Card}(Z_H(-\infty, -1)) &= [\text{Card}(P_H) - \text{Card}(Z_{H_I}^*)] \\ &\quad - [\text{Card}(P_H) - \text{Card}(Z_H)] \end{aligned}$$

The theorem now follows by identifying the terms in the brackets with $\text{Card}(Z_{H_I}^*)$ and $\text{Card}(Z_{H_I}^0)$ respectively. Q.E.D.

It is important to note that in determining the exact value of m the relative degree of $H(s, \epsilon)$ should be known in general. In other words knowing only the fast transfer function does not help one to determine m in general as stated by Theorem 5. However if the relative degree of $H(s, \epsilon)$ is not known *a priori* an upper bound for m can still be obtained as the following corollary shows.

Corollary 1 Let $H(s, \epsilon)$ satisfy assumptions (A1)–(A2). Then

$$\text{Card}(Z_H(-\infty, -1)) \leq \text{Card}(Z_{H_I}^*)$$

There is of course a special case where the knowledge of the fast transfer function is sufficient to determine m . This special case is treated in the following corollary.

Corollary 2 Let $H(s, \epsilon)$ satisfy assumptions (A1)–(A2). If $H_I(p)$ is not strictly proper, then

- 1) $\text{Card}(Z_{H_I}^*) = 0$ i.e. $H(s, \epsilon)$ is not strictly proper either
- 2) $\text{Card}(Z_H(-\infty, -1)) = 0$

Proof Since $H_I(p)$ is proper but not strictly proper, $\text{Card}(Z_{H_I}^*) = 0$. By Theorem 5 this implies $\text{Card}(Z_H(-\infty, -1)) = -\text{Card}(Z_{H_I}^*)$. The results now follow. Q.E.D.

Theorem 5 can also be used to prove a scalar version of Lemma 2.5 in [4].

Corollary 3 Let $H(s, \epsilon)$ satisfy assumptions (A1)–(A2). Then $H^{-1}(s, \epsilon) \in T$ iff $H(s, \infty) \neq 0$ and $H_I(\infty) \neq 0$.

Proof: (\Rightarrow): Since $H_s(s)$ and $(H^{-1}(s, \epsilon))_s = (H_s(s))^{-1}$ are proper, $\text{Card}(Z_{H_s}^\infty) = 0$. On the other hand, properness of $H(s, \epsilon)$ and $H^{-1}(s, \epsilon)$ imply that $\text{Card}(Z_H^\infty) = 0$. Since $H^{-1}(s, \epsilon) \in T_+$, we also have $\text{Card}(Z_H(-\infty, -1)) = 0$ and $\text{Card}(Z_H(-1, 0)) = 0$. Hence, by Theorem 5, $\text{Card}(Z_{H_F}^\infty) = 0$.

(\Leftarrow): Since $H_F(\infty) \neq 0$, Part 1 of Corollary 2 shows that $\text{Card}(Z_H^\infty) = 0$. Hence, $H^{-1}(s, \epsilon)$ is proper. Part 2 of Corollary 2 shows that $\text{Card}(Z_H(-\infty, -1)) = 0$. Hence, for $H^{-1}(s, \epsilon)$ to be in T_+ , it suffices to show that $\text{Card}(Z_H(-1, 0)) = 0$. But this follows since $H_F(0) = H_s(\infty) \neq 0$ implies $\text{Card}(Z_{H_F}^0) = 0$ and $\text{Card}(Z_{H_F}^\infty) = 0$. So, by Theorem 4, $\mu_3 = m_3 = 0$. Q.E.D.

Example 2: Reconsider Example 1. Suppose that $H_s(s)$ and $H_F(p)$ are given. Suppose it is also known that $H(s, \epsilon)$ has no lost poles. Since the slow transfer function has no finite zeros, Parts 1 and 4 of Theorem 2 are vacuously true. Part 2 of that theorem shows that $H(s, \epsilon)$ has no zeros with type index $\nu \geq 0$. In particular, $H(s, \epsilon)$ has no zeros at the origin. Since $Z_{H_F}(-1) = 0$, Part 4 of Theorem 3 is vacuously true. Part 2 of Theorem 3 shows that $H(s, \epsilon)$ must have two zeros with type indices in the interval $(-1, \infty)$. Since $H(s, \epsilon)$ has no zeros with type index $\nu \geq 0$, we conclude that $H(s, \epsilon)$ must have two zeros with type indices in the interval $(-1, 0)$. This result can also be verified from Theorem 4 which gives $m_1 = 1$, $\nu_1 = 2$, and $\dot{\nu}_3(0) = 1$. Moreover, Corollary 2 applies to the present case. Therefore, we conclude that $H(s, \epsilon)$ has a zero polynomial of the form $\epsilon s^2 + r_M(s, \epsilon)$ where $r_M(s, \epsilon) \in \mathcal{R}_r[s]$ has degree of either zero or one and $r_M(0, 0) = 1$.

Remark 1: The results obtained in this paper are also useful when studying the asymptotic behavior of the poles of a certain class of singularly perturbed system which are more general than TFS systems [17]. To see this, let $H(s, \epsilon)$ be the transfer function of a (not necessarily standard) singularly perturbed system. Assume that $H^{-1}(s, \epsilon) \in T_+$. In particular, this means that $H(s, \epsilon)$ is invertible. From [3], we know that $H^{-1}(s, \epsilon)$ has a standard singularly perturbed state space realization

$$\left(\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \begin{bmatrix} B_1 \\ B_2 \end{bmatrix}, [C_1 \ C_2], D \right),$$

where all matrices are functions of ϵ which are analytic at $\epsilon = 0$ and $A_{22}(0)$ is invertible. The original system $H(s, \epsilon)$ has the realization

$$\left(\begin{bmatrix} A_{11}^x & A_{12}^x \\ A_{21}^x & A_{22}^x \end{bmatrix}, \begin{bmatrix} B_1 D^{-1} \\ B_2 D^{-1} \end{bmatrix}, [-D^{-1} C_1 \ -D^{-1} C_2], D^{-1} \right),$$

where $A_{ij}^x := A_{ij} - B_i D^{-1} C_j$ for $i, j = 1, 2$. Hence, when $A_{22}^x(0)$ is invertible, the original system is a TFS system and its poles have the usual TFS behavior. However, when $A_{22}^x(0)$ is not invertible, one gets more complicated asymptotic behavior as described in this paper. Since poles of the original system are zeros of the inverse system, the asymptotic behavior of poles of $H(s, \epsilon)$ can be studied in terms of the asymptotic behavior of the zeros of $H^{-1}(s, \epsilon)$ using the results obtained in this paper.

Semi-Global Stabilizability of Linear Null Controllable Systems with Input Nonlinearities

Andrew R. Teel

Abstract—An H_∞ -based Lyapunov proof is provided for a result recently established by Lin and Saberi: if a linear system is asymptotically null controllable with bounded controls then, when subject to input saturation, it is semi-globally stabilizable by linear state feedback. A new result is that if the system is also detectable then it is semi-global stabilizable by completely linear output feedback. Further, an extension which relaxes the requirements on the input characteristic is obtained.

1. INTRODUCTION

There has been much interest in the last few years concerning stabilization of linear systems subject to actuator saturation. Several important papers have focused on systems which are null controllable with bounded controls. A linear system is said to be asymptotically null controllable with bounded controls if any initial condition can be

IEEE Log Number 9407016.

driven to the origin, perhaps in the limit as $t \rightarrow \infty$, using arbitrarily small controls. It is well known that asymptotic null controllability with bounded controls is equivalent to the usual notion of linear stabilizability plus the added condition that the open loop eigenvalues have nonpositive real part. For a thorough treatment of this concept see [7] or [8]. It is also well known that, in general, a linear feedback cannot be used to globally asymptotically stabilize the origin of a linear system null controllable with bounded controls if the system has input constraints. This was first pointed out in [3] and elaborated on in [10]. On the other hand, it was established in [9] that, for this same class of systems, the origin is globally asymptotically stabilizable by nonlinear feedback. A particular algorithm using multiple saturation functions was initiated in [13] and completed in [11].

On a slightly different front, there has been renewed interest in the domains of attraction that can be achieved using linear feedback. In a pair of recent papers, Lin and Saberi have shown that, both for discrete time [4] and continuous time [5], the domain of attraction for a linear system null controllable with bounded controls and subject to input saturation can be made arbitrarily large using appropriately tuned linear feedback. The purpose of this note is to provide a simple Lyapunov proof for the result of [5] which, at the same time, allows for some extensions. In addition, it is illustrated with an example that the result of this note is useful for semi-global stabilization of some nonlinear systems that appear unrelated to the problem of stabilization with input saturation.

The particular choice of feedback that is used to achieve the extensions of this note is based on the solution to a family of "full information" H_∞ control problems [2]. The solution to this problem provides a family of arbitrarily small feedback gains and a corresponding family of Lyapunov functions. Given a prescribed compact set, a member of this feedback family is selected which exhibits stability robust to input nonlinearities for initial conditions in this compact set.

II. PROBLEM STATEMENT

We initially consider systems of the form:

$$\begin{aligned} \dot{x} &= Ax + \sigma(u) \\ y &= C'x, \end{aligned} \quad (1)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, $y \in \mathbb{R}^p$ and $\sigma: \mathbb{R}^m \rightarrow \mathbb{R}^m \subset \mathbb{R}^m$ where Γ is some bounded neighborhood of the origin and $\sigma(0) = 0$. The objective is to find a family of linear controllers that can be used to make the domain of attraction for the point $x = 0$ arbitrarily large. This problem is referred to as the semi-global stabilization problem:

Definition 2.1: The point $x = 0$ of (1) is semi-globally stabilizable by linear state feedback if, for each compact set U , there exists a feedback $u = Kx$ such that the origin is a locally asymptotically stable equilibrium with domain of attraction containing U .

Definition 2.2: The point $x = 0$ of (1) is semi-globally stabilizable by linear dynamic output feedback if, for each compact set U , there exist a dynamic output feedback of the form

$$\begin{aligned} \dot{\zeta} &= F\zeta + G y \\ u &= K\zeta \end{aligned} \quad (2)$$

and a compact set U_ζ such that the point $(x, \zeta) = (0, 0)$ is a locally asymptotically stable equilibrium with domain of attraction containing $U \times U_\zeta$.

We make the following assumptions:

Assumption 1: The linear approximation of (1) exists and is stabilizable with bounded controls, i.e., the pair $(A, \sigma'(0))$ is stabilizable, and the eigenvalues of A have nonpositive real part.

Assumption 2: The pair (C', A) is detectable.

The next section is dedicated to a Lyapunov proof for the following result:

Theorem 1: If Assumption 1 is satisfied then the origin of (1) is semi-globally stabilizable by linear state feedback. If Assumptions 1 and 2 are satisfied then the origin of (1) is semi-globally stabilizable by linear dynamic output feedback.

Remark 2.1 Lin and Saberi have proved this result in [5] under the additional assumptions that $\sigma(u) = B\bar{\sigma}(u)$ where (A, B) is stabilizable, the i th entry of the vector $\bar{\sigma}(u)$ depends only on u_i and each entry is linear near the origin, and the nonlinear element σ is used in the compensator (2).

To motivate the solution to this problem, we note that, for each $\rho > 0$, $\exists \Delta > 0$ such that

$$|\sigma(u) - \sigma'(0)u| \leq \rho|u| \quad \forall u \in \mathbb{R}^m, |u| \leq \Delta. \quad (3)$$

This bound can be exploited if $|u|$ can be kept sufficiently small. For a linear system of the form

$$\dot{x} = Ax + \sigma'(0)u \quad (4)$$

satisfying Assumption 1, for any compact set of initial conditions, a linear stabilizing feedback can be chosen which makes $\sup_{t \geq 0} |u(t)|$ arbitrarily small. This was shown in [5] for example. The contribution of this note is that feedbacks with this same property can be constructed from the solution to an appropriate full information H_∞ control problem, thereby achieving stability robust to perturbations of the form $\sigma(u) - \sigma'(0)u$ satisfying the bound (3) for ρ sufficiently small.

III. PROOF OF THEOREM 1

We will solve a more general problem than the one considered in Section II. Consider the system:

$$\dot{x} = Ax + B_1 u + B_2 g(u). \quad (5)$$

We recover (1) by taking $B_1 = \sigma'(0)$, $B_2 = I$ and $g(u) = \sigma(u) - \sigma'(0)u$. Then Assumption 1 becomes:

Assumption 1b: The pairs (A, B_1) and (A, B_2) are stabilizable and the eigenvalues of A have nonpositive real part.

We will form a family of semi-globally stabilizing feedbacks for (5) from the following result:

Lemma 3.1. Let Assumption 1b hold. If $Q: (0, 1] \rightarrow \mathbb{R}^{n \times n}$ is a continuous, positive definite matrix valued function and

$$\lim_{\epsilon \rightarrow 0} \lambda_{\max}(Q(\epsilon)) = 0 \quad (6)$$

then there exists a positive real number γ such that, for each $\epsilon \in (0, 1]$, $\exists P(\epsilon) > 0$ satisfying

$$\begin{aligned} 1) \quad & A'P(\epsilon) + P(\epsilon)A + P(\epsilon)\left(\frac{1}{\gamma^2}B_2B_2' - B_1B_1'\right)P(\epsilon) + Q(\epsilon) = 0 \\ 2) \quad & \end{aligned} \quad (7)$$

$$\lim_{\epsilon \rightarrow 0} \lambda_{\max}(P(\epsilon)) = 0. \quad (8)$$

Proof: Using the results of [2], since Q is positive definite for each $\epsilon \in (0, 1]$ and (A, B_1) and (A, B_2) are stabilizable pairs, for each $\epsilon \in (0, 1]$ there exists $\gamma_{opt}(\epsilon)$ such that, for each $\gamma > \gamma_{opt}(\epsilon)$, there exists $P(\epsilon, \gamma) > 0$ satisfying

$$A^T P + P A + P \left(\frac{1}{\gamma^2} B_2 B_2^T - B_1 B_1^T \right) P + Q(\epsilon) = 0. \quad (9)$$

In addition, since

$$\sup_{\epsilon \in (0, 1]} \lambda_{\max}(Q(\epsilon)) < \infty \quad (10)$$

we can choose γ to satisfy

$$\gamma > \bar{\gamma} := \sup_{\epsilon \in (0, 1]} \gamma_{opt}(\epsilon) \quad (11)$$

so that, for each $\epsilon \in (0, 1]$, there exists $P(\epsilon) > 0$ satisfying (7).

To establish (8), we first note that, for each $\epsilon \in (0, 1]$, there exists $X_2(\epsilon) > 0$ satisfying

$$A^T X_2(\epsilon) + X_2(\epsilon) A - X_2(\epsilon) B_1 B_1^T X_2(\epsilon) + Q(\epsilon) = 0 \quad (12)$$

and

$$\lim_{\epsilon \rightarrow 0} \lambda_{\max}(X_2(\epsilon)) = 0. \quad (13)$$

This follows from a result of [16] which gives that, since the eigenvalues of A have nonpositive real part, $X_2 = 0$ is the unique positive semi-definite solution to

$$A^T X_2 + X_2 A - X_2 A - X_2 B_1 B_1^T X_2 = 0 \quad (14)$$

and the result of [15] on continuity of the solution to the algebraic Riccati equation (12) under the condition (6). Second, using (11) and [6, Theorem 3.1], we have that, for each $\epsilon \in (0, 1]$,

$$P(\epsilon) \leq \frac{\gamma}{\gamma^2 - \bar{\gamma}^2} X_2(\epsilon) \quad (15)$$

where $P(\epsilon)$ and $X_2(\epsilon)$ are the solutions to the Riccati equations (7) and (12), respectively. The bound (15) can also be established with the tools of [2, Section VI.A, VII.C]. Then (8) follows from (13) and (15).

A. The State Feedback Result

Assumption 3: There exist positive definite matrix valued functions $Q: (0, 1] \rightarrow \mathbb{R}^{n \times n}$ and $P: (0, 1] \rightarrow \mathbb{R}^{n \times n}$ and strictly positive real numbers γ and Δ satisfying (6)–(8) and

$$|g(u)| \leq \frac{1}{\Delta}, \quad \forall u \in \{u \in \mathbb{R}^m : |u| \leq \Delta\}. \quad (16)$$

Remark 3.1: There is no requirement that g be differentiable at the origin. All that is required is that $g(0) = 0$ and g is locally Lipschitz at the origin with a sufficiently small Lipschitz constant.

From (3) and Lemma 3.1, Assumption 3 holds if Assumption 1 holds. Thus, the state feedback result of Theorem 1 is a consequence of the following result:

Proposition 3.1: If Assumption 3 holds then the family of linear state feedbacks:

$$u = -B_1^T P(\epsilon)x, \quad (17)$$

parameterized by ϵ , semi-globally stabilizes the origin of (5).

Proof: Define $\nu = \lambda_{\max}(\sqrt{B_1 B_1^T})$. Let U be a compact set such that $x(0) \in U$. Let c be a strictly positive real number such that

$$c^2 \geq \sup_{\substack{x \in U \\ \epsilon \in (0, 1]}} \{x^T P(\epsilon)x\} \quad (18)$$

and pick $\epsilon^* \in (0, 1]$ so that

$$\lambda_{\max}(P(\epsilon^*)) \leq \left(\frac{\Delta}{c\nu} \right)^2. \quad (19)$$

Since (8) holds, c and ϵ^* exist. Define $z = P^{\frac{1}{2}}(\epsilon^*)x$ so that $u = -B_1^T P^{\frac{1}{2}}(\epsilon^*)z$. From (19) it follows that

$$(20)$$

In the z coordinates, the closed loop is given by

$$\begin{aligned} \dot{z} &= P^{\frac{1}{2}}[AP^{-\frac{1}{2}}z - B_1 B_1^T P^{\frac{1}{2}}z + B_2 g(u(z))] \\ &= A_z z + P^{\frac{1}{2}} B_2 g(u(z)). \end{aligned} \quad (21)$$

Note from (8) that

$$A_z^T + A_z = -\frac{1}{\gamma^2} P^{\frac{1}{2}} B_2 B_2^T P^{\frac{1}{2}} - P^{\frac{1}{2}} B_1 B_1^T P^{\frac{1}{2}} - P^{-\frac{1}{2}} Q P^{-\frac{1}{2}}. \quad (22)$$

Let $V(z) = z^T z$ and consider \dot{V} on the set

$$D = \{z : V(z) \leq c^2\}. \quad (23)$$

From (16) and (20) it follows that

$$|g(u(z))| \leq \frac{1}{\Delta} |u(z)| \quad \forall z \in D. \quad (24)$$

Therefore, $\forall z \in D$,

$$\begin{aligned} \dot{V} &= -z^T \left(\frac{1}{\gamma^2} P^{\frac{1}{2}} B_2 B_2^T P^{\frac{1}{2}} + P^{\frac{1}{2}} B_1 B_1^T P^{\frac{1}{2}} + P^{-\frac{1}{2}} Q P^{-\frac{1}{2}} \right) z \\ &\quad + 2z^T P^{\frac{1}{2}} B_2 g(u(z)) \\ &\leq -\frac{1}{\gamma^2} |B_2^T P^{\frac{1}{2}} z|^2 - |B_1^T P^{\frac{1}{2}} z|^2 - |Q^{\frac{1}{2}} P^{-\frac{1}{2}} z|^2 \\ &\quad + \frac{2}{\gamma} |B_2^T P^{\frac{1}{2}} z| |B_1^T P^{\frac{1}{2}} z| \\ &\leq -|Q^{\frac{1}{2}} P^{-\frac{1}{2}} z|^2. \end{aligned} \quad (25)$$

Since Q is positive definite, (25) and the definition of V imply that every initial condition in the set D converges exponentially to the origin. From (18) and (23), $x \in U \Rightarrow z \in D$.

B. The Output Feedback Result

Assumption 3b: There exist positive definite matrix valued functions $Q: (0, 1] \rightarrow \mathbb{R}^{n \times n}$ and $P: (0, 1] \rightarrow \mathbb{R}^{n \times n}$, strictly positive real numbers γ and Δ and a matrix of gains L such that

- 1) (6)–(8) are satisfied,
- 2) $A + LC$ is Hurwitz
- 3) defining:

- a) $\beta = \lambda_{\max}(P_\alpha)$ where $(A + LC)^T P_\alpha + P_\alpha (A + LC) = -I$,
- b) $\nu = \sqrt{\lambda_{\max}(B_1 B_1^T)}$,
- c) $\kappa = \sup_{\epsilon \in (0, 1]} \lambda_{\max}(P(\epsilon))$,

- d) $\mu = \sqrt{6} \max\{\beta(2 + 4v^2\kappa^2), \gamma\}$,
 e) we have

$$|g(u)| \leq \frac{1}{\mu}|u| \quad \forall u \in \{u \in \mathbb{R}^m : |u| \leq \Delta\}. \quad (26)$$

From (3) and Lemma 3.1, Assumption 3b holds if Assumptions 1 and 2 hold. Thus, the output feedback result of Theorem 1 follows from the result:

Proposition 3.2: If Assumption 3b holds then the family of dynamic, linear output feedbacks:

$$\begin{aligned} \dot{\hat{x}} &= A\hat{x} + B_1 u + L(C\hat{x} - y) \\ u &= -B_1^T P(\epsilon)\hat{x} \end{aligned} \quad (27)$$

parameterized by ϵ , \hat{x} initialized in a compact subset of \mathbb{R}^n , semi-globally stabilizes the origin of (5).

Proof: With P_o , v and κ defined in Assumption 3b, define

$$\begin{aligned} \lambda_{\min}(P_o) \\ \tau &= 2 + 4v^2\kappa^2. \end{aligned} \quad (28)$$

Let U and U_x be compact sets such that $(x(0), \hat{x}(0)) \in U \times U_x$ and let c be a strictly positive real number such that

$$c^2 > \sup \{x^T P(\epsilon)x + \tau(x - \hat{x})^T P_o(x - \hat{x})\}. \quad (29)$$

Pick $\epsilon^* \in (0, 1]$ so that

$$\lambda_{\max}(P(\epsilon^*)) \leq \min \left\{ \left(\frac{\Delta}{2c\tau} \right)^2, \sqrt{\alpha\tau}\Delta \right\} \quad (30)$$

Define $e = x - \hat{x}$ and $z = P^{\frac{1}{2}}(\epsilon^*)e$. Observe that

$$u = -B_1^T P^{\frac{1}{2}}z + B_1^T P e \quad (31)$$

and, from the definition of v in Assumption 3b and (30), it follows that

$$|u| \leq \frac{\Delta}{2c}(|z| + \sqrt{\alpha\tau}|e|). \quad (32)$$

In the coordinates e , z the dynamics are given by

$$\begin{aligned} \dot{e} &= A_e e + B_2 g(u) \\ \dot{z} &= A_z z + P^{\frac{1}{2}} B_1 B_1^T P e + P^{\frac{1}{2}} B_2 g(u), \end{aligned} \quad (33)$$

where A_z is defined in (21). Choose the Lyapunov function candidate

$$V(z, e) = z^T z + \tau e^T P_o e \quad (34)$$

and consider \dot{V} on the set

$$\mathcal{D} = \{(z, e) : V(z, e) \leq c^2\} \quad (35)$$

with c defined in (29). Observe that

$$\begin{aligned} \max_{(z,e) \in \mathcal{D}} |z| &= c \\ \max_{(z,e) \in \mathcal{D}} |e| &= c(\sqrt{\tau\alpha})^{-1}. \end{aligned} \quad (36)$$

Then, from (26) and (32),

$$|g(u)| \leq \frac{1}{\mu} \quad \forall (z, e) \in \mathcal{D}. \quad (37)$$

Also, from the definition of v and κ in Assumption 3b,

$$|B_1^T P e| \leq v\kappa|e|. \quad (38)$$

Therefore, $\forall (z, e) \in \mathcal{D}$,

$$\begin{aligned} \dot{V} &= -\tau|e|^2 + 2\tau e^T P_o B_2 g(u) \\ &\quad - z^T \left(\frac{1}{\gamma^2} P^{\frac{1}{2}} B_2 B_2^T P^{\frac{1}{2}} + P^{\frac{1}{2}} B_1 B_1^T P^{\frac{1}{2}} + P^{-\frac{1}{2}} Q P^{-\frac{1}{2}} \right) z \\ &\quad + 2z^T P^{\frac{1}{2}} B_1 B_1^T P e + 2z^T P^{\frac{1}{2}} B_2 g(u) \\ &\leq -\tau|e|^2 + \frac{2\tau\beta}{\mu}|e|(|B_1^T P^{\frac{1}{2}}z| + v\kappa|e|) \\ &\quad - \frac{1}{\gamma^2}|B_2^T P^{\frac{1}{2}}z|^2 - |B_1^T P^{\frac{1}{2}}z|^2 - |Q^{\frac{1}{2}} P^{-\frac{1}{2}}z|^2 \\ &\quad + 2|B_1^T P^{\frac{1}{2}}z|(|v\kappa|e|) + \frac{2}{\mu}|B_2^T P^{\frac{1}{2}}z|(|B_1^T P^{\frac{1}{2}}z| + v\kappa|e|). \end{aligned} \quad (39)$$

Using, for all real numbers a and b ,

$$ab \leq \frac{1}{3}a^2 + \frac{2}{3}b^2 \quad (40)$$

we get

$$\begin{aligned} &\frac{2\tau\beta}{\mu}|e|(|B_1^T P^{\frac{1}{2}}z| + v\kappa|e|) \\ &\leq \frac{6\tau^2\beta^2}{\mu^2}|e|^2 + \frac{1}{3}|B_1^T P^{\frac{1}{2}}z|^2 + \frac{1}{3}v^2\kappa^2|e|^2 \\ &\quad 2|B_1^T P^{\frac{1}{2}}z|(|v\kappa|e|) \\ &\leq \frac{1}{3}|B_1^T P^{\frac{1}{2}}z|^2 + 3v^2\kappa^2|e|^2 \\ &\quad \frac{2}{\mu}|B_2^T P^{\frac{1}{2}}z|(|B_1^T P^{\frac{1}{2}}z| + v\kappa|e|) \\ &\leq \frac{6}{\mu^2}|B_2^T P^{\frac{1}{2}}z|^2 + \frac{1}{3}|B_1^T P^{\frac{1}{2}}z|^2 + \frac{1}{3}v^2\kappa^2|e|^2. \end{aligned} \quad (41)$$

It follows that, $\forall (z, e) \in \mathcal{D}$,

$$\begin{aligned} \dot{V} &\leq -\tau|e|^2 + \frac{6\tau^2\beta^2}{\mu^2}|e|^2 + 4v^2\kappa^2|e|^2 - \frac{1}{\gamma^2}|B_2^T P^{\frac{1}{2}}z|^2 \\ &\quad + \frac{6}{\mu^2}|B_2^T P^{\frac{1}{2}}z|^2 - |Q^{\frac{1}{2}} P^{-\frac{1}{2}}z|^2. \end{aligned} \quad (42)$$

Then, from (28) and the definition of μ in Assumption 3b,

$$\dot{V} \leq -|e|^2 - |Q^{\frac{1}{2}} P^{-\frac{1}{2}}z|^2 \quad \forall (z, e) \in \mathcal{D}. \quad (43)$$

Since Q is positive definite, (43) and (34) imply that every initial condition in the set \mathcal{D} converges exponentially to the origin. Finally, from (29) and (35), $(x, \hat{x}) \in U \times U_x \Rightarrow (z, e) \in \mathcal{D}$.

IV. APPLICATION: A SYSTEM NONLINEAR IN THE STATE

The result of this note can be used as a tool for semi-globally stabilizing the origin of the system

$$\begin{aligned} \dot{x}_1 &= x_2 + x_3^2 \\ \dot{x}_2 &= x_3 \\ \dot{x}_3 &= u \end{aligned} \quad (44)$$

for example, using linear feedback. A nonlinear globally stabilizing solution is given in [14]. Indeed, semi-global stabilization by linear feedback can be accomplished in two steps. First, using the results described here, the origin of

$$\begin{aligned} \dot{x}_1 &= x_2 + v^2 \\ \dot{x}_2 &= v \end{aligned} \quad (45)$$

can be semi-globally stabilized using linear state feedback, $v = -p_{21}(\epsilon)x_1 - p_{22}(\epsilon)x_2$. Moreover, a Lyapunov function that demonstrates the result is available. Then, using the semi-global backstepping tool of [12], the origin of (44) can be semi-globally stabilized

with a linear state feedback of the form

$$u = -K(x_3 - p_{21}(\epsilon)x_1 + p_{22}(\epsilon)x_2). \quad (46)$$

Likewise, with the output feedback result of this note, the origin of (44) is semi-globally stabilizable by linear dynamic feedback with x_1 and x_3 as measurements.

V. CONCLUSION

A solution to the problem of semi-global stabilization by linear feedback for linear systems with input saturation has been proposed which is an alternative to the solution given in [5]. The approach used is based on the solution to a family of H_∞ Riccati equations. As compared with the result in [5], the semi-global result is achieved while significantly relaxing the requirements on the input characteristic. Moreover, an output feedback solution is derived which is completely linear and hence does not explicitly use the input characteristic. On the other hand, we have not attempted to make any comparison with [5] regarding numerical and implementation issues.

It has also been demonstrated that this result is useful for semi-global stabilization of some nonlinear systems that would otherwise seem unrelated to the problem of stabilization with input saturation.

Stability and Exponential Stability of an Adaptive Control Scheme for Plants of any Relative Degree

Giorgio Bartolini, Antonella Ferrara, and Alexander A. Stotsky

Abstract—Relying on a new adaptive pole assignment control scheme for plants with unknown relative degree and uncertain order which can be made minimum phase by means of a relative-degree-one first order parallel compensator, a new adaptation mechanism is proposed in this note in order to tackle with the problem of the attainment of an exponentially stable behavior of the output error. In particular, the connection between exponential stability and persistent excitation is outlined, and a complete stability analysis is performed.

I. INTRODUCTION

Starting from the works by Landau, Monopoli, and Narendra [1], [2], [3], the research activity relevant to the model reference approach to the adaptive control of LTI SISO systems has been mainly oriented towards both the simplification of the basic schemes and the modification of the adaptation mechanisms to cope with the nonstandard cases of unmodeled dynamics and bounded disturbances [4]-[7]. The common target has been however represented by the necessity of assuring, at least, the boundedness of tracking and parameter errors.

Recently, the attention has been focused on the development of adaptive schemes for plants with unknown relative degree. In [7], for instance, the relative degree is uncertain but its uncertainty is tied to the uncertainty on the plant description which is expressed in multiplicative as well as additive form however required to be small enough. While in [8] and [9], a simplified adaptive control scheme has been presented, which performs the regulation of uncertain plants via pole assignment without requiring the perfect knowledge of the relative degree of the plant to be controlled and independently of the magnitude of the unmodeled dynamics. Yet, in this simplified scheme, traditional integral adaptation mechanisms have been adopted. Consequently, no great emphasis has been placed on the analysis of transient behaviors, as usually happens when only asymptotic stability is ensured.

Manuscript received October 19, 1992; revised March 23, 1994.

As a matter of fact, the convergence rate of the adjustable parameters when using traditional integral adaptation mechanism can be slow even under the condition of persistency of excitation and can be improved by the introduction of a prediction error into the adaptation law. Controllers composed of the terms driven by both the tracking and the prediction error for robot manipulators were proposed by Slotine and Li [10]. To avoid the measurement of the derivatives of the tracking error when getting the prediction error, various types of filtering have been proposed [6], [11], [12]. However, in previous works, the term which is responsible for filter design was not included in the Lyapunov function.

The design procedure for constructing a prediction error used in this note is based on the Lyapunov function method and allows one to perform the filter design simultaneously with algorithm design, to connect the parameters of filter with algorithm parameters and to include a relay term driven by the estimate of the prediction error in the filter for robustness enhancement, in accordance with [13].

The main contribution of this note is the introduction of a new combined direct and indirect adaptive algorithm, driven by both the tracking and the prediction error, which does not require the perfect knowledge of the relative degree of the plant. Moreover, exponential stability of both the tracking and the parameter error is established when some persistent excitation requirements are met.

The present work is organized as follows. In the next section the existence of a control structure characterized by a complexity which is independent of both the relative degree and the precise knowledge of the order is first discussed. Section III is devoted to the construction of a suitable error model relevant to the adaptive case. Finally, the description of the new adaptation mechanism and the analysis of the stability properties of the overall adaptive scheme is provided in Section IV.

II. THE UNDERLYING LINEAR STRUCTURE OF THE CONTROLLER

We consider the following LTI SISO plant

$$\begin{aligned} \dot{x}_p(t) &= \Lambda_p x_p(t) + b_p u_p(t) \\ y_p(t) &= h_p^T x_p(t) \end{aligned} \quad (1)$$

where $x_p(t) \in \mathcal{R}^q$, with $n_1 \leq q \leq n_2$, $u_p(t) \in \mathcal{R}^1$, Λ_p is a matrix of suitable dimension, and, using the operational notation $s = d/dt$,

$$y_p(t) = h_p^T (sI - \Lambda_p)^{-1} b_p = k_p \frac{B(s)}{A(s)} u_p(t). \quad (2)$$

This plant is assumed to satisfy the following assumptions: a) $A(s)$, $B(s)$ are coprime not necessarily Hurwitz polynomials; b) $\deg(B(s)) \leq q - 1$; c) the parameters of Λ_p , b_p , h_p are supposed to be unknown; d) only the input $u_p(t)$ and the output $y_p(t)$ are assumed available; e) the sign of the gain k_p is known. Note that this set of assumptions allows us to deal with the case in which the reference model order is lower than the plant order. In particular, to simplify the treatment, we shall make use of a first order strictly proper model, although the plant relative degree and order are not exactly known as happens in any general representation of systems with unmodeled dynamics [6].

The control problem we are dealing with can be stated as follows.

Problem 1: Find a control law $u_p = u_p(t, y_p(t), r(t))$ such that for any possible value of the plant order q

$$y_p(t) = k_p \frac{B(s)}{A_q(s)} r(t), \quad (3)$$

where $r(t)$ is a suitable reference input which is assumed to be bounded, and $A_q(s)$ is a polynomial with degree equal to q belonging to a set of arbitrarily chosen Hurwitz polynomials with degree between n_1 and n_2 (in practice, a pole assignment control problem has to be solved in spite of the uncertainty we assume on the plant).

To face the control problem above introduced, the following parameterization of the control law $u_p(t)$ can be chosen

$$u_p(t) = \Theta^{*T} X(t), \quad (4)$$

where $X^T(t) = [x_1^T(t) y_a(t) x_2^T(t) r(t) x_3^T(t)]$ is the vector containing the signals of interest. Among them, the vector signals $x_i(t)$ are the states of three state variable filters described by the following differential equations

$$\begin{aligned} \dot{x}_1(t) &= \Lambda x_1(t) + b_1 u_p(t) \\ \dot{x}_2(t) &= \Lambda x_2(t) + b_1 y_a(t) \\ \dot{x}_3(t) &= \Lambda x_3(t) + b_1 r(t), \end{aligned} \quad (5)$$

where Λ is a $n_2 \times n_2$ stable matrix, and $y_a(t)$ is an auxiliary signal obtained as $y_a(t) = y_p(t) + y_r(t)$, $y_r(t)$ being the output signal generated by a rational feedforward compensator, namely,

$$\dot{y}_r(t) = -a y_r(t) + k_1 u_p(t), \quad (6)$$

(k_1 and a positive constants). Hence, $y_a(t)$ can be regarded as the output of the parallel between the plant and a first order relative-degree-one filter. Finally, Θ^* is a constant vector of suitable dimension, containing the parameters which solve the control problem. The introduction of the parallel compensator (6) is motivated by the following considerations. The relative degree of the parallel connection of the plant and the first order filter turns out to be one regardless of the relative degree and of the order of the true plant. Indeed,

$$\begin{aligned} y_a(t) &= k_p \frac{B(s)}{A(s)} u_p(t) + \frac{k_1}{s+a} u_p(t) \\ &= \frac{k_1 A(s) + k_p B(s)(s+a)}{A(s)(s+a)} u_p(t). \end{aligned} \quad (7)$$

Note that in this work we assume that a known parallel compensator $H(s) = N_r(s)/D_r(s)$, with relative degree equal to one, such that $N_r(s)A(s) + k_p D_r(s)B(s)$ is Hurwitz exists. This means that the class of systems to which the proposed approach is applicable is enlarged with respect to classical MRAC schemes to contain those nonminimum phase systems whose zeros can be robustly located in the complex l.h.p. by the parallel connection with a known relative-degree-one compensator [14]. In particular, in [14] the conditions under which the problem is solvable by means of a first order parallel compensator are reported. While, with reference to systems for which the above robust stabilization problem cannot be solvable, a possible solution to the control problem has been proposed in [15]. However, this topic is still under investigation (see [16] for some preliminary results).

More precisely, in writing (6)–(7), for the sake of simplicity we are implicitly assuming that $H(s) = 1/(s+a)$, (i.e., $k_1 = 1$) suffices to satisfy the minimum phase requirement for the roots of the numerator of the transfer function in (7). On the basis of these considerations, it is possible to claim that, by means of the parallel compensator, an auxiliary minimum phase and relative-degree-one plant has been obtained. Then, we are in a position to cope with the relevant control problem previously stated. To this end, let us introduce the following results.

Theorem 1: For any minimum phase and relative-degree-one plant represented by the input output pair $\{u_p(t), y_p(t)\}$ whose order can range between two known values $[n_1, n_2]$, there exists a parameter vector pair θ_1^*, θ_2^* of fixed dimensions, and a scalar value θ_{20}^* , such that, by using a control law of the type

$$u_p^*(t) = -\theta_1^{*T} x_1(t) - \theta_2^{*T} x_2(t) - \theta_{20}^* y_p(t) + w^*(t), \quad (8)$$

where $x_1(t), x_2(t) \in \mathcal{R}^{n_2}$, and $w^*(t)$ is a signal depending on the reference input, as will be specified below, a unique transfer function $T_m(s)$ exists such that the following condition is satisfied

$$y_p(t) = y_n^*(t) = T_m(s)w^*(t) \quad (9)$$

$T_m(s)$ being a strictly positive real (SPR) transfer function.

Proof: If $D(s)$ is the arbitrarily chosen characteristic polynomial of degree equal to n_2 associated with matrix Λ in (5), and $F_1(s), F_2(s)$ are the numerators of $\theta_1^{*T}(sI - \Lambda)^{-1}b_j$ and $\theta_2^{*T}(sI - \Lambda)^{-1}b_j + \theta_{20}^*$, respectively, denoting with $\tilde{B}(s)/\tilde{A}(s)$ the transfer function of the parallel structure (auxiliary plant) indicated in (7), then the transfer function between $w^*(t)$ and $y_p(t)$ results

$$T_m(s) = \frac{\tilde{B}(s)D(s)}{\tilde{A}(s)(D(s) - F_1(s)) - F_2(s)\tilde{B}(s)} \quad (10)$$

The model transfer function $T_m(s)$ needs to be independent of the considered auxiliary plant $\tilde{B}(s)/\tilde{A}(s)$. Keeping in mind this fact, the proof can be developed by introducing the following factorization $D(s) = \prod_{i=1}^q (s + d_i) = \prod_{i=q+1}^{n_2} (s + d_i) \prod_{j=1}^q (s + d_j) = D'(s)D''(s)$ and choosing

$$\begin{aligned} F_1(s) - D(s) &= D'(s)\tilde{B}(s) \\ F_2(s) &= D'(s)(\tilde{A}(s) - \hat{A}_q(s)), \end{aligned} \quad (11)$$

where the monic polynomial $\hat{A}_q(s)$, with the same degree as $\tilde{A}(s)$, can be expressed as $\hat{A}_q(s) = (s + a)A_q(s)$, and $A_q(s)$ belongs to a fixed set of polynomials of the type $\{A_k(s); A_{k+1}(s) = (s + \lambda_k)A_k(s), k = n_1, \dots, n_2\}$, with $A_{n_1}(s)$ and $\{\lambda_k\}$ chosen so that for any q , $A_q(s)$ is the relevant characteristic polynomial to be assigned to the plant.

From (10) and (11), $T_m(s)$ results equal to $D''(s)/\hat{A}_q(s)$, and can be invariant for any q only if $D''(s)$ and $\hat{A}_q(s)$ have common factors. Due to the arbitrariness of the choice of $D(s)$ and $A_k(s)$, we can always assume that this is the case. Therefore, $T_m(s)$ can be rewritten as

$$T_m(s) = \frac{D_m(s)}{A_m(s)} \quad (12)$$

where $A_m(s) := \hat{A}_{n_1}(s)$. Note that in (12) the following factorization has been used

$$\hat{A}_q(s) = A_m(s)D'''(s) \quad D''(s) = D_m(s)D'''(s) \quad (13)$$

Hence, the same $T_m(s)$ is obtained starting from any admissible plant, and polynomials $F_1(s), F_2(s)$, and $D(s)$ are of constant degree (so that θ_1^* and $[\theta_{20}^* \theta_2^{*T}]^T$, which contain the coefficients of $F_1(s)$ and $F_2(s)$, are of fixed dimensions) even if the degree of $\tilde{A}(s)$ ranges in the interval $[n_1 + 1, n_2 + 1]$, which completes the proof. \square

Theorem 2: In the same conditions as in Theorem 1, there exists a parameter vector $[\theta_{30}^* \theta_3^{*T}]^T$, such that the choice

$$w^*(t) = \theta_{30}^{*T} x_3(t) + \theta_3^{*T} r(t) \quad (14)$$

ensures the complete satisfaction of the control object (3), for any plant belonging to the set of systems fulfilling assumptions a)–d).

Proof: The transfer function between $w^*(t)$ and $y_p(t)$, due to the choice of the control law indicated in (8), results

$$y_p(t) = T_m(s) \frac{k_p B(s)(s + a)}{\tilde{B}(s)} w^*(t), \quad (15)$$

where, for the sake of simplicity, $T_m(s) = D_m(s)/A_m(s)$ can be chosen as $T_m(s) = 1/(s + a)$, i.e., $A_m(s) = (s + a)D_m(s)$. By posing $w^*(t) = (F_3(s)/D(s))r(t)$, where the coefficients of polynomial $F_3(s)$ coincide with the components of the vector $[\theta_{30}^* \theta_3^{*T}]^T$, we obtain

$$y_p(t) = \frac{k_p B(s)F_3(s)}{\tilde{B}(s)D(s)} r(t). \quad (16)$$

Hence, choosing

$$F_3(s) = \tilde{B}(s)D'(s), \quad (17)$$

where $D'(s)$ has been specified above, it results

$$y_p(t) = \frac{k_p B(s)}{D''(s)} r(t). \quad (18)$$

Taking into account (10)–(11), the definition of $A_q(s)$ and the choice above made for $T_m(s)$, one has $T_m(s) = D''(s)/[(s + a)A_q(s)] = 1/(s + a)$. Therefore, $D''(s) = A_q(s)$ which is the relevant characteristic polynomial to be assigned. So the pole assignment requirement is fulfilled and Theorem 2 is proved. \square

It should be explicitly noted that the number of parameter sets to be tuned is only two (namely, the sets of coefficients of polynomials $F_1(s)$ and $F_2(s)$), because of the relationship between $F_1(s)$ and $F_3(s)$ expressed by (11) and (17).

Indeed,

$$\frac{F_1(s)}{D(s)} = \theta_{30}^* + \frac{F_3(s) - D(s)}{D(s)} \quad (19)$$

($\theta_{30}^* = 1$, since $F_3(s)$ and $D(s)$ are monic), and $F_3(s) - D(s) = F_1(s)$, so that

$$\theta_1^* = \theta_1^* + \underline{d} \quad (20)$$

\underline{d} being the vector of the known coefficients of $D(s)$. Moreover, with respect to classical adaptive control schemes, the present one solves a trivial Bezout equation which does not require any matrix inversion.

III. THE ADAPTIVE CASE: CONSTRUCTION OF THE ERROR MODEL

Let us now consider the ideal control law expressed by (8), (11), (14), and (17). When the plant is unknown, it is possible to choose a control law with the same structure, that is

$$\begin{aligned} u_p(t) &= -\theta_1^T(t)x_1(t) - \theta_2^T(t)x_2(t) - \theta_{20}(t)y_p(t) + w(t) \\ w(t) &= \theta_{30}^T(t)x_3(t) + r(t). \end{aligned} \quad (21)$$

Defining, as usual in the MRAC context,

$$\hat{u}_p(t) = u_p(t) - u_p^*(t) \quad (22)$$

where $u_p^*(t)$ is the ideal control law determined from (8) and (11), one has

$$\begin{aligned} \hat{u}_p(t) &= -(\theta_1^T(t) - \theta_1^{*T})x_1(t) - (\theta_{20}(t) - \theta_{20}^*)y_p(t) \\ &\quad - (\theta_2^T(t) - \theta_2^{*T})x_2(t) + (\theta_{30}^T(t) - \theta_{30}^{*T})x_3(t). \end{aligned} \quad (23)$$

Thus, the auxiliary plant state equation can be rewritten as follows

$$\begin{aligned} \dot{x}_a(t) &= A_a x_a(t) + b_a u_p(t) \\ &= A_a x_a(t) + b_a (u_p^*(t) + \hat{u}_p(t)) \\ y_a(t) &= h_a^T x_a(t) \end{aligned} \quad (24)$$

where $x_a(t) \in \mathcal{R}^{q+1}$ and Λ_a is a $(q+1) \times (q+1)$ matrix. Taking into account (8), the first of (24) becomes

$$\dot{r}_1(t) = \Lambda_a x_a(t) - b_a(\theta_1^{*T} r_1(t) + \theta_2^{*T} r_2(t) + \theta_{20}^* y_a(t)) + b_a(u^*(t) + u_p(t)) \quad (25)$$

This equation is identical to the state equation of the ideal auxiliary plant (i.e., the auxiliary plant in the known parameters case), with an input signal $(u^*(t) + \dot{u}_p(t))$ instead of simply $u^*(t)$. From Theorems 1 and 2 we know that the zero state response of $y_a(t)$ is expressible as the solution of the following first order differential equation

$$\dot{y}_a(t) = -a y_a(t) + (u^*(t) + u_p(t)) \quad (26)$$

Therefore, by introducing a parallel model of the type

$$\begin{aligned} \dot{z}_a(t) &= -a z_a(t) + u(t) \\ z_a(t) &= -a z_a(t) + \theta_1^T(t) r_1(t) + \theta_2^T(t) r_2(t) + \theta_{20}(t) y_a(t), \end{aligned} \quad (27)$$

the final error equation, due to the error on the control signal $u_p(t)$, results

$$\begin{aligned} \nu(t) &= y_1(t) - z_a(t) \\ \dot{\nu}(t) &= -a\nu(t) - \theta_1^T(t) r_1(t) - \theta_2^T(t) r_2(t) - \theta_{20}(t) y_a(t) \\ &= -a\nu(t) + \Theta^T(t) \mathbf{X}(t) \end{aligned} \quad (28)$$

where

$$\begin{aligned} \Theta^T(t) &= [-\theta_1^T(t) - \theta_{20}(t) - \theta_2^T(t)] \\ \mathbf{X}^T(t) &= [r_1^T(t) y_1(t) r_2^T(t)] \end{aligned}$$

Thus the adaptive control problem has been reduced to the standard form, i.e., $\nu(t) = I_m(s)\Theta^T(t)\mathbf{X}(t)$ with $I_m(s) = 1/(s+a) \in \text{SPR}$, and $\nu(t)$ playing the role of tracking error

IV. THE ADAPTIVE CASE: INTRODUCTION OF A COMBINED DIRECT AND INDIRECT ADAPTIVE LAW

Let us consider the ideal control law expressed by (8), and the error model previously derived, i.e. $\nu(t) = -a\nu(t) + \Theta^T(t)\mathbf{X}(t)$ with $\Theta(t) \in \mathcal{R}^m$, $\nu(t) \in \mathcal{R}^1$. We propose the following adjustment law

$$\dot{\Theta}(t) = -\Gamma(t)[\mathbf{X}(t)\nu(t) + a\varphi(t)(\nu(t) - \epsilon(t)) + \varphi(t)\epsilon(t)] \quad (29)$$

where $\varphi(t) \in \mathcal{R}^m$, $\epsilon(t) \in \mathcal{R}^1$, $\Gamma(t)$ is a $m \times m$ matrix, and they are adjusted as follows

$$\dot{\varphi}(t) = -a\varphi(t) + \mathbf{X}(t) \quad (30)$$

$$\begin{aligned} \dot{\epsilon}(t) &= -a\epsilon(t) + \varphi^T(t) \mathbf{I}(t) [\mathbf{X}(t)\nu(t) \\ &\quad + a\varphi(t)(\nu(t) - \epsilon(t)) + \varphi(t)\epsilon(t)] + \epsilon(t)(\nu - \epsilon) \end{aligned} \quad (31)$$

$$\dot{\mathbf{I}}(t) = -a\Gamma(t)\varphi(t)\varphi^T(t)\Gamma(t) + a(\Gamma(t) + \Gamma^T(t)\Gamma(t)/k_0), \quad (32)$$

where $0 < \Gamma(0) \leq k_0 I_m$, $k_0 > 0$ being an upperbound on the gain matrix, and $\epsilon(t)(\nu - \epsilon) \in \mathcal{R}^1$ satisfies the following inequality

$$\epsilon(t)(\nu - \epsilon)(\nu(t) - \epsilon(t)) \geq 0 \quad (33)$$

Note that $(\nu(t) - \epsilon(t))$ is playing the role of the prediction error estimate. The function $\epsilon(\nu, \epsilon)$ can be chosen as $\epsilon(\nu, \epsilon) = \gamma_1 \text{sign}(\nu(t) - \epsilon(t))$, $\gamma_1 > 0$. The introduction of the relay term $\epsilon(\nu, \epsilon)$ driven by the estimate of the prediction error is essential for robustness enhancement, when bounded disturbances are acting on the plant [13].

Moreover, it is worth remarking that the least squares gain update (32) is a special case of the modification of least squares update law proposed by Lozano *et al.* in [17].

By taking into account the combined adaptive algorithm (29)–(32) we can prove the following result

Theorem 3 Consider the error model (28) with adjustment (29)–(32). If the reference input $r(t)$ is bounded then the tracking error $\nu(t)$ and the prediction error estimate $\epsilon(t)$ converge to zero asymptotically and all the trajectories of the system remain bounded. Moreover, if $\mathbf{X}(t)$ is persistently exciting, the tracking error $\nu(t)$ and the parameter error $\Theta(t)$ are globally exponentially convergent.

Proof The stability of the system can be studied by using the following Lyapunov function

$$V = \frac{1}{2}\nu^2(t) + \frac{1}{2}(\nu(t) - \epsilon(t) - \varphi^T(t)\Theta(t))^2 + \frac{1}{2}\|\Theta(t)\|_{\Gamma(t)}^2 \quad (34)$$

whose derivative along the solutions of (28), (29)–(32) is

$$\begin{aligned} \dot{V} &= \nu(-a\nu + \Theta^T\mathbf{X}) + (\nu - \epsilon - \varphi^T\Theta)\{-a\nu \\ &\quad + \mathbf{X}^T\Theta + a\epsilon - \varphi^T\Gamma(t)[\mathbf{X}\nu + a\varphi(\nu - \epsilon) + \varphi\epsilon] - \\ &\quad + a\varphi^T\Theta - \mathbf{X}^T\Theta + \varphi^T\Gamma(t)[\mathbf{X}\nu + a\varphi(\nu - \epsilon) + \varphi\epsilon]\} \\ &\quad - \Theta^T[\mathbf{X}\nu + a\varphi(\nu - \epsilon) + \varphi\epsilon] + \frac{a}{2}\Theta^T\varphi\varphi^T\Theta \\ &\quad - \frac{a}{2}\|\Theta\|_{\Gamma(t)-I_m/k_0}^2 \\ &= -a\nu^2 - a(\nu - \epsilon - \varphi^T\Theta)^2 - (\nu - \epsilon)\epsilon \\ &\quad + \Theta^T\varphi\epsilon - a\Theta^T\varphi(\nu - \epsilon) - \Theta^T\varphi\epsilon \\ &\quad + \frac{a}{2}\Theta^T\varphi\varphi^T\Theta - \frac{a}{2}\|\Theta\|_{\Gamma(t)-I_m/k_0}^2 \end{aligned} \quad (35)$$

(note that for the sake of simplicity the dependence of $\nu, \epsilon, \varphi, \Theta$ on time has been omitted)

Taking into account (33) and decomposing the second term we have

$$\begin{aligned} \dot{V} &\leq -a\nu^2 - \frac{a}{2}(\nu - \epsilon - \varphi^T\Theta)^2 \\ &\quad - \frac{a}{2}(\nu - \epsilon)^2 - \frac{a}{2}\|\Theta\|_{\Gamma(t)-I_m/k_0}^2 \end{aligned} \quad (36)$$

From this we conclude that $\nu(t)$, $(\nu(t) - \epsilon(t) - \varphi^T(t)\Theta(t))$ are bounded and square-integrable, $\Theta(t)$ is bounded and $(\nu(t) - \epsilon(t))$ is square-integrable. Now, let us examine the boundedness of $\dot{\nu}(t)$. Since $r(t)$ is bounded, $r_1(t)$ is bounded as well (see (5)). From (27) we conclude that the boundedness of $r(t)$, $\Theta(t)$ and $r_1(t)$ implies the boundedness of $\dot{z}_a(t)$ and in turn the boundedness of $y_1(t)$ since $\nu(t)$ is bounded. From (5) we conclude that $r_2(t)$ is bounded since y_1 is bounded. Examining the boundedness of $u_1(t)$, from (7) we see that $u_1(t)$ is bounded since the auxiliary plant transfer function has zeros in the open left half plane and according to, for instance, Lemma 4 in [3], its input cannot grow faster than its output, namely $y_1(t)$, which is bounded. From the boundedness of $u_1(t)$ we conclude the boundedness of $r_1(t)$, and that of the output of the parallel compensator $y_1(t)$, as well as, in turn, the boundedness of the plant output $y_1(t)$, since $y_a(t)$ is bounded. From the boundedness of $\mathbf{X}(t)$ it follows the boundedness of $\varphi(t)$ and $\varphi^T(t)$. The boundedness of $\varphi(t)$, $\mathbf{I}(t)$, $\mathbf{X}(t)$, $\nu(t)$ and $\epsilon(t)$ implies the boundedness of $\epsilon(t)$ and $\epsilon(t)$ and hence we conclude the boundedness of $\Theta(t)$. Since $\nu(t)$ and $(\nu(t) - \epsilon(t))$ are square-integrable and $\nu(t)$ and $(\nu(t) - \epsilon(t))$ are bounded, they both converge to zero.

Now consider the case when $\mathbf{X}(t)$ is persistently exciting. The excitation of the regressor $\mathbf{X}(t)$ is connected with the excitation strength of the reference input $r(t)$ [18]. If $\mathbf{X}(t)$ is persistently exciting then $\varphi(t)$ is exciting as well. Note that the modified least squares estimator (32) presents the following properties: a) $\mathbf{I}(t) \leq k_0 I_m$ for any $t \geq 0$, b) if $\varphi(t)$ is persistently exciting, i.e., there exist strictly positive constants δ, β, β_1 such that

$$\beta_1 I_m \geq \int_t^{t+\delta} \varphi(\tau)\varphi^T(\tau) d\tau \geq \beta I_m \quad (37)$$

then, there exist $\lambda_1 > 0$ and $\lambda_2 > 0$ such that $(\Gamma^{-1}(t) - I_m/k_0) \geq \lambda_1 I_m$ and $\Gamma^{-1}(t) \leq \lambda_2 I_m$ for any $t \geq 0$. Indeed, define $z(t) = x^T \Gamma^{-1}(t)x$, where $x \in \mathbb{R}^m$ is any constant unitary vector. Differentiating $z(t)$ and taking into account that $\Gamma^{-1}(t) = -\Gamma^{-1}(t)\dot{\Gamma}(t)\Gamma^{-1}(t)$ we have $\dot{z}(t) = ax^T \varphi(t)\varphi^T(t)x - az(t) + a/k_0 \geq -az(t) + a/k_0$ which implies that $\Gamma(t) \leq k_0 I_m$. Integrating $\dot{z}(t)$ and taking into account (37), we obtain $z(t+h) - z(t) \geq ah - a \int_t^{t+h} z(\tau) d\tau + ah/k_0$. This, in turn implies that there exists $\lambda_1 > 0$ such that $(\Gamma^{-1}(t) - I_m/k_0) \geq \lambda_1 I_m$. Using similar arguments one can show that there exists $\lambda_2 > 0$ such that $\Gamma^{-1}(t) \leq \lambda_2 I_m$ for any $t \geq 0$.

Then, by using the above properties of the estimator (32) we can write (35) as

$$\dot{V} \leq -\frac{a}{2}\nu^2 - \frac{a}{2}(\nu - \epsilon - \varphi^T \dot{\Theta})^2 - \frac{a\lambda_1}{2\lambda_2} \|\dot{\Theta}\|^2. \quad (38)$$

Let a_1 be a positive constant such that $a_1 = \min[a, a\lambda_1/\lambda_2]$. Then $\dot{V} \leq -a_1 V$ which implies the exponential convergence of $\nu(t)$, $(\nu(t) - \epsilon(t) - \varphi^T(t)\dot{\Theta}(t))$ and $\dot{\Theta}(t)$ to zero. \square

To conclude the treatment, it should be noted that no direct adaptation of the parameter vector $\theta_3(t)$ is performed, since this vector does not affect the output error $\nu(t)$. Yet, the parameters $\theta_3(t)$ can be indirectly adjusted on the basis of (20). Since the exponential convergence of $\theta_1(t)$, $\theta_2(t)$, $\theta_{20}(t)$ to their ideal values has been ensured, also the convergence of $\theta_3(t)$ to θ_3^* is guaranteed. This corresponds to the attainment of the control objective (3) in Problem 1.

V. CONCLUSIONS

In this note, an alternative adaptive control approach is presented so as to deal with plants with unknown relative degree and uncertain order which can be made minimum phase by means of a relative-degree-one first order parallel compensator. Apart from the fundamental feature of having a complexity which turns out to be independent of the relative degree of the plant, the proposed control scheme is characterized by the use of a nonstandard adaptation mechanism which includes a time-varying gain and can be viewed as a combined direct/indirect mechanism, being based on the use of a prediction error estimate. The introduction of this modified adaptation mechanism allows us to prove that the tracking error asymptotically converges to zero and that all the trajectories of the system remain bounded. Moreover, under a suitable assumption of persistent excitation, the tracking error and the parameter error turn out to be globally exponentially convergent. This latter property is indirectly used to complete the design of the control scheme so as to assign the desired dynamics to the true plant output.

Preservation of Reachability and Observability under Sampling with a First-Order Hold

Tomomichi Hagiwara

Abstract—This paper gives the necessary and sufficient condition for the reachability of the sampled-data system S_1 obtained by the discretization of a linear time-invariant continuous-time system with a first-order hold. Equivalence of the reachability and controllability of S_1 is also shown. Similar results are given also for observability and reconstructibility. It turns out that S_1 is reachable only if S_0 is reachable, while S_1 is observable if and only if $S_1/0$ is observable, where S_0 is the sampled-data system obtained by the discretization with a zero-order hold of the same sampling period.

I. INTRODUCTION

In sampled-data control, hold circuits are used to convert the discrete-time signals from digital compensators into the continuous-time signals to be applied to the continuous-time systems. Hold circuits can be viewed also as filters which attenuate the high-frequency alias spectra generated by sampling continuous-time signals. Typical hold circuits are a zero-order hold and a first-order hold [1], but the former seems to be particularly popular in industrial applications. The primary reason for this is that a zero-order hold can be implemented

Manuscript received October 20, 1993; revised February 20, 1994.

quite easily by using the function of D/A converters while a first-order hold can be implemented only with the aid of some additional analog circuits. Another reason might be that, when viewed as continuous-time filters, the phase lag of a first-order hold is greater than that of a zero-order hold for high-frequency ranges, which seems to be a disadvantage from the point of view of closed-loop stability. However, the latter reason seems to apply mainly in the case when a digital compensator is obtained by a digital redesign method [2] of a continuous-time compensator and closed-loop stability is not necessarily assured theoretically. If we could use a first-order hold in such a way that closed-loop stability can be assured, then it might provide some advantages over a zero-order hold, such as reduction of the intersample ripple of the response.

Based upon the above consideration, the aim of this paper is to provide a basis for the use of a first-order hold in the context of the state-space approach of control system design. For this purpose, we give the necessary and sufficient condition for the reachability of the sampled-data system obtained by the discretization of a linear time-invariant continuous-time system with a first-order hold. In addition, we show the equivalence of the reachability and controllability of this sampled-data system. Furthermore, we give similar results for observability and reconstructibility. (For the standard definitions of these concepts, see [3].)

II. DISCRETIZATION WITH A FIRST-ORDER HOLD

We consider the system given by

$$\frac{dx}{dt} = Ax + Bu, \quad y = Cx, \quad (1)$$

where $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, and $C \in \mathbb{R}^{p \times n}$. Suppose a first-order hold is connected to the input. Then, $u(t)$ is given by

$$u(t) = u(kT) + \frac{u(kT) - u(\bar{k} - 1T)}{T}(t - kT) \quad (kT \leq t < \bar{k} + 1T), \quad (2)$$

where T denotes the sampling period ($u(kT)$ stands for $u(kT + 0)$). It should be noted that there is a built-in constraint that the input $u(t)$ ($kT \leq t < \bar{k} + 1T$) depends not only on $u(kT)$ but also on $u(\bar{k} - 1T)$, which shows sharp contrast with a zero-order hold. In particular, $u(t)$ ($0 \leq t < T$) depends on $u(-T)$, which has been determined before $t = 0$ and cannot be changed by the compensator at $t = 0$.

The resulting sampled-data system can be described by the equation (see [4], [5])

$$\begin{aligned} x(\bar{k} + 1T) &= Ax(kT) + B^+ u(kT) + B^- u(\bar{k} - 1T), \\ y(kT) &= Cx(kT) \end{aligned} \quad (3)$$

where,

$$\begin{aligned} A &= \exp(AT), \quad B^+ = \int_0^T \left(2 - \frac{t}{T}\right) \exp(A, t) B, dt, \\ B^- &= \int_0^T \left(\frac{t}{T} - 1\right) \exp(A, t) B, dt. \end{aligned} \quad (4)$$

We denote the system (3) by S_1 , which can be rewritten in the form of the ordinary discrete-time state equation as

$$\begin{bmatrix} x(\bar{k} + 1T) \\ u(kT) \end{bmatrix} = \begin{bmatrix} A & B^- \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x(kT) \\ u(\bar{k} - 1T) \end{bmatrix} + \begin{bmatrix} B^+ \\ I_m \end{bmatrix} u(kT). \quad (5)$$

$$y(kT) = [C \ 0] \begin{bmatrix} x(kT) \\ u(\bar{k} - 1T) \end{bmatrix}. \quad (6)$$

III. CONTROLLABILITY AND REACHABILITY OF S_1

A. Definitions of Controllability and Reachability and Their Equivalence

In this subsection, we first give the definitions of the controllability and reachability of S_1 . In view of the discrete-time state equation (5), let us adopt the following definition.

Definition 1: S_1 is controllable if the pair (A_1, B_1) is controllable, where

$$(A_1, B_1) := \left(\begin{bmatrix} A & B^- \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} B^+ \\ I_m \end{bmatrix} \right)$$

Now, let us verify that the above formal definition matches our practical control purposes in spite of the built-in constraint of a first-order hold.

If we regard S_1 simply as an ordinary discrete-time system, then its controllability might be defined as the property that, given any initial condition $x(0)$, there exists a sequence $u(kT)$ ($k = 0, \dots, N-1$) such that $x(NT) = 0$. However, this is not appropriate, because this property does not reflect real purposes of control. Namely, this definition does not always imply the property that there exists a sequence $u(kT)$ ($k = 0, \dots, N-1, N, \dots$) such that $x(t) = 0$ ($\forall t \geq NT$), because of the built-in constraint of a first-order hold as discussed in the previous section. (This can be easily understood if we notice that $u(t) = 0$ ($NT \leq t < \bar{N} + 1T$) implies $u(\bar{N} - 1T) = u(NT) = 0$ from (2).) Therefore, to define controllability, we must require that there exists a sequence $u(kT)$ ($k = 0, \dots, N-2$) such that this together with $u(\bar{N} - 1T) = 0$ implies $x(NT) = 0$. Likewise, as discussed in the previous section, $u(t)$ ($0 \leq t < T$) is constrained by the unprescribable value $u(-T)$. Despite this constraint, $x(NT)$ is required to be made 0.

From the above consideration, the controllability of S_1 should be defined as the property that, given any initial conditions $x(0)$ and $u(-T)$, there exists a sequence $u(kT)$ ($k = 0, \dots, N-2$) such that this together with $u(\bar{N} - 1T) = 0$ implies $x(NT) = 0$. Obviously, this definition is equivalent to the controllability of the discrete-time system (5). Thus, validity of the above definition is assured.

Similarly, we are led to the following definition (see [6] for details).

Definition 2: S_1 is reachable if the pair (A_1, B_1) is reachable.

Now, in spite of the singularity of A_1 , we can establish the following result (the straightforward proof [6] is omitted here).

Theorem 1. S_1 is reachable if and only if it is controllable.

B. Condition for Preservation of Reachability

In this subsection, we study the necessary and sufficient condition for the reachability of S_1 in terms of A , B , and T . From Definition 2, it is reachable if and only if

$$\text{rank} \begin{bmatrix} A - zI_n & B & B^+ \\ 0 & I_m - zI_m & I_m \end{bmatrix} = n + m \quad (\forall z \in \mathbb{C}) \quad (8)$$

where $B := B^+ + B^- = \int_0^T \exp(A, t) B, dt$. (Note that (A, B) is nothing but the pair of the sampled-data system obtained by the discretization of (1) with a zero-order hold, which we denote by S_0 .) The condition (8) is nothing but the reachability condition for the pair

$$(A_2, B_2) := \left(\begin{bmatrix} A & B \\ 0 & I_m \end{bmatrix}, \begin{bmatrix} B^+ \\ I_m \end{bmatrix} \right). \quad (9)$$

This pair can be regarded as the pair obtained by the discretization of the fictitious T -dependent continuous-time pair

$$(A_2, B_2) := \left(\begin{bmatrix} A & B \\ 0 & 0 \end{bmatrix}, \begin{bmatrix} B \\ I_m/T \end{bmatrix} \right) \quad (10)$$

with a zero-order hold, because $A_2 = \exp(A, T)$, $B_2 = \int_0^T \exp(A_2, t) B_2, dt$.

Remark 1: (A_{2t}, B_{2t}) is reachable if and only if a) (A_t, B_t) is reachable and b) A_t does not have the eigenvalue $-1/T$.

Since the eigenvalues and left eigenvectors of A_{2t} are not dependent on T , we can apply the necessary and sufficient condition [7] for the reachability of S_0 to the pair (A_{2t}, B_{2t}) . Then, the following theorem is obtained (see Appendix for proof).

Theorem 2: S_1 is reachable if and only if the following two conditions are satisfied.

- a) S_0 is reachable.
- b) A_t does not have the eigenvalue $-1/T$.

Remark 2: Suppose that we define the stabilizability of S_1 by the stabilizability of the pair (A_1, B_1) . Then, the necessary and sufficient condition for the stabilizability of S_1 is given by the stabilizability of S_0 (the condition b) can be dropped). Although we can rewrite the reachability/stabilizability of S_0 as the conditions on A_t, B_t , and T (see [7], and Theorem A.1 in Appendix), we did not do this because the importance of the theorem seems to be much clearer in the present form of the statement.

IV. OBSERVABILITY AND RECONSTRUCTIBILITY OF S_1

As in the preceding section, let us consider how to define the observability and reconstructibility of S_1 , taking account of practical purposes.

If we regard S_1 simply as an ordinary discrete-time system, then its observability might be defined as the property that its initial state $x(0)$ can be uniquely determined from the input data $u(kT)$ ($k = 0, \dots, N-1$) and the output data $y(kT)$ ($k = 0, \dots, N$). However, this is not appropriate, because $u(t)$ ($0 \leq t < T$) cannot be known completely from the knowledge of the above input data, as discussed in Section II, and it is clearly impossible to determine $x(0)$ under this lack of knowledge. Therefore, to define observability, we must assume that $u(t)$ ($0 \leq t < T$) is also known. This assumption is equivalent to the assumption that $u(-T)$ as well as the above input and output data can be used. Noting that $x(0)$ can be determined uniquely if and only if $[x(0)^T, u(-T)^T]^T$ can be determined uniquely (if we know $u(-T)$), we are led to the following definition.

Definition 3: S_1 is observable if the pair (C_1, A_1) is observable, where

$$C_1 := \begin{bmatrix} C' & 0 \\ 0 & I_m \end{bmatrix}. \quad (11)$$

Similarly, we are led to the following definition (see [6] for details).

Definition 4: S_1 is reconstructible if the pair (C_1, A_1) is reconstructible, where

$$C_1 := [C' \ 0]. \quad (12)$$

(C_1, A_1) is reconstructible if and only if (C_1, A_1) is reconstructible. Furthermore, in spite of the singularity of A_1 , we can readily show that (C_1, A_1) is reconstructible if and only if it is observable. Thus we obtain the following result.

Theorem 3: S_1 is observable if and only if it is reconstructible.

Now, from Definition 3, S_1 is observable if and only if

$$\text{rank} \begin{bmatrix} A - zI_n & B^- \\ 0 & -zI_m \\ C' & 0 \\ 0 & I_m \end{bmatrix} = n + m \quad (\forall z \in \mathbb{C}). \quad (13)$$

Since (C', A) is the pair of S_0 , we readily obtain the following theorem.

Theorem 4: S_1 is observable if and only if S_0 is observable.

Remark 3: Suppose that we define the detectability of S_1 by the detectability of the pair (C_1, A_1) . Then, the necessary and sufficient condition for the detectability of S_1 is given by the detectability of S_0 . The condition for observability/detectability of S_0 in terms of C, A_t and T is given by [7] (see also Remark A.1 in Appendix).

V. CONCLUSION

In this paper, we studied the use of a first-order hold in the context of the state-space approach of control system design. We first studied how to define the controllability and reachability for the sampled-data system S_1 obtained by the discretization of a linear time-invariant continuous-time system with a first-order hold, taking account of the built-in constraint of a first order hold. Next, we showed the equivalence of these two concepts for S_1 . Then, we studied the necessary and sufficient condition for the reachability of S_1 in terms of the parameters of the continuous-time system and the sampling period. We also gave similar results for observability and reconstructibility. In particular, it turned out that S_1 is reachable only if S_0 is reachable, while S_1 is observable if and only if S_0 is observable, where S_0 is the sampled-data system for the zero-order hold case. The compensator design problem under the use of a first-order hold is also studied in [6].

APPENDIX

PROOF OF THEOREM 2

Before proving Theorem 2, we give a more comprehensible statement of the necessary and sufficient condition for the reachability of S_0 derived in [7].

Let $\lambda(A_t)$ denote the set of the eigenvalues of A_t . For each $\lambda_i \in \lambda(A_t)$, we define

$$\Lambda(\lambda_i) := \{\lambda \mid \lambda \in \lambda(A_t), \text{Re}(\lambda) = \text{Re}(\lambda_i), \text{Im}(\lambda) - \text{Im}(\lambda_i) = 2k\pi/T \quad (k = 0, \pm 1, \pm 2, \dots)\}. \quad (14)$$

Note that $\lambda_i \in \Lambda(\lambda_j)$, and that $\Lambda(\lambda_i) = \Lambda(\lambda_j)$ if $\lambda_i \in \Lambda(\lambda_j)$. Our interest is only in the sets $\Lambda(\lambda_i)$ which have at least two elements. Let Λ_l ($l = 1, \dots, L$) be such distinct sets, where we assume that Λ_l ($l = 1, \dots, L^+ (\leq L)$) are the sets corresponding to the eigenvalues with nonnegative real parts (L and L^+ might be zero). We denote the elements of Λ_l by λ_{lk} ($k = 1, \dots, K_l$).

Next, for each $\lambda_i \in \lambda(A_t)$, we define

$$\Gamma(\lambda_i) := \begin{bmatrix} \eta_{i,1}^T \\ \vdots \\ \eta_{i,\nu_i}^T \end{bmatrix}, \quad (15)$$

where ν_i denotes the geometric multiplicity of the eigenvalue λ_i , and $\eta_{i,k}^T$ ($k = 1, \dots, \nu_i$) the corresponding linearly independent left eigenvectors. That is to say, all the linearly independent left eigenvectors of A_t corresponding to the eigenvalue λ_i form the rows of $\Gamma(\lambda_i)$. We further define

$$\Gamma(\Lambda_l) := \begin{bmatrix} \Gamma(\lambda_{l1}) \\ \vdots \\ \Gamma(\lambda_{lK_l}) \end{bmatrix} \quad (16)$$

for $l = 1, \dots, L$. That is to say, all the linearly independent left eigenvectors of A_t corresponding to the eigenvalues in the set Λ_l form the rows of $\Gamma(\Lambda_l)$.

Now, we obtain the following theorem, which is merely a restatement of Theorem 2 of [7].

Theorem A.1: S_0 is reachable (respectively, stabilizable) if and only if the following three conditions hold:

- a) (A_l, B_l) is reachable (respectively, stabilizable).
- b) A_l does not have the nonzero eigenvalue

$$j2k\pi/T \quad (k = \pm 1, \pm 2, \dots). \quad (17)$$

- c) $\Gamma(\Lambda_l)B_l$ has full row rank for $l = 1, \dots, L$ (respectively, $l = 1, \dots, L^+$).

Remark A.1: The conditions for the observability and the detectability of S_0 are given by the dual of the conditions a) and c) of the above theorem. (This is a restatement of Theorem 3 of [7].)

Remark A.2: Note that $\Gamma(\Lambda_l)$ never contains the left eigenvectors for the zero eigenvalue of A_l if the condition b) holds.

Now, we give the proof of Theorem 2.

Proof of Theorem 2: Without loss of generality, we assume that

$$A_l = \begin{bmatrix} \hat{A}_l & 0 \\ 0 & Z \end{bmatrix}, \quad B_l = \begin{bmatrix} \hat{B}_{l1} \\ \hat{B}_{l2} \end{bmatrix}, \quad (18)$$

where \hat{A}_l is nonsingular and all the eigenvalues of Z are zero. Then, applying the similarity transformation by the matrix

$$\begin{bmatrix} I & 0 & -A_l^{-1}\hat{B}_{l1} \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} \quad (19)$$

to the pair (10), we obtain the pair

$$\left(\begin{bmatrix} A_l & 0 & 0 \\ 0 & Z & B_{l2} \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} (I + \hat{A}_l^{-1}/T)\hat{B}_{l1} \\ B_{l2} \\ I/T \end{bmatrix} \right). \quad (20)$$

Applying Theorem A.1 to the pair (10) for the conditions a) and b), and to the pair (20) for the condition c), and taking Remarks 1 and A.2 into account, we can obtain the following necessary and sufficient condition for the reachability of S_1 :

- A1) (A_l, B_l) is reachable.
- A2) A_l does not have the eigenvalue $-1/T$.
- B) A_l does not have the nonzero eigenvalue

$$j2k\pi/T \quad (k = \pm 1, \pm 2, \dots). \quad (21)$$

- C) $\Gamma(\hat{\Lambda}_l)(I + A_l^{-1}/T)\hat{B}_{l1}$ has full row rank for $l = 1, \dots, \hat{L}$, where $\hat{\Lambda}_l$, $\Gamma(\hat{\Lambda}_l)$ and \hat{L} are defined for \hat{A}_l in a consistent way with the above definitions of Λ_l , $\Gamma(\Lambda_l)$ and L .

Since the rows of $\hat{\Gamma}(\Lambda_l)$ are the left eigenvectors of \hat{A}_l by definition, under condition A2) the condition C) is equivalent to

$$C') \hat{\Gamma}(\Lambda_l)\hat{B}_{l1} \text{ has full row rank for } l = 1, \dots, \hat{L}.$$

In view of the form of (18), the conditions B) and C') are equivalent to the conditions b) and c) of Theorem A.1. Since the condition A1) is the same as the condition a) of Theorem A.1, and since the condition (A2) is the same as the condition b) of Theorem 2, the proof has become complete. Q.E.D.

ACKNOWLEDGMENT

The author wishes to express his gratitude to Prof. M. Kimura, motivating the research through discussions.

On Robust Asymptotic Tracking: Perturbations on Coprime Factors and Parameterization of All Solutions

Gilberto O. Corrêa and Marcos A. da Silva

Abstract—The robust asymptotic tracking problem is analyzed in this paper relative to unstructured perturbations on each coprime factor of the transfer functions from the control input to the measured and controlled outputs. In each case, necessary and sufficient conditions for the existence of solutions are presented which are explicitly given in terms of problem data. Under such conditions, explicit parameterizations are given of all controllers which achieve robust asymptotic tracking, in terms of free, rational proper, and stable matrices.

I. NOMENCLATURE

\mathbb{C}	Set of complex numbers.
\mathbb{R}_p	Set of real-rational and proper functions from \mathbb{C} to \mathbb{C} .
\mathbb{S}	Ring of real-rational, stable, and proper functions from \mathbb{C} to \mathbb{C} .
$\mathcal{M}(X)$	Set of matrices with entries in X .
$\text{GLCD}\{A, B\}$	Greatest left common divisor of A and B .
A	Column vector obtained by stacking the rows of A .
$A \otimes B$	Kronecker product of A and B .
RCP	Right coprime.
LCP	Left coprime.

II. INTRODUCTION

The robust asymptotic tracking problem (RATP) can be roughly stated as that of finding a stabilizing controller which ensures asymptotic tracking of a given class of reference signals for any plant model P "sufficiently close" to a nominal model P_0 . Early references on this problem include [1]–[4]. The emergence of factorization methods led to fresh approaches to this problem, among which one could mention [5]–[7]. In contrast with previous work which considered unity feedback systems, [8]–[10] addressed the RATP for plant-sensor systems and two-degree-of-freedom controllers. In particular, [10] considered perturbations in the plant model (and not in the sensor) and presented a parameterization of the set of solutions where the "free" parameter must satisfy a "skew" diophantine equation.

The RATP for four-block multivariable linear systems (following [11]) was considered in [12] and [13]. The former considered the robust asymptotic tracking problem relative to perturbations only in the numerator of the transfer function relating the control u to the measured output z and, separately, relative to perturbations only in the denominator of the same transfer function—essentially, the existence of solutions to the RATP relative to perturbations on each coprime factor is shown to be equivalent to the existence of a stabilizing controller which satisfies an internal model condition on its corresponding coprime factor. The latter considered the RATP relative to perturbations constrained by a special linear relation involving the numerators of the transfer functions from u to the controlled and measured outputs (y and z , respectively).

The present note considers perturbed model classes obtained by allowing a single coprime factor of the transfer functions from u to y and z to vary while the others are held fixed, with the following aims: to give explicit necessary and sufficient conditions on problem data for the existence of solutions to the RATP relative to such classes; to give an explicit parameterization of all controllers which solve the RATP relative to such model perturbation classes.

This note is organized as follows. In Section II, the RATP is precisely formulated and the required background material is concisely described. In Sections III, IV, and V, the RATP is considered for perturbed model classes where, respectively, only the numerator of the transfer function from u to z , its denominator, and the numerator or denominator of the transfer function from u to y are allowed to vary. The Lemmas required in the main text can be found in the Appendix; proofs omitted here are to be found in [14]. Notation is essentially the same as in [7].

III. PROBLEM STATEMENT

Consider linear closed-loop systems defined by

$$\begin{bmatrix} y \\ z \end{bmatrix} = P \begin{bmatrix} u \\ d \end{bmatrix} = \begin{bmatrix} P_1 & \bar{P}_1 \\ P_2 & \bar{P}_2 \end{bmatrix} \begin{bmatrix} u \\ d \end{bmatrix},$$

$$\dot{u} = C \begin{bmatrix} r \\ \dot{z} \end{bmatrix} = \begin{bmatrix} C_1 & C_2 \end{bmatrix} \begin{bmatrix} r \\ \dot{z} \end{bmatrix}$$

$$u = \hat{u} + w, \quad z = \hat{z} + v,$$

where P and C are, respectively, the plant and controller transfer functions, $P_i, \bar{P}_i, C_i, i = 1, 2$, are real-rational and proper matrices, d, w, v denote disturbances, r the reference signal, u the control variable, y the controlled output, and z the measurement output. The closed-loop transfer matrix from r to y is $P_1 Q_1$, where $Q_1 \triangleq (I - C_2 P_2)^{-1} C_1$.

Let a class of reference signals be given by $S_r = \{r = \psi_r^{-1} \mu_r : \mu_r \in \mathcal{M}(\mathcal{S}) \text{ and is strictly proper}\}$, where ψ_r is a given biproper, square, and nonsingular matrix in $\mathcal{M}(\mathcal{S})$ such that the zeroes of its determinant have nonnegative real parts.

Given P and ψ_r , the so-called asymptotic tracking problem is to find a stabilizing controller C such that the error $e = r - y = (I - P_1 Q_1)r = (I - P_1 Q_1)\psi_r^{-1} \mu_r$ goes to zero as time goes to infinity for all strictly proper μ_r in $\mathcal{M}(\mathcal{S})$ (hence, in particular, for all strictly proper μ_r in $\mathcal{M}(\mathcal{S})$ such that μ_r and ψ_r are left coprime). By Lemma 5.7.6 [7], this is achieved iff $(I - P_1 Q_1)\psi_r^{-1} \in \mathcal{M}(\mathcal{S})$.

Accordingly, given P_0 and ψ_r , the so-called RATP can be roughly stated as that of finding a controller that solves the asymptotic tracking problem for P and ψ_r , for all P "sufficiently close" to P_0 . Before introducing a precise definition for the RATP for P_0 and ψ_r , and since, in any case, it involves closed-loop stabilization, the results of the latter problem which are required below are collected in the following theorem (see [11]).

Theorem 1: If $P \in \mathcal{M}(\mathbb{R}_p)$ is stabilizable then:

- for $P_1 = N_1 D_1^{-1}, P_2 = N_2 D_2^{-1}$ RCP factorizations, there exists $M \in \mathcal{M}(\mathcal{S})$ such that $D_2 = D_1 M$.
- The set of all stabilizing controllers is given by:

$$S_C = \{C = (K \hat{N}_2 + Y)^{-1} [R : K \hat{D}_2 - X] : R, K \in \mathcal{M}(\mathcal{S}), \det \{(K \hat{N}_2 + Y)(\infty)\} \neq 0\}$$

where $X, Y \in \mathcal{M}(\mathcal{S})$ are such that $X N_2 + Y D_2 = I, P_2 = D_2^{-1} N_2, \hat{N}_2$ and \hat{D}_2 LCP. The corresponding set of closed-loop transfer matrices from r to (y, z) is $\{[N_1^T : N_2^T]^T R : R \in \mathcal{M}(\mathcal{S})\}$, where $\hat{N}_1 \triangleq N_1 M$.

A natural way of considering plant models close to the nominal one (P_{10}, P_{20}) would be to consider small perturbations on the RCP factors $(N_{20}, D_{20}), (N_{10}, D_{10})$ of $P_{10} = N_{10} D_{10}^{-1}, P_{20} = N_{20} D_{20}^{-1}$. However, condition (I.1) of Theorem 1 implies that

$$P_{10} = N_{10} D_{10}^{-1} = (N_{10} M) D_{20}^{-1} = N_{10} D_{20}^{-1}.$$

As a result, one could consider perturbations on (N_{20}, D_{20}, N_{10}) as the general setup where the RATP would be precisely formulated.

To this effect, define, for $\epsilon > 0$

$$\mathcal{V}(\epsilon, P_0) = \{(P_1, P_2) \in \mathcal{M}(\mathbb{R}_p)^2 : P_2 = N_2 D_2^{-1}, P_1 = \hat{N}_1 D_2^{-1}, \text{ for some } \hat{N}_1, N_2, D_2\}$$

such that N_2, D_2 are RCP and $\|[(N_2 - N_{20})^T, (D_2 - D_{20})^T, (\hat{N}_1 - \hat{N}_{10})^T]^T\|_\infty < \epsilon\}$.

The RATP for a given pair (ψ_r, P_0) relative to a model class which contains (P_{10}, P_{20}) can now be precisely defined.

Definition 1: Let a class of models $\mathcal{V} \subset \mathcal{M}(\mathbb{R}_p)$ be given where $(P_{10}, P_{20}) \in \mathcal{V}$. A controller $C \in \mathcal{M}(\mathbb{R}_p)$ is said to solve the RATP for (ψ_r, P_{10}, P_{20}) relative to \mathcal{V} if and only if there exists $\epsilon_0 > 0$ such that, for any (P_1, P_2) in $\mathcal{V} \cap \mathcal{V}(\epsilon_0, P_0)$, C stabilizes (P_1, P_2) and $(I - P_1 Q_1)\psi_r^{-1} \in \mathcal{M}(\mathcal{S})$.

Consider a doubly coprime factorization $(N_{20}, D_{20}, \hat{N}_{20}, \hat{D}_{20}, N_{10}, Y_0, \hat{N}_{10}, \hat{Y}_{10})$ of P_{20} (see [7, p. 48]), i.e., $P_{20} = N_{20} D_{20}^{-1} =$

$D_{20}^{-1}\dot{N}_{20}$ with

$$\begin{bmatrix} -X_0 & Y_0 \\ \dot{D}_{20} & \dot{N}_{20} \end{bmatrix} \begin{bmatrix} -N_{20} & \dot{X}_0 \\ D_{20} & \dot{Y}_0 \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} - \begin{bmatrix} -N_{20} & \dot{X}_0 \\ D_{20} & \dot{Y}_0 \end{bmatrix} \begin{bmatrix} -X_0 & Y_0 \\ \dot{D}_{20} & \dot{N}_{20} \end{bmatrix}.$$

The following proposition gives necessary and sufficient conditions for a controller C to achieve robust asymptotic tracking.

Proposition 1: Let (ψ, P_{10}, P_{20}) be given, $P_{20} = N_{20}D_{20}^{-1}$ RCP, $P_{10} = \dot{N}_{10}D_{20}^{-1}$. Let $\mathcal{V} \subset \mathcal{M}(\mathbb{R}_p)$ be such that $(P_{10}, P_{20}) \in \mathcal{V}$. A controller solves the RATP for (ψ, P_{10}, P_{20}) relative to \mathcal{V} iff C is given by $C(R, K) = \dot{D}_C^{-1}(K)[R\dot{N}_C(K)]$, $\dot{N}_C(K) = K\dot{D}_{20} - X_0$, $\dot{D}_C(K) = K\dot{N}_{20} + Y_0$, for some R, K in $\mathcal{M}(\mathcal{S})$ such that $\det\{(K\dot{N}_2 + Y_0)(\infty)\} \neq 0$ and

- $(I - \dot{N}_{10}R)\psi^{-1} \in \mathcal{M}(\mathcal{S})$;
- there exists $\epsilon_0 > 0$ such that for any $(P_1, P_2) \in \mathcal{V} \cap \mathcal{V}(\epsilon_0, P_0)$

$$\begin{aligned} &[\Delta\dot{N}_1 + \dot{N}_{10}(\dot{N}_C(K)\Delta N_2 - \dot{D}_C(K)\Delta D_2)] \\ &\cdot (I - N_C(K)\Delta N_2 + \dot{D}_C(K)\Delta D_2)^{-1}\psi^{-1} \in \mathcal{M}(\mathcal{S}), \end{aligned}$$

where $R\psi^{-1} = \tilde{\psi}^{-1}R$ are coprime factorizations, $\dot{N}_1 = \dot{N}_{10} + \Delta\dot{N}_1$, $N_2 = N_{20} + \Delta N_2$, $D_2 = D_{20} + \Delta D_2$.

Remark: Note that condition a) corresponds to the requirement of nominal asymptotic tracking and that b) is obtained by taking the difference between the perturbed and the nominal $(I - P_1Q_1)\psi^{-1}$.

IV. NUMRATOR PERTURBATIONS ON P_2

In this section the RATP for (ψ, P_{10}, P_{20}) is addressed relatively to the model class \mathcal{N} in which N_2 can vary freely around N_{20} while N_1 and D_2 are held fixed, i.e.,

$$\mathcal{N} \triangleq \{(\dot{N}_{10}D_{20}^{-1}, N_2D_{20}^{-1}) : N_2 \in \mathcal{M}(\mathcal{S}), N_2 \text{ and } D_{20} \text{ RCP}\}.$$

To this effect, note first that $C(R, K)$ solves the RATP for (ψ, P_{10}, P_{20}) relative to \mathcal{N} if and only if R satisfies condition a) and $\dot{N}_{10}\dot{N}_C(K)\Delta N_2(I - \dot{N}_C(K)\Delta N_2)^{-1}\psi^{-1} \in \mathcal{M}(\mathcal{S})$ for all ΔN_2 such that $\|\Delta N_2\|_\infty < \epsilon$ for some $\epsilon > 0$ (this follows from Proposition 1). The aforementioned condition is equivalent to $N_{10}\dot{N}_C(K)\varphi^{-1} = \dot{N}_{10}(K\dot{D}_{20} - X_0)\varphi^{-1} \in \mathcal{M}(\mathcal{S})$, due to Lemma 1, where φ is the greatest invariant factor of ψ , hence the greatest invariant factor of $\tilde{\psi}$ (because $R\psi$ are coprime factorizations). This condition, in turn, is equivalent to $N_\varphi D_\varphi^{-1}\dot{N}_C(K) \in \mathcal{M}(\mathcal{S})$, where $\dot{N}_{10}\varphi^{-1} = N_\varphi D_\varphi^{-1}$, N_φ and D_φ RCP. Due to [7, Lemma 5.7.6], the aforementioned condition is equivalent to $D_\varphi^{-1}\dot{N}_C(K) \in \mathcal{M}(\mathcal{S})$, i.e.,

$$\text{there exists } \bar{N}_C \in \mathcal{M}(\mathcal{S}) \text{ such that } -D_\varphi\bar{N}_C + K\dot{D}_{20} = X_0. \quad (1)$$

Now, $K\dot{D}_{20} - D_\varphi\bar{N}_C = X_0$ implies $K\dot{N}_{20}D_{20} - D_\varphi\bar{N}_C N_{20} = X_0 N_{20}$ and hence (since $X_0 N_{20} + Y_0 D_{20} = I$) $(K\dot{N}_{20} + Y_0)D_{20} + D_\varphi(-\bar{N}_C N_{20}) = I$. Thus, Condition 1 implies that D_φ and D_{20} are ESP. Conversely, suppose that there exists $(\dot{X}, \dot{Y}) \in \mathcal{M}(\mathcal{S}) \times \mathcal{M}(\mathcal{S})$ such that $D_\varphi\dot{X} + \dot{Y}D_{20} = I$. Then, $D_\varphi\dot{X}X_0 + \dot{Y}D_{20}X_0 = X_0$, which is equivalent to $D_\varphi(\dot{X}X_0) + (\dot{Y}Y_0)\dot{D}_{20} = X_0$ (since $D_{20}X_0 = Y_0\dot{D}_{20}$). Thus, if D_φ and D_{20} are ESP, (1) is satisfied by $K = \dot{Y}Y_0$ and $\bar{N}_C = -\dot{X}X_0$. Finally, whenever D_φ and D_{20} are ESP, the set of K which satisfy Condition 1 is obtained by directly applying Lemma 3 to (1). The following theorem can then be stated.

Theorem 2: Let (ψ, P_{10}, P_{20}) be as above

- The set C_1 of all controllers which solve the RATP for (ψ, P_{10}, P_{20}) relative to \mathcal{N} is nonempty iff \mathcal{N} and ψ are ESP and D_φ and D_{20} are ESP.
- In this case, C_1 is given by

$$C_1 = \{(K\dot{N}_{20} + Y_0)^{-1}[R(K\dot{D}_{20} - X_0)] : (R, K) \in S_1, \det\{(K\dot{N}_{20} + Y_0)(\infty)\} \neq 0\}$$

where $S_1 = \{(R, K) : R = \dot{X}\dot{I} - D, R, K = -Y_0\dot{X}_0 - \dot{D}_\varphi\dot{K}, (\dot{R}, \dot{K}) \in \mathcal{M}(\mathcal{S}) \times \mathcal{M}(\mathcal{S})\}$;

$$M_1 = \text{GLCD}\{(\dot{N}_{10} + I), (I - \psi^{-1}), (N_{10} - I) = M_1 N_{10}, (I \times \psi^{-1}) = M_1 \psi^{-1},$$

\dot{I}, \dot{X} and D_φ are defined by $I = M_1 \dot{I}, N_{10}\dot{X} + \psi^{-1}Y = I$, and $\psi^{-1}\dot{N}_{10} = N$, D_φ^{-1} (an RCP factorization), the existence of $\dot{I}, \dot{X}, \dot{Y}, N$, and D_φ being a consequence of the externally skew-primeness of \dot{N}_{10} and ψ ;

$$M_N = \{\text{GLCD}\{(D_\varphi^{-1} - I), (I - \dot{D}_{20}^I)\}, (D_\varphi^{-1} - I) = M_N D_\varphi^{-1}, (I - \dot{D}_{20}^I) = M_N \dot{D}_{20}, \dot{X}_0, Y_0, D_\varphi$$

are defined by $X_0 = M_N \dot{X}_0, D_\varphi Y_0 + \dot{D}_{20}Y_0 = I$, and $\dot{D}_{20}\dot{D}_\varphi = \dot{D}_\varphi\dot{D}_{20}$ which exist since D_φ and D_{20} are ESP.

Proof: In the light of the derivation preceding Theorem 2, only the expression for S_1 needs a proof. For that, note that Lemma 3 applied to (1) and to $\dot{N}_{10}R + W\psi^{-1} = I$ gives the desired expression.

V. DENOMINATOR PERTURBATION ON P_2

In this section, the RATP for (ψ, P_{10}, P_{20}) is addressed relative to the model class \mathcal{D} in which D_2 can vary freely around D_{20} while N_1 and N_2 are held fixed, i.e.,

$$\mathcal{D} \triangleq \{(\dot{N}_{10}D_2^{-1}, N_{20}D_2^{-1}) \in \mathcal{M}(\mathbb{R}_p) \times \mathcal{M}(\mathbb{R}_p) : D_2 \in \mathcal{M}(\mathcal{S}), N_{20} \text{ and } D_2 \text{ RCP}\}.$$

To this effect, note first that $C(R, K)$ solves the RATP for (ψ, P_{10}, P_{20}) relative to \mathcal{D} if and only if R satisfies condition a) and $\dot{N}_{10}\dot{D}_C(K)\Delta D_2(I + \dot{D}_C(K)\Delta D_2)^{-1}\psi^{-1} \in \mathcal{M}(\mathcal{S})$, for all ΔD_2 such that $\|\Delta D_2\|_\infty < \epsilon$ for some $\epsilon > 0$ (this follows from Proposition 1). Due to Lemma 1, the aforementioned condition is equivalent to $\dot{N}_{10}\dot{D}_C(K)\varphi^{-1} \in \mathcal{M}(\mathcal{S})$, i.e., $N_\varphi D_\varphi^{-1}(K\dot{N}_{20} + Y_0) \in \mathcal{M}(\mathcal{S})$, which is equivalent to $D_\varphi^{-1}(K\dot{N}_{20} + Y_0) \in \mathcal{M}(\mathcal{S})$, i.e., there exists $\bar{D}_C \in \mathcal{M}(\mathcal{S})$ such that $-D_\varphi\bar{D}_C + K\dot{N}_{20} = -Y_0$. This equation is formally identical to (1); thus, the arguments which led to Theorem 2 apply *mutatis mutandis* to it and lead to the following theorem.

Theorem 3: Let (ψ, P_{10}, P_{20}) be as above.

- The set C_2 of all controllers which solve the RATP for (ψ, P_{10}, P_{20}) relative to \mathcal{D} is nonempty iff \dot{N}_{10} and ψ are ESP and D_φ and N_{20} are ESP.
- In this case, C_2 is given by

$$C_2 = \{(K\dot{N}_{20} + Y_0)^{-1}[R(K\dot{D}_{20} - X_0)] : (R, K) \in S_2, \det\{(K\dot{N}_{20} + Y_0)(\infty)\} \neq 0\}$$

where $S_2 = \{(R, K) : R = \dot{X}\dot{I} - D, \dot{R}, K = -Y_0\dot{Y}_0 - \dot{D}_\varphi\dot{K}, (\dot{R}, \dot{K}) \in \mathcal{M}(\mathcal{S}) \times \mathcal{M}(\mathcal{S})\}$, the expression for R is the same as in Theorem 2,

$$M_D = \text{GLCD}\{(D_\varphi^{-1} - I), (I - \dot{N}_{20}^I)\}, (D_\varphi^{-1} - I) = M_D \bar{D}_\varphi^{-1}, (I - \dot{N}_{20}^I) = M_D \bar{N}_{20},$$

with $(\bar{D}_\varphi, \bar{N}_{20})$ LCP, \bar{Y}_0, Y_D , and \hat{D}_φ are defined by $Y_0 = M_D \bar{Y}_0$

$$\bar{D}_\varphi X_D + \bar{N}_{20} Y_D = I \quad \text{and} \quad \bar{N}_{20} \hat{D}_\varphi = \bar{D}_\varphi \hat{N}_{20},$$

for some $X_D \in \mathcal{M}(\mathbf{S})$, $\hat{N}_{20} \in \mathcal{M}(\mathbf{S})$. \square

Remark: If \hat{N}_{10} and ψ_r are ESP and $\hat{N}_{10}^{-1} I, I, \psi_r^T$ are RCP, the expression for R in Theorems 2 and 3 does not require Kronecker products (see [14]). Analogously, if $\hat{D}_\varphi = I$ and I, \hat{D}_{20}^T , respectively, I, \hat{N}_{20}^T are RCP, no Kronecker products are needed in the expression for K in Theorem 2, respectively, Theorem 3. \square

Remark: It is worth noting that since $\hat{D}_\varphi = K \hat{N}_{20} + Y_0$ and $\hat{N}_\varphi = K \hat{D}_{20} - X_0$ are LCP, there is no controller which solves the RATP when free, independent perturbations on both N_2 and D_2 are allowed while \hat{N}_1 is held fixed.

VI. PERTURBATIONS ON D_1, M , AND N_1

Perturbations are now considered which are defined on the basis of the coprime factors of P_1 . To this effect, write $P_1 = N_1 D_1^{-1}$ and $P_2 = N_2 D_2^{-1}$ RCP factorizations—due to stabilizability requirements (Theorem 1), $D_2 = D_1 M$, so that $P_1 = \hat{N}_1 D_2^{-1}$, $\hat{N}_1 = N_1 M$.

The RATP for (ψ_r, P_{10}, P_{20}) is now addressed relative to the model class \mathcal{D}_1 , in which D_1 can vary freely around D_{10} while N_1, N_2 , and M are held fixed, i.e.,

$$\mathcal{D}_1 = \{(N_{10} D_1^{-1}, N_{20} (D_1 M_0)^{-1}) \in \mathcal{M}(\mathbf{R}_p) \times \mathcal{M}(\mathbf{R}_p);$$

$$D_1 \in \mathcal{M}(\mathbf{S}), (N_{10}, D_1) \text{RCP}, (N_{20}, D_1 M_0) \text{RCP}\}.$$

Note first that, in this case, $\Delta \hat{N}_1 = 0$, $\Delta N_2 = 0$ and $\Delta D_2 = \Delta D_1 M_0$; thus, it follows from Proposition 1 (and [7, Lemma 5.7.6]), that if $C(R, K)$ solves the RATP for (ψ_r, P_{10}, P_{20}) relative to \mathcal{D}_1 then

$$\begin{aligned} & \hat{N}_{10} \hat{D}_\varphi(K) \Delta D_1 M_0 \\ & \cdot (I + \hat{D}_\varphi(K) \Delta D_1 M_0)^{-1} \psi_r^{-1} \hat{R} \in \mathcal{M}(\mathbf{S}) \\ & \Leftrightarrow \hat{N}_{10} \hat{D}_\varphi(K) \Delta D_1 (I + M_0 \hat{D}_\varphi(K) \Delta D_1)^{-1} \\ & \cdot (M_0 R) \psi_r^{-1} \in \mathcal{M}(\mathbf{S}). \end{aligned}$$

Writing $(M_0 R) \psi_r^{-1} = \hat{\psi}_{r,m}^{-1} M_{r,0}$ (coprime factorizations), it follows from Lemma 1 that the last condition is verified if and only if

$$\hat{N}_{10} \hat{D}_\varphi(K) \varphi_r^{-1} = N_{10} (K \hat{N}_{20} + Y_0) \varphi_r^{-1} \in \mathcal{M}(\mathbf{S})$$

(recall that under the nominal tracking condition $(M_0 R)$ and ψ_r are RCP, so that the greatest invariant factors of $\psi_{r,0}, \psi_{r,m}$, and ψ_r are the same φ_r). This is the same condition found in Section IV, so that Theorem 3 applies here with D replaced by D_1 .

Consider now perturbed model classes \mathcal{D}_{M1} in which M can vary freely around M_0 while N_1, N_2 , and D_1 are held fixed, i.e.,

$$\begin{aligned} \mathcal{D}_{M1} = \{ & (N_{10} D_{10}^{-1}, N_{20} (D_{10} M)^{-1}) \in \mathcal{M}(\mathbf{R}_p) \times \mathcal{M}(\mathbf{R}_p); \\ & M \in \mathcal{M}(\mathbf{S}), (N_{20}, D_{10} M) \text{RCP}\}. \end{aligned}$$

$C(R, K)$ solves the RATP for (ψ_r, P_{10}, P_{20}) relative to \mathcal{D}_{M1} iff R satisfies condition a) of Proposition 1 and

$$\begin{aligned} & (N_{10} \Delta M - N_{10} M_0 \hat{D}_\varphi(K) D_{10} \Delta M) (I + \hat{D}_\varphi(K) D_{10} \Delta M)^{-1} \\ & \cdot \hat{\psi}_{r,m}^{-1} \in \mathcal{M}(\mathbf{S}) \quad \text{for all } \Delta M \end{aligned}$$

such that $\|D_{10} \Delta M\| < \epsilon$, for some $\epsilon > 0$ (this is due to Proposition 1). The last condition is equivalent, by Lemma 1, to $N_{10} (I - M_0 \hat{D}_\varphi(K) D_{10}) \varphi_r^{-1} \in \mathcal{M}(\mathbf{S})$. Let $(\hat{N}_\varphi, \hat{D}_\varphi)$ RCP be defined by $N_{10} \varphi_r^{-1} = \hat{N}_\varphi \hat{D}_\varphi^{-1}$; then the condition above holds iff

$$\begin{aligned} & \text{there exist } K \text{ and } Z \text{ in } \mathcal{M}(\mathbf{S}) \text{ such that } M_0 \hat{D}_\varphi(K) D_{10} \\ & + \hat{D}_\varphi Z = I. \quad (2) \end{aligned}$$

This, in turn, implies that \hat{D}_φ, M_0 LCP and \hat{D}_φ, D_{10} ESP, which by Lemma 2, are equivalent to the existence of $(X, Y) \in \mathcal{M}(\mathbf{S}) \times \mathcal{M}(\mathbf{S})$ such that $M_0 X D_{10} + \hat{D}_\varphi Y = I$. Conversely, suppose that there exists such (X, Y) ; then $M_0 X D_{10} (I - M_0 Y_0 D_{10}) + \hat{D}_\varphi [Y (I - M_0 Y_0 D_{10})] = I - M_0 Y_0 D_{10}$ or, equivalently, $M_0 X D_{10} - M_0 X (D_{10} M_0 Y_0) + \hat{D}_\varphi Z_0 = I - M_0 Y_0 D_{10}$, where $Z_0 \triangleq Y (I - M_0 Y_0 D_{10})$. Now, $D_{10} M_0 Y_0 = D_{20} Y_0 = I - \hat{Y}_0 \hat{N}_{20}$ so that

$$M_0 X D_{10} - M_0 X D_{10} + M_0 X \hat{Y}_0 \hat{N}_{20} D_{10} + \hat{D}_\varphi Z_0 = I - M_0 Y_0 D_{10}$$

or, equivalently,

$$M_0 (X \hat{Y}_0) N_{20} D_{10} + \hat{D}_\varphi Z_0 = I - M_0 Y_0 D_{10},$$

$$M_0 [(X Y_0) N_{20} + Y_0] D_{10} + \hat{D}_\varphi Z_0 = I.$$

It has thus been established that " $\exists (K, Z) \in \mathcal{M}(\mathbf{S}) \times \mathcal{M}(\mathbf{S})$ such that $M_0 \hat{D}_\varphi(K) D_{10} + \hat{D}_\varphi Z = I$ iff $\exists (X, Y) \in \mathcal{M}(\mathbf{S}) \times \mathcal{M}(\mathbf{S})$ such that $M_0 X D_{10} + \hat{D}_\varphi Y = I$ ". By Lemma 2, it then follows that there exists such (K, Z) if and only if M_0 and \hat{D}_φ are LCP and \hat{D}_φ and D_{10} are ESP.

The following theorem can then be stated.

Theorem 4: Let (ψ_r, P_{10}, P_{20}) be as above.

a) The set C_1 of all controllers which solve the RATP for (ψ_r, P_{10}, P_{20}) relative to \mathcal{D}_{M1} , is nonempty iff \hat{D}_φ and M_0 are LCP and \hat{D}_φ and D_{10} are ESP.

b) In this case, C_1 is given by

$$\begin{aligned} C_1 = \{ & (K \hat{N}_{20} + Y_0)^{-1} [R : K \hat{D}_{20} - X_0] : (R, K) \in S_1, \\ & \det \{(K N_{20} + Y_0)(\infty)\} \neq 0 \} \end{aligned}$$

where $S_1 \triangleq \{(R, K) \in \mathcal{M}(\mathbf{S}) \times \mathcal{M}(\mathbf{S}) : R = \hat{N}_1 \hat{I} - D_1 R, K = Y_{M1} X_0 - \hat{D}_{\varphi 1} K \text{ for some } (\hat{R}, \hat{K}) \in \mathcal{M}(\mathbf{S}) \times \mathcal{M}(\mathbf{S})\}$, the expression for R is the same as in Theorem 2,

$$M_{M1} = \text{GLCD} \{(D_\varphi - I), (M_0 - D_{10} \hat{N}_{20}^T)\},$$

$$(D_\varphi - I) = M_{M1} \hat{D}_{\varphi 1}, \quad (M_0 - D_{10} \hat{N}_{20}^T) = M_{M1} N_{20}$$

(which implies \hat{D}_φ, N_{20} LCP), \hat{X}_0, Y_{M1} , and $\hat{D}_{\varphi 1}$ are defined by

$$I - (M_0 - D_{10}^T) Y_0 = M_{M1} X_0, \quad D_{M1} X_{M1} + \hat{N}_{20} Y_{M1} = I,$$

and

$$\hat{N}_{20} \hat{D}_{\varphi 1} = \hat{D}_{\varphi 1} \hat{N}_{20} \quad \text{for some } X_{M1} \in \mathcal{M}(\mathbf{S}), \hat{N}_{20} \in \mathcal{M}(\mathbf{S}).$$

Proof: The proof is exactly like the proof of Theorem 2 when \mathcal{N} and the equation " $K \hat{D}_{20} - D_\varphi \hat{N}_{20} = X_0$ " are replaced, respectively, by \mathcal{D}_{M1} and (2), i.e., " $M_0 K \hat{N}_{20} D_{10} + \hat{D}_\varphi Z = I - M_0 Y_0 D_{10}$ ". \square

Remark: As in the last Remark in Section IV, there is no controller which solves the RATP when free independent perturbations on M and D_1 are allowed while N_1 is held fixed.

Remark It can be shown that if D_φ and M_0 are LCP, then \hat{D}_φ and D_{10} are ESP if and only if D_φ and D_{20} are ESP (the last condition also appears in Theorem 2)

Finally, perturbations on N_1 are considered with D_1, N_2 , and M held fixed. In this case, arbitrary perturbations on N_1 lead to RATPS with no solutions and the most general perturbed model class for which the RATP has a solution is given by

$$\mathcal{V}_\lambda^0(R_0) = \{(N_1 D_{10}^{-1}, N_{20} D_{20}^{-1}) \mid V_1 = V_{10} + S \psi_{10}, S \in \mathcal{M}(\mathcal{S})\}$$

where $\psi_{10} M^{-1} = M_1^{-1} \psi_{10}$, $\psi_{10} R_0 = R_0 \psi_{10}$, for some R_0 satisfying condition a) of Proposition 1 (see [14]), where all controllers that solve the RATP for (ψ_1, P_{10}, P_{20}) relative to $\mathcal{V}_\lambda^0(R_0)$ are explicitly parameterized. An entirely similar situation occurs when perturbations on N_1 are considered with N_2 and D_2 are held fixed (cf. [14])

VII. CONCLUDING REMARKS

In this note, the robust asymptotic tracking problem was addressed for model perturbation classes obtained by allowing one of the coprime factors of the transfer functions from u to y and v to vary while the others are held fixed. In each such a case, explicit, necessary, and sufficient conditions on the problem data are given for the existence of solutions, and, under these conditions, an explicit parameterization of all solutions to each of these problems has been obtained.

APPENDIX

Lemma 1 Let A, B, C, M, Q be matrices in $\mathcal{M}(\mathcal{S})$, ψ_1 non singular biproper, and let φ be the greatest invariant factor of ψ_1 . Then $A(B\Delta\psi + C\Delta D)(I + M\Delta\psi + Q\Delta D)^{-1} \in \mathcal{M}(\mathcal{S})$ for

any $(\Delta\psi, \Delta D)$ such that $\|[\Delta\psi^T, \Delta D^T]^T\|_\infty < \epsilon$ for some $\epsilon > 0$ if and only if $A B \varphi^{-1} \in \mathcal{M}(\mathcal{S})$, $A C \varphi^{-1} \in \mathcal{M}(\mathcal{S})$. If B, C are LCP, the condition above is equivalent to $A \varphi^{-1} \in \mathcal{M}(\mathcal{S})$.

Lemma 2 Let A, B, C be matrices in $\mathcal{M}(\mathcal{S})$. Then there exist X and Y (matrices in $\mathcal{M}(\mathcal{S})$) such that $A \psi B + Y C = I$ if and only if A, C are ESP and B, C are RCP.

Lemma 3 Let A, B, C, D , and Q be matrices in $\mathcal{M}(\mathcal{S})$. The equation $A \psi B + D Y C = Q$ has a solution $(X, Y) \in \mathcal{M}(\mathcal{S}) \times \mathcal{M}(\mathcal{S})$ if and only if $M = \text{GCLD}\{(A, B^T), (D, C^T)\}$ is a left divisor of Q (the column form of Q), i.e., there is a \mathcal{S} -matrix \hat{Q} such that $Q = M \hat{Q}$. In this case, writing $(A, B^T) = M \hat{A}, (D, C^T) = M \hat{C}$ then \hat{A}, \hat{C} are LCP and all pairs (X, Y) in the set defined by $X = \hat{A} \hat{Q} + C K, Y = \hat{C} \hat{Q} - A K, \forall K \in \mathcal{M}(\mathcal{S})$, are solutions of $A \psi B + D Y C = Q$ where X, Y, A and C are \mathcal{S} -matrices such that $A X + C Y = I, A C = C A$ (which exist by the left-coprimeness of A, C). Moreover, if M is nonsingular this is indeed the set of all solutions.

A Version of Hautus' Test for Tandem Connection of Linear Systems

Andrea Bacciotti and Giannina Beccari

Abstract—In this note, we consider systems which can be decomposed as a cascade connection of linear subsystems. The second subsystem is assumed to have the controller canonical form. The main result is a version of Hautus' test, which allows us to check controllability and stabilizability properties of these systems by means of reduced-order rank computations.

1. INTRODUCTION

The study of structural properties of interconnected systems is a classical subject (see, for instance, [2], [4], [6], [11]) which has been recently revitalized ([1], [8], [10]). In this note we are interested in autonomous linear control systems of the form

$$\begin{cases} \dot{y} = Ay + B \\ \dot{z} = Cz + Gu \end{cases} \quad (1)$$

where $y \in \mathbb{R}^l$, $z \in \mathbb{R}^q$ denote the state variables and $u \in \mathbb{R}^m$ is the input ($m \leq q$). They can be considered as the tandem (or cascade) connection of the two subsystems

$$\dot{y} = Ay + Bu \quad (1a)$$

(with input $u \in \mathbb{R}^m$) and

$$\dot{z} = Cz + Gu \quad (1b)$$

Manuscript received June 24, 1993; revised December 8, 1993 and March 18, 1994.

The authors are with the Dipartimento di Matematica del Politecnico, 10129 Torino, Italy.

the connection being established setting $v = z$.

In the sequel, we denote by $\mathbb{R}^{\nu, \mu}$ (respectively, $\mathbb{C}^{\nu, \mu}$) the space of real (respectively, complex) matrices with ν rows and μ columns. Accordingly, $A \in \mathbb{R}^{p, p}$, $B \in \mathbb{R}^{p, q}$, $F \in \mathbb{R}^{q, q}$, and $G \in \mathbb{R}^{q, m}$.

It is well known that if (1) is controllable [stabilizable] then (1a) and (1b) are separately controllable [stabilizable] (see [4]). However, the converse is false in general (see again [4] and the simple example in Section II). Thus, it is natural to ask what kind of condition should be imposed on (1a) and (1b) in order to guarantee controllability [stabilizability] of the overall system (1).

It is easy to see that if $q = m$ and G is not singular, then (1) is controllable [stabilizable] if and only if (1a) is controllable [stabilizable]. However, this assumption is too conservative to be interesting. From a more general point of view, the problem is addressed in [6], [2] and especially in [4] using a state-space description similar to (1), and in [11], [3] using differential operator representation and coprime factorization. We note that the necessary and sufficient conditions obtained in [4] require some restrictions about the Jordan canonical form of matrices A and F . For instance, it is assumed that there is only one Jordan block for each possible common eigenvalue of A and F .

In this note, we assume that

$$F = \text{diag}(C_1, \dots, C_m), \quad G = \text{diag}(g_1, \dots, g_m) \quad (2)$$

where for each $i = 1, \dots, m$

$$C_i = \begin{pmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 1 \\ 0 & 0 & 0 & \dots & 0 \end{pmatrix} \in \mathbb{R}^{k_i, k_i}$$

and

$$g_i = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix} \in \mathbb{R}^{k_i, 1} \quad (3)$$

($k_1 + \dots + k_m = q$). In other words, we assume that (1b) is in Brunowski's canonical form (see [9, p. 139]). From a practical point of view, we can think of (1), (2), and (3) as a plant represented by the linear system (1a) and coupled with m parallel chains of integrators of (possibly) different lengths.

Chains of integrators are easy to implement. A typical situation occurs when (1a) is given and one has to design a dynamical compensator. Usually, in these cases only the first component of the state vector z affects directly the first subsystem. Moreover, the form (1), (2), (3) incorporates systems whose behavior depends on the derivatives of the input map. These possible applications will be shortly discussed in Section IV.

When (1b) is in Brunowski's canonical form, then F has zero as a unique eigenvalue. Since $m \geq 1$ and zero is allowed to be an eigenvalue of A as well, our result applies also to cases not covered by [4]. Finally, we note that if (1b) is controllable, then the structure (2) and (3) can be recovered up to a linear change of coordinates

$$\begin{pmatrix} Y \\ Z \end{pmatrix} = \begin{pmatrix} I_p & O \\ O & T \end{pmatrix} \begin{pmatrix} y \\ z \end{pmatrix} \quad (4)$$

(where $T \in \mathbb{R}^{q, q}$), a preliminary linear feedback transformation and the elimination of possible redundant input channels ([9]). Thus, the assumption that (1b) is in Brunowski's canonical form turns out to be restrictive only when we are interested in the stabilizability problem.

Of course, we can think of system (1), (2), (3) as a whole system. To this purpose, we set $n = p + q$, $x = (y, z)$

$$\dot{A} = \begin{pmatrix} A & B \\ O & F \end{pmatrix}, \quad \dot{B} = \begin{pmatrix} O \\ G \end{pmatrix} \quad (5)$$

where we denote by O some matrices with zero entries. Accordingly, its properties can be investigated with the aid of some classical criterion. For instance, Hautus' test (see [9, p. 93, 153]) states that the system is controllable if and only if

$$\text{rank}[\dot{A} - \lambda I_n, \dot{B}] = n \quad (6)$$

for each $\lambda \in \mathbb{C}$, and stabilizable if and only if (6) holds for each $\lambda \in \mathbb{C}_0^+ = \{z \in \mathbb{C} : \text{Re } z \geq 0\}$. Note that the matrix in (6) has n rows and $n + m$ columns.

However, as remarked in [4], with this approach, it is difficult to state the conditions in terms of the subsystems. Moreover, disregarding the structure, there is no gain in the process insight.

The main contribution of this note is a version of Hautus' test which, taking into account the form of the system, allows us to check the controllability and stabilizability properties by computing the rank of a reduced-order matrix, namely a matrix with p rows and $p + m$ columns. The result is stated in Section II and proved in Section III. Additional comments and remarks are finally provided in Section IV.

II. THE RESULT

As already mentioned, if (1a) and (1b) are both controllable [stabilizable], (1) is not necessarily controllable [stabilizable].

Example: Consider the following system with $p = 1$, $q = 2$:

$$\begin{cases} \dot{y} = y + z_1 - z_2 \\ \dot{z}_1 = z_2 \\ \dot{z}_2 = u. \end{cases}$$

Both subsystems are controllable, but the overall system is not even stabilizable.

In the following theorem a special role is played by the columns of B . We introduce some notation. Let us write $B = (B_1, \dots, B_m)$, where for each $i = 1, \dots, m$

$$B_i = [b_{i,1}, b_{i,2}, \dots, b_{i,k_i}] \in \mathbb{R}^{p, k_i}.$$

Moreover, let

$$h_i(\lambda) = b_{i,1} + \lambda b_{i,2} + \lambda^2 b_{i,3} + \dots + \lambda^{k_i-1} b_{i,k_i}$$

and

$$H(\lambda) = [h_1(\lambda), \dots, h_m(\lambda)] \in \mathbb{C}^{p, m}.$$

Now, the main result of this note can be stated.

Theorem: Let \dot{A}, \dot{B} be given by (5), (2), (3), and let $\lambda \in \mathbb{C}$. Then, $\text{rank}[\dot{A} - \lambda I_n, \dot{B}] = n = p + q$, i.e., maximal, if and only if

$$\text{rank}[A - \lambda I_p, H(\lambda)] = p. \quad (7)$$

i.e., maximal.

It follows that System (1), (2), (3) is controllable [stabilizable] if and only if (7) holds for each $\lambda \in \mathbb{C}$ [for each $\lambda \in \mathbb{C}_0^+$]. As explained in the Introduction, we have so obtained a criterion which allows us to investigate the controllability and stabilizability properties of the overall system by means of reduced-order matrix rank computations. This is illustrated by the following example.

Example: Let us consider a system of the form (1), (2), (3) with

$$A = \begin{pmatrix} 3 & 3 \\ 4 & 7 \end{pmatrix} \quad \text{and} \quad B = \begin{pmatrix} 1 & k & 1 \\ 2 & 4 & 0 \end{pmatrix}$$

where k is a real parameter. Let $m = 1$, so that

$$\tilde{A} = \begin{pmatrix} 3 & 3 & 1 & k & 1 \\ 4 & 7 & 2 & 4 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \quad \text{and} \quad \tilde{B} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

In order to apply Hautus' test to the pair (\tilde{A}, \tilde{B}) , we should compute the rank of $(\tilde{A} - \lambda I_5, \tilde{B})$ for each eigenvalue λ of \tilde{A} (actually, it is not difficult to see that we can limit ourselves to the eigenvalues of A). The eigenvalues of A are, in this case, $\lambda = 1$ and $\lambda = 9$. Let us take for instance $\lambda = 1$. The matrix to be considered is

$$\begin{pmatrix} 2 & 3 & 1 & k & 1 & 0 \\ 4 & 6 & 2 & 4 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 \end{pmatrix}.$$

Clearly, the rank of this matrix is maximal if and only if the 4×4 matrix obtained by deleting the first column, the last column, and the last row is nonsingular. The problem is so reduced to the (borrowing) computation of the determinant of a fourth-order matrix.

Using our criterion, one is led to consider the simpler matrix

$$(A - I, b_0 + b_1 + b_2) = \begin{pmatrix} 2 & 3 & 2+k \\ 4 & 6 & 6 \end{pmatrix}.$$

It is immediate to see that its rank is maximal if and only if $k \neq 1$.

III. THE PROOF

Let $M = [\tilde{A} - \lambda I_n, \tilde{B}]$. In order to compute its rank, it is convenient to multiply M on the right by an invertible matrix Q . The construction of Q will be accomplished in three steps.

In what follows, we denote by $O_{\nu, \mu}$ the matrix with ν rows, μ columns, and zero entries (to simplify the notation, the subscripts ν, μ will be suppressed whenever the matrix dimensions are clear from the context).

Step 1: It is convenient to look at M as a block-matrix of the form

$$[M_0, M_1, \dots, M_m, N_1, \dots, N_m],$$

where

$$M_0 = \begin{pmatrix} A - \lambda I_p \\ O_{q, p} \end{pmatrix} \in \mathbb{C}^{n, p},$$

$$M_i = \begin{pmatrix} B_i \\ O_{k_i, k_i} \\ \vdots \\ C_i - \lambda I_{k_i} \\ \vdots \\ O_{k_m, k_i} \end{pmatrix} \in \mathbb{C}^{n, k_i} \quad \text{and} \quad N_i = \begin{pmatrix} O_{p, 1} \\ O_{k_1, 1} \\ \vdots \\ g_i \\ \vdots \\ O_{k_m, 1} \end{pmatrix} \in \mathbb{C}^{n, 1}$$

($i = 1, \dots, m$). We perform a reordering of the blocks of M , by multiplying on the right by a suitable invertible matrix Q^1 . It is convenient to define Q^1 as a block matrix. More precisely, we set $Q^1 = (Q^1_{ij})(i, j = 0, 1, \dots, 2m)$ where

$$Q^1_{0,0} = I_p,$$

$$Q^1_{i, 2i-1} = I_{k_i} \quad \text{and} \quad Q^1_{s+m, 2s} = 1 \quad \text{for } r, s = 1, \dots, m$$

$$Q^1_{i,j} = 0 \quad \text{otherwise.}$$

As a result, we obtain $MQ^1 = [M_0, M_1, N_1, \dots, M_m, N_m]$.

Step 2: Let us multiply MQ^1 on the right by another invertible matrix Q^2 . In order to describe Q^2 , it is convenient to think on Q^2 as a block-matrix in a different way

$$MQ^1 = \begin{pmatrix} A' & B' \\ O & F' \end{pmatrix}$$

where

$$A' = A - \lambda I_p,$$

$$B' = [B'_1, \dots, B'_m] \quad \text{and} \quad B'_i = [B_i, O_{p, 1}] \in \mathbb{C}^{p, k_i+1},$$

$$F' = \text{diag}(C'_1, \dots, C'_m)$$

and

$$C'_i = [C_i - \lambda I_{k_i}, g_i] = \begin{pmatrix} -\lambda & 1 & 0 & \dots & 0 & 0 \\ 0 & -\lambda & 1 & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & -\lambda & 1 \end{pmatrix} \in \mathbb{C}^{k_i, k_i+1}.$$

The matrix Q^2 has the form

$$Q^2 = \begin{pmatrix} I_p & O \\ O & \Lambda \end{pmatrix}$$

where $\Lambda = \text{diag}(\Lambda_1, \dots, \Lambda_m) \in \mathbb{C}^{q+m, q+m}$ and

$$\Lambda_i = \begin{pmatrix} 1 & 0 & 0 & \dots & 0 \\ \lambda & 1 & 0 & \dots & 0 \\ \lambda^2 & \lambda & 1 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ \lambda^{k_i} & \lambda^{k_i-1} & \lambda^{k_i-2} & \dots & 1 \end{pmatrix} \in \mathbb{C}^{k_i+1, k_i+1}.$$

As a consequence

$$MQ^1 Q^2 = \begin{pmatrix} A' & B' \Lambda \\ O & F' \Lambda \end{pmatrix} \quad (8)$$

where

$$B' \Lambda = [B'_1 \Lambda_1, \dots, B'_m \Lambda_m] = [B''_1, \dots, B''_m],$$

$$B''_i = (b''_{i,1}, b''_{i,2}, \dots, b''_{i,k_i}, O_{p,1}) \in \mathbb{C}^{p, k_i+1},$$

$$b''_{i,r} = b_{i,r} + \lambda b_{i,r+1} + \lambda^2 b_{i,r+2} + \dots + \lambda^{k_i-r} b_{i,k_i}$$

and

$$F' \Lambda = \text{diag}(J_1, \dots, J_m), \quad J_m = [O_{k_m, 1}, I_{k_m}] \in \mathbb{C}^{k_m, k_m+1}.$$

The result of this second transformation is that the dependence on λ has been eliminated in the second row of (8).

Step 3: Finally, let us rewrite $MQ^1 Q^2$ as a block matrix with one row

$$MQ^1 Q^2 = [M_0, H_1, K_1, \dots, H_m, K_m]$$

with

$$H_i = \begin{pmatrix} h_i(\lambda) \\ O_{q, 1} \end{pmatrix},$$

$$h_i(\lambda) = b_{i,1} + \lambda b_{i,2} + \lambda^2 b_{i,3} + \dots + \lambda^{k_i-1} b_{i,k_i}$$

and

$$K_i = \begin{pmatrix} b''_{i,2} & \dots & b''_{i,k_i} & O_{p,1} \end{pmatrix}.$$

The purpose of the third transformation is to provide a further reordering of the columns of MQ^1Q^2 . Setting $Q^3 = (Q_{i,j}^3)(i, j = 0, 1, \dots, 2m)$ where

$$Q_{0,0}^3 = I_p$$

$$Q_{2r-1,r}^3 = 1, \quad \text{and} \quad Q_{2s,s+m}^3 = I_{h_s} \quad \text{for } r, s = 1, \dots, m,$$

$$Q_{i,j}^3 = 0 \quad \text{otherwise,}$$

we obtain $MQ^1Q^2Q^3 = [M_0, H_1, \dots, H_m, K_1, \dots, K_m]$.

We are now ready to get the conclusion. Let $Q = Q^1Q^2Q^3$. It is clear that

$$[\tilde{A} - \lambda I_n, \tilde{B}]Q = \begin{pmatrix} A - \lambda I_p & H(\lambda) & L(\lambda) \\ O_{q,p} & O_{q,m} & I_q \end{pmatrix}$$

where $L(\lambda)$ is some matrix which we need not specify. As an immediate consequence, we see that

$$\text{rank}[\tilde{A} - \lambda I_n, \tilde{B}] = \text{rank}[\tilde{A} - \lambda I_n, \tilde{B}]Q = n$$

if and only if $\text{rank}[A - \lambda I_p, H(\lambda)] = p$.

We note that in the case $m = 1$, we have $Q^1 = Q^3 = I_n$. In other words, if $m = 1$ no reordering is needed.

IV. FINAL REMARKS

Condition (7) implies, in particular, that

$$\text{rank}[A - \lambda I_p, B] = p$$

and so we recover the well-known fact that controllability [stabilizability] of (1a) is necessary for controllability [stabilizability] of (1). More precisely, let us define the deficiency of A relative to a set $S \subseteq \mathbb{C}$ as

$$d(A, S) = p - \min_{\lambda \in S} \text{rank}[A - \lambda I_p].$$

According to our theorem, a necessary condition for controllability [stabilizability] of (1) is that

$$d(A, \mathbb{C}) \leq m, \quad \text{respectively } d(A, \mathbb{C}_0^+) \leq m.$$

This conclusion is not surprising. Indeed, if we want to control (1a) and the control inputs are implemented through (1b), then it should be actually possible to control (1a) by means of $m \leq q$ independent inputs.

Sometimes, systems of the form

$$\begin{cases} \dot{y} = Ay + bz_1 \\ \dot{z}_1 = z_2 \\ \vdots \\ \dot{z}_q = u \end{cases} \quad (9)$$

where $b \in \mathbb{R}^p$ and $z_1, \dots, z_q, u \in \mathbb{R}$, have been considered in the literature ([8]). They represent a situation where the second subsystem is a chain of integrators with output z_1 , and the first subsystem depends only on z_1 . System (9) is a particular case of System (1). (2), (3), with $m = 1$. Hence, it follows from our theorem that (9) is controllable [stabilizable] if and only if the pair (A, b) is controllable [stabilizable].

As already recalled in the Introduction, there are other ways to study system (1). For instance, in [4] a change of coordinates

$$\begin{pmatrix} y \\ z \end{pmatrix} = \begin{pmatrix} P & O \\ O & T \end{pmatrix} \begin{pmatrix} y \\ z \end{pmatrix}$$

(more general than (4)) is used in order to put A and F in Jordan canonical form. From a numerical point of view, the difficulties encountered in obtaining Brunowski's canonical form are comparable to those encountered in obtaining Jordan form. Thus, the approach followed in the present note should be considered as an alternative to the approach of [4].

Sometimes, systems involving an input map and its derivatives are considered in the control theory literature (see, for instance, [5], [7]). These systems have the form

$$\dot{y} = Ay + B_0v + B_1\dot{v} + \dots + B_lv^{(l)} \quad (10)$$

where $v \in \mathbb{R}^m$ and $B_i \in \mathbb{C}^{n \times m}$ ($i = 0, \dots, l$). Setting

$$z_1 = v, z_2 = \dot{v}, \dots, z_{l+1} = v^{(l)}, \quad \text{and} \quad v^{(l+1)} = u$$

(10) can be equivalently rewritten as

$$\begin{cases} \dot{y} = Ay + B_0z_1 + \dots + B_lz_{l+1} \\ \dot{z}_1 = z_2 \\ \vdots \\ \dot{z}_{l+1} = u \end{cases}$$

(note that here $z_{i+1} \in \mathbb{R}^m$ for each $i = 0, \dots, l$). Up to a reordering of the variables, (10) appears to be a particular case of (1), (2), (3) and its controllability properties can be tested by means of the Theorem of Section II. It turns out that (10) is controllable [stabilizable] if and only if

$$\text{rank}[A - \lambda I_p, B_0 + \lambda B_1 + \dots + \lambda^l B_l] = p$$

for each $\lambda \in \mathbb{C}$ [for each $\lambda \in \mathbb{C}_0^+$].

A different criterion for controllability of (10) can be found in [5]. It is actually an extension of well-known Kalman's controllability matrix rank condition.

Poisson LQR Design for Asynchronous Multirate Controllers

Robert P. Leland

Abstract—We derive the optimal LQR controller for asynchronous multirate digital control. Independent processors operating without synchronization update different components of the control vector at Poisson arrival times. An iterative algorithm to compute the steady-state control law and optimal cost is described and its convergence is demonstrated.

I. INTRODUCTION

For complex systems, such as aircraft, it can be desirable to distribute the control task among several processors, rather than using a single central computer. If these processors are not triggered by a common clock pulse, and their computation, sampling, and hold activities are not synchronized, we call them asynchronous controllers. In addition, these processors need not operate with the same sampling rate. Multirate sampling in control systems has been of interest since the 1950s. The sampling rates of the controllers are typically assumed to be integrally proportional, and sampling is synchronized to make the sampling process periodic, with a period equal to an integral multiple of the largest sampling period ([1], [2], [5], [7] and others). We will allow arbitrary sampling rates, and random sampling times for each processor, so sampling is no longer periodic.

We wish to control the continuous-time system

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (1)$$

to minimize the cost functional

$$J = E \int_0^T [Qx(t), x(t)] + [Ru(t), u(t)] dt, \quad Q \geq 0, R > 0. \quad (2)$$

We partition the control vector $u(t) \in R^m$ into $n \leq m$ (possibly vector) components:

$$\begin{aligned} u_1(t) \\ \vdots \\ u_n(t) \end{aligned} \quad (3)$$

and assign an independent processor to each of the components $u_i(t)$. Processor i updates $u_i(t)$ at discrete times, with $u_i(t)$ constant between updates. The processors operate asynchronously, hence the update times of the processors are not coordinated in any way. We also assume the update times of processor i occur randomly as the arrival times of a Poisson process $N_i(t)$, where $N_1(t) \cdots N_n(t)$ are independent Poisson processes with arrival rates $\lambda_1 \cdots \lambda_n$. The output of processor i is described by the stochastic differential equation

$$du_i(t) = dN_i(t)(v_i(t) - u_i(t)). \quad (4)$$

If τ is an arrival time of $N_i(t)$, $v_i(\tau)$ is the control update computed by processor i .

We consider such asynchronous LQR controllers, assuming each processor has access to the entire state and all control signals at the time the control signal is calculated.

Manuscript received February 22, 1993; revised January 12, 1994.

The author is with the Department of Electrical Engineering, University of Alabama, Tuscaloosa, AL 35487 USA.

IEEE Log Number 9407021.

The Poisson process approach, although allowing additional uncertainty in sampling times, removes the need to synchronize sampling and permits multirate sampling with sampling rates that are not integral multiples.

Poisson processes have appeared in control problems in several contexts. A large body of literature exists on the control of jump parameter linear systems, in which the system parameters change at random times, e.g., [6], [12], and [15]. The LQR problem for such systems was solved in [8], [13], and [17], and the LQG controller is derived in [6].

Stability and control of systems effected by Poisson noise are treated in [9] and [17]. Malliavin calculus for systems driven by Poisson processes is described in [3].

In the asynchronous control problem, jumps occur in the state, rather than in the parameters. The LQR controller for systems with jumps in the state due to compound Poisson noise was derived in [17]. An LQR controller for systems with jumps in the state due to switching between linearized system models was derived in [14]. Existence of the optimal control and continuity of the optimal cost for diffusion processes with jumps were shown in [11]. In each case the Poisson processes represented noise, rather than a control update, and the control signal could be updated in continuous time.

Optimal impulsive control, where control decisions are only made at discrete Poisson arrival times, is treated in [4] for a class of problems in operations research, and existence of the optimal control is demonstrated using likelihood ratios. In [10], the existence of an optimal impulsive control for Markov processes is shown, and the cost-to-go, or value function, is shown to be a function of the current state and control values.

In this note, we formulate and solve the LQR problem for asynchronous multirate controllers using stochastic differential equations. We assume the control signal, or part of it, can only be updated at Poisson arrival times, as in the impulse control problem, treated in the general case in [4] and [10]. We consider the specific case of the LQR problem, and obtain explicit expressions for the optimal control and cost. Our problem also differs slightly from that of [10], in that the control task is distributed among several asynchronous processors, and only part of the control vector can be updated at a single arrival time. When a steady-state controller exists, we describe an iterative algorithm to compute the control gain, and demonstrate its convergence. We compute the control gain for a system of three masses with springs and dampers, and compare the cost to that for a continuous time LQR controller.

II. SYSTEM MODEL

The controller described by (4) can be rewritten in vector form as

$$du(t) = dN(t)(v(t) - u(t)) \quad (5)$$

where $v(t) = [v_1(t)^* \cdots v_n(t)^*]^*$ is a vector of potential control signal updates

$$N(t) = \sum_{i=1}^n N_i(t)I_i.$$

I_i is the $m \times m$ projection matrix that projects the control input space R^m onto the subspace of R^m updated by processor i . Thus, $I_i u(t) = [0 \cdots 0 u_i(t)^* 0 \cdots 0]^*$, where $u_i(t)$ is the (possibly vector)

part of $u(t)$ updated by processor i . As an example, if $m = 7$ and $n = 3$,

$$u(t) = \begin{bmatrix} u_1(t) \\ u_2(t) \\ u_3(t) \end{bmatrix}, \quad I_1 = \begin{bmatrix} I & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

$$I_2 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad I_3 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & I \end{bmatrix}.$$

The stochastic differential equation (5) is understood as the limit of

$$u(t+h) - u(t) = (N(t+h) - N(t))(v(t) - u(t))$$

as $h \rightarrow 0$. Thus, each arrival of $N_i(t)$ causes an update of component $u_i(t)$, where $u_i(t)$ is set to $v_i(t)$, newly calculated by processor i , or $u(t)$ is replaced by $u(t) + I_i(v(t) - u(t))$.

We define the Poisson rate matrix Λ as

$$\Lambda = \sum_{i=1}^n \lambda_i I_i. \quad (6)$$

We define an augmented state vector for this system by adding "hold" states

$$X(t) = \begin{bmatrix} x(t) \\ u(t) \end{bmatrix}. \quad (7)$$

Then the entire system can be described by the following stochastic differential equation:

$$dX(t) = \begin{bmatrix} A dt & B dt \\ 0 & -dN(t) \end{bmatrix} X(t) + \begin{bmatrix} 0 \\ dN(t) \end{bmatrix} v(t). \quad (8)$$

Since $X(t)$ is a Markov process, the control updates $v_i(t)$, $i = 1 \dots n$, will only depend on $X(t)$, and not on the time since the last update.

We define a matrix function $\delta(\cdot)$ on $m \times m$ square matrices as

$$\delta(P) = \sum_{i=1}^n I_i P I_i. \quad (9)$$

The function δ keeps only the block diagonal terms of matrix P . $\delta(P)$ can be computed easily using an element-by-element multiplication by a matrix of ones and zeros. A matrix P is suitably block diagonal if $\delta(P) = P$. The following properties hold for such suitably block diagonal matrices: i) $I_i P = P I_i$, ii) $P^{-1} = \delta(P^{-1})$ if P^{-1} exists, iii) $\Lambda P = P \Lambda$, iv) If $P > 0$, then $\delta(P) > 0$.

III. OPTIMAL POISSON LQR CONTROLLER

We derive an optimal Poisson LQR controller using dynamic programming. We assume up-to-date analog measurements of the entire state vector and all control signals are available to each controller at that controller's update times. In the augmented state-space formulation, the cost function (2) may be rewritten as

$$J = E \int_0^T [QX(t), X(t)] dt$$

$$Q = \begin{bmatrix} Q & 0 \\ 0 & R \end{bmatrix}.$$

To apply dynamic programming, let the cost-to-go be

$$V(X, t) = E \left[\int_t^T [QX(\tau), X(\tau)] d\tau \mid X(t) = X \right].$$

A necessary condition for optimality is given by the following Hamilton-Jacobi-Bellman equation:

$$0 = \frac{\partial}{\partial t} V(X, t) + \min_v \{ \mathcal{L}_v V(X, t) + [QX, X] \}$$

where \mathcal{L}_v is the generator for the stochastic differential equation (8):

$$\mathcal{L}_v G(X) = \nabla G(X) \cdot AX + \sum_{i=1}^n \lambda_i \left\{ G \left(X - \begin{bmatrix} 0 & 0 \\ 0 & I_i \end{bmatrix} X + \begin{bmatrix} 0 \\ I_i \end{bmatrix} v \right) - G(X) \right\}$$

where we denote

$$A = \begin{bmatrix} A & B \\ 0 & 0 \end{bmatrix}.$$

We assume a solution of the form

$$V(X, t) = [M(T-t)X, X].$$

Let

$$M = \begin{bmatrix} M_1 & M_2 \\ M_2^* & M_3 \end{bmatrix}.$$

Then $\mathcal{L}_v[MX, X]$ can be expressed as

$$\begin{aligned} \mathcal{L}_v[MX, X] &= [(MA + A^*M)X, X] \\ &\quad + \sum_{i=1}^n \lambda_i \left\{ \left[M \left(X - \begin{bmatrix} 0 & 0 \\ 0 & I_i \end{bmatrix} X + \begin{bmatrix} 0 \\ I_i \end{bmatrix} v \right) \right. \right. \\ &\quad \left. \left. \left(X - \begin{bmatrix} 0 & 0 \\ 0 & I_i \end{bmatrix} X + \begin{bmatrix} 0 \\ I_i \end{bmatrix} v \right) \right] - [MX, X] \right\} \\ &= \left\{ \left[(MA + A^*M) - M \begin{bmatrix} 0 & 0 \\ 0 & \Lambda \end{bmatrix} \right. \right. \\ &\quad \left. \left. - \begin{bmatrix} 0 & 0 \\ 0 & \Lambda \end{bmatrix} M + \begin{bmatrix} 0 & 0 \\ 0 & \Lambda \delta(M_3) \end{bmatrix} \right] X, X \right\} \\ &\quad + [\Lambda [M_2^* (M_3 - \delta(M_3))] X, v] \\ &\quad + [v, \Lambda [M_2^* (M_3 - \delta(M_3))] X] \\ &\quad + [\Lambda \delta(M_3) v, v]. \end{aligned}$$

This is minimized by a choice of

$$v = -\delta(M_3)^{-1} [M_2^* (M_3 - \delta(M_3))] X$$

which is the optimal linear feedback control law. Then

$$\begin{aligned} \min_v \mathcal{L}_v[MX, X] &= [(MA + A^*M)X, X] \\ &\quad - \left[M \begin{bmatrix} 0 \\ I \end{bmatrix} \Lambda \delta(M_3)^{-1} [0 \ I] MX, X \right]. \end{aligned}$$

Thus, the Hamilton-Jacobi-Bellman equation is satisfied if $M(T-t)$ satisfies

$$\begin{aligned} 0 &= \frac{\partial}{\partial t} M(T-t) + A^* M(T-t) + M(T-t)A + Q \\ &\quad - M(T-t) \mathcal{E} \Lambda \delta(M_3(T-t))^{-1} \mathcal{E}^* M(T-t) \end{aligned}$$

with endpoint condition $M(0) = 0$, where

$$\mathcal{E} = \begin{bmatrix} 0 \\ I \end{bmatrix}.$$

The optimal control is

$$v(t) = -\delta(M_3(T-t))^{-1} [M_2^*(T-t)^* (M_3(T-t) - \delta(M_3(T-t)))] X(t) \quad (10)$$

and the optimal cost is

$$V(X(0), 0) = [M(T)X(0), X(0)]. \quad (11)$$

Note that $v(t)$ depends on both $x(t)$ and $u(t)$, however $v_i(t)$, the potential update for controller i depends only on the state $x(t)$ and the other control signals $u_k(t)$, $k \neq i$.

IV. STEADY-STATE CONTROLLER

It is difficult to determine the existence of a steady-state controller because the system contains a random matrix multiplied by the state. However, given a solution to the steady-state Riccati equation, we can show the existence of a steady-state control.

Theorem 4.1: Suppose that the steady-state Riccati equation (SSRE)

$$0 = A^*M + MA + Q - M\bar{B}\bar{A}\delta(M_3)^{-1}\bar{B}^*M \quad (12)$$

has a nonnegative solution M' . Then as $T \rightarrow \infty$, $M(T)$ converges monotonically upward to a limit M'' , where M'' satisfies the SSRE (12), and $M'' \leq M'$.

Proof: $M(T)$ is monotonically nondecreasing in T , since $[M(T)X(0), X(0)]$ is the optimal cost for the T time-horizon problem. The minimal cost for the cost functional

$$J' = E \left[\int_0^T [QX(t), X(t)] dt + [M'X(T), X(T)] \right]$$

is $J' = [M'X(0), X(0)]$, since M' is a constant solution to the Riccati equation with initial condition $M(0) = M'$. Since $J' \geq J$, we must have $M' \geq M(T)$ for all T . Since $M(T)$ is bounded above and nondecreasing, $M(T)$ converges to a matrix M'' , and $M'' \leq M'$. \square

By iteratively solving a sequence of steady-state Riccati equations, we can calculate matrix M'' whenever it exists.

Theorem 4.2: Suppose that (A, B) is controllable, (Q, A) is observable, and $R > 0$ is suitably block diagonal $R = \delta(R)$. Suppose also that there exists a nonnegative solution M' to the SSRE (12). Then the steady-state solution to the Riccati equation $M'' = \lim_{T \rightarrow \infty} M(T)$ can be calculated by iteratively solving the Riccati equation

$$0 = A^*M^{(n+1)} + M^{(n+1)}A + Q - M^{(n+1)}\bar{B}\bar{A}\delta(M_3^{(n)})^{-1}\bar{B}^*M^{(n+1)} \quad (13)$$

with $\delta(M_1^{(0)}) = \Lambda^{-1}R$, and the sequence $M^{(n)}$ converges to M'' as $n \rightarrow \infty$.

Proof: Denote by $M = \Phi(P)$ the solution to the Riccati equation

$$0 = A^*M + MA + Q - M\bar{B}\bar{A}P^{-1}\bar{B}^*M \quad (14)$$

for any positive definite suitably block diagonal $m \times m$ matrix $P = \delta(P) > 0$. Also, for the solution M , denote $\delta(M_3) = \Phi_3(P)$. For every $P > 0$, (14) has a unique positive definite solution $M = \Phi(P)$, since (A, \bar{B}) is controllable (implied by (A, B) controllable), and (Q, A) is observable (implied by (Q, A) observable and $R > 0$). Our iterative algorithm is $M^{(n+1)} = \Phi(\delta(M_1^{(n)}))$.

If $P \geq P'$, then by [16, Theorem 1], $\Phi(P) \geq \Phi(P')$, and hence $\Phi_3(P) \geq \Phi_3(P')$. Thus, Φ and Φ_3 are both nondecreasing functions.

We wish to show the sequence $M^{(n)}$ is nondecreasing if we take as our initial condition the following:

$$M^{(0)} = \begin{bmatrix} 0 & 0 \\ 0 & \Lambda^{-1}R \end{bmatrix}$$

Then $M^{(1)} = \Phi(\Lambda^{-1}R)$, and $\Delta M = M^{(1)} - M^{(0)}$, then

$$0 = (A - \bar{B}\bar{A}\bar{B}^*)^* \Delta M + \Delta M(A - \bar{B}\bar{A}\bar{B}^*) - \Delta M\bar{B}\bar{A}R^{-1}\bar{A}\bar{B}^*\Delta M$$

$$Q_0 = \begin{bmatrix} Q & 0 \\ 0 & 0 \end{bmatrix}$$

Equation (15) has unique nonnegative definite solution ΔM since $(A - \bar{B}\bar{A}\bar{B}^*, \bar{B})$ is controllable (implied by (A, B) controllable) and $(Q_0, A - \bar{B}\bar{A}\bar{B}^*)$ is detectable (implied by (Q, A) observable). Hence $M^{(1)} \geq M^{(0)}$ and $\delta(M_3^{(1)}) \geq \delta(M_3^{(0)})$.

Performing the next iteration yields: $M^{(2)} = \Phi(\delta(M_1^{(1)})) \geq \Phi(\delta(M_1^{(0)})) = M^{(1)}$, and $\delta(M_3^{(2)}) \geq \delta(M_3^{(1)})$. By induction both $M^{(n)}$ and $\delta(M_3^{(n)})$ are nondecreasing sequences.

To show convergence, we must show that $M^{(n)}$ is uniformly bounded above. By Theorem 4.1, $M(T) \rightarrow M''$, where $M'' \leq M'$ is a solution to the SSRE. Our desired solution can then be written as $M'' = \Phi(\delta(M_1''))$.

We claim that $M_1'' \geq \Lambda^{-1}R$. If $x(0) = 0$, the optimal cost for the infinite time-horizon problem is $[M_1''u(0), u(0)]$. The cost accrued prior to the first update of each processor is

$$[\Lambda^{-1}Ru(0), u(0)] = \sum_{i=1}^n \lambda_i^{-1} [Ri, u(0), I, u(0)]$$

where λ_i^{-1} is the expected value of the first update time of processor i . Hence $M_1'' \geq \Lambda^{-1}R$ since M_1'' describes the cost for a longer time interval. Hence also, $\delta(M_3^{(0)}) = \Lambda^{-1}R \leq \delta(M_1'')$. Therefore, $\delta(M_3^{(n)}) \leq \delta(M_1'')$ for all n , since $\delta(M_3^{(0)}) \leq \delta(M_1'')$, and Φ_3 is a nondecreasing function. Hence $M^{(n)} \leq M''$ for all n , and $M^{(n)}$ converges. Denote $M''' = \lim_{n \rightarrow \infty} M^{(n)}$. Then $M''' \leq M''$. The optimal cost using a controller based on M''' is $[M'''X(0), X(0)]$. But $M''' \geq M''$, since M'' yields the minimal cost $[M''X(0), X(0)]$. Hence, $M^{(n)}$ converges, and the limit is $\lim_{n \rightarrow \infty} M^{(n)} = M''$. \square

We need only iteratively solve for $\delta(M_1^{(n)})$, which reduces the number of parameters that need to converge. Let P be the solution to the steady-state Riccati equation

$$0 = A^*P + PA + Q - P\bar{B}\bar{A}P^{-1}\bar{B}^*P.$$

A better initial value for $\delta(M_1)$ can be found as follows. Take

$$M_1 = P + (A^*P + PA) / (\max_i \lambda_i)$$

$$M_2 = M_1\bar{B}\bar{A}^{-1} + 4^*M_1\bar{B}\bar{A}^{-2}$$

$$\delta(M_1) = \Lambda^{-1}\delta(R + M_2^*B + B^*M_2).$$

The computations can be accelerated by using an intermediate update for $\delta(M_1)$. Let

$$\delta(M_1^{(n+1/2)}) = \Lambda^{-1}\delta[R - (M_1^{(n)} - \delta(M_1^{(n)}))\bar{A}\delta(M_1^{(n)})^{-1} \cdot (M_1^{(n)} - \delta(M_1^{(n)})) + M_2^{(n)*}B + B^*M_2^{(n)}].$$

Then $M^{(n+1)}$ is obtained by solving the algebraic Riccati equation

$$0 = A^*M^{(n+1)} + M^{(n+1)}A + Q - M^{(n+1)}\bar{B}\bar{A}\delta(M_1^{(n+1/2)})^{-1}\bar{B}^*M^{(n+1)}.$$

$$K = \begin{bmatrix} -0.0562 & 0.4086 & 0.7610 & 2.278 & -0.0507 & 0.0479 & 0 & 0.0446 & 0.0083 \\ 0.0463 & 0.2132 & 0.4914 & 2.264 & -0.0422 & 0.0523 & 0.0143 & 0 & 0.0085 \\ 0.0162 & 0.0258 & 0.0756 & 0.2742 & -0.1450 & 0.1344 & 0.0017 & 0.0053 & 0 \end{bmatrix}.$$

V. EXAMPLE: THREE MASSES WITH SPRINGS AND DAMPERS

A system of three masses and a fixed object linked by springs and dampers is given by

$$\begin{aligned}\ddot{y}_1 &= 2(\dot{y}_2 - \dot{y}_1) + 10(y_2 - y_1) + u_1 \\ 10\ddot{y}_2 &= 2(\dot{y}_1 - \dot{y}_2) + 10(y_1 - y_2) + .5(\dot{y}_3 - \dot{y}_2) + (y_3 - y_2) + u_2 \\ 2\ddot{y}_3 &= .5(\dot{y}_2 - \dot{y}_3) + (y_2 - y_3) - 2\dot{y}_3 - 8y_3 + u_3\end{aligned}$$

where y_i is the displacement of mass i , and the control input u_i is a force on mass i . The augmented state vector is $X = [y_1, \dot{y}_1, y_2, \dot{y}_2, y_3, \dot{y}_3, u_1, u_2, u_3]^T$. The control signals u_1, u_2, u_3 are assigned to three asynchronous processors with rates $\lambda_1 = 15, \lambda_2 = 5, \lambda_3 = 3$. The optimal steady-state Poisson LQR controller for $Q = I, R = I$ is $v(t) = -KX(t)$ is found in the equation at the bottom of the previous page. The diagonal terms in the part of K that is multiplied by $u_i(t)$ are zero, hence the update value $v_i(t)$ does not depend on $u_i(t)$, but may depend on other components of $u(t)$.

If $u(0) = 0$, the cost is given by $[M_1 x(0), x(0)]$, and $Tr.M_1$ is a good figure of merit for our design. For the continuous time LQR controller, a good figure of merit is $Tr.P$, where P is the solution to the continuous time steady-state Riccati equation. For our system, $Tr.P = 35.88$ and $Tr.M_1 = 37.61$, an increase of less than 5%. The cost is increased due to sampling and uncertainty in the sampling times.

VI. CONCLUSION

We derived the optimal control for a Poisson LQR asynchronous multirate controller. The optimal control for the i th processor involved feedback of both the state and control signals from other processors. The optimal control gain can be found by an iterative algorithm.

On Solving Diophantine Equations by Real Matrix Manipulation

Manabu Yamada, Piao Chung Zun, and Yasuyuki Funahashi

Abstract—This note presents simple algorithms for obtaining the solutions of the Diophantine equation. Our methods can produce classes of all solutions with lower degree than a specified number. The previous algorithms involve some troublesome computations, e.g., the calculation of both the controllability indexes and the observability indexes or the solution of a pole assignment problem, etc. Our contribution is that our algorithm requires only basic matrix operations such as addition, subtraction, multiplication, and inversion of given real matrices. In addition, by solving simple linear equations, the class of all minimum degree solutions can be given. Therefore the computational efforts are reduced compared with previous algorithms.

I. INTRODUCTION

Consider the following problem: given three polynomial matrices, $D(s) \in \mathbb{R}[s]^{p \times p}$, $N(s) \in \mathbb{R}[s]^{p \times m}$, and $L(s) \in \mathbb{R}[s]^{p \times l}$, find polynomial matrices, $X(s) \in \mathbb{R}[s]^{p \times l}$ and $Y(s) \in \mathbb{R}[s]^{m \times l}$, such that

$$D(s)X(s) + N(s)Y(s) = L(s) \quad (1)$$

where $\mathbb{R}[s]^{p \times m}$ denotes a set of $p \times m$ polynomial matrices with real coefficients. We assume that $D(s)$ and $N(s)$ are left coprime and, without loss of generality, $D(s)$ is row-reduced [2, p. 68]. It is well-known that the former assumption ensures existence of solutions to (1) for arbitrary $L(s)$ [1]–[3]. Equation (1) is termed the Diophantine equation and plays an important role in many different aspects of linear system theory. Our interest is to develop a simple algorithm for obtaining solutions of the aforementioned problem, to which considerable attention has been paid during the last years [4]–[9].

The algorithms of [4]–[7] present the class of all solutions. Those of [4] and [9] provide the minimal degree solutions in terms of the rows of $Y(s)$ and the columns of $[X(s)^T, Y(s)^T]^T$, respectively, and left coprimeness of $D(s)$ and $N(s)$ is not required. However, their algorithms involve some troublesome computational efforts: the procedure in [4] requires controllability indexes and observability indexes of a realization of $D(s)^{-1}N(s)$ and the division of a polynomial matrix. The size of the matrix in [9], in which linearly

IEEE Log Number 9407022.

dependent columns are sought by a column-searching algorithm, is very large. The algorithms in [5] and [6] involve a solution of a pole assignment problem and determination of a real number so as to make a matrix nonsingular. The synthesis of [7] requires selection of some appropriate feedback matrices to make cyclic the realization of $D(s)^{-1}N(s)$ and calculation of inversion of a polynomial matrix.

This note presents a simple algorithm for obtaining the class of all solutions with lower degree than a specified number in terms of $Y(s)$. For the computational aspects, we have some advantages. The proposed procedure requires no aforementioned troublesome computation. Our algorithm is performed by only basic matrix operations such as addition, subtraction, multiplication, and inversion of given real matrices. In addition, by solving simple linear equations, the class of all solutions with the minimum degree in terms of the columns of $Y(s)$ can be also given. Thus, the computational efforts are reduced compared with previous algorithms.

II. PRELIMINARIES

Let $\delta_{r,i}[\cdot]$ denote the i th row degree, i.e., the highest degree of all entries of the i th row vector, of a polynomial matrix and let $\delta_{c,i}[\cdot]$ denote the i th column degree. Assume that $\delta_{c,i}[D(s)] > \delta_{c,i}[N(s)]$, $i = 1 \cdots p$. This assumption assures that $D(s)^{-1}N(s)$ is strictly proper [1, p. 385]. This will be removed in the Appendix in a similar way to [7]. Define

$$d_i = \delta_{c,i}[D(s)], \quad i = 1 \cdots p$$

$$S(s) = \text{diag}\{s^{d_1}, i = 1 \cdots p\}, \quad (2)$$

$$\Psi(s) = \text{block diag}\{[s^{d_i-1} \cdots s-1], i = 1 \cdots p\}, \quad (3)$$

and let $D_h \in \mathbb{R}^{n \times p}$ and $D_l \in \mathbb{R}^{n \times p}$ be the highest row degree coefficient matrix and the lower row degree coefficient one of $D(s)$, respectively. From the aforementioned assumption, $D(s)$ and $N(s)$ are expressed by

$$D(s) = S(s)D_h + \Psi(s)D_l, \quad (4)$$

$$N(s) = \Psi(s)N_l \quad (5)$$

where $N_l \in \mathbb{R}^{m \times m}$. When all entries of $L(s)$ are separated into polynomials with the lower row degree than that of $S(s)$ and the remaining ones, the lower degree polynomial matrix can be represented by $\Psi(s)L_l$ and the remaining one by $S(s)L_h(s)$, i.e.,

$$L(s) = S(s)L_h(s) + \Psi(s)L_l, \quad (6)$$

where $L_l \in \mathbb{R}^{n \times l}$ and $L_h(s) \in \mathbb{R}[s]^{n \times l}$. Let

$$J = \text{block diag}\{J_1, J_2, \cdots, J_p\}$$

$$J_i = \begin{bmatrix} 0 & 1 & & 0 \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ 0 & & & 0 \end{bmatrix} \in \mathbb{R}^{d_i \times d_i}, \quad i = 1 \cdots p$$

$$C_0 = \text{block diag}\{[1 \ 0 \ \cdots \ 0] \in \mathbb{R}^{d_i}, i = 1 \cdots p\}.$$

Since the row-reducedness of $D(s)$ means that D_h is nonsingular [2, p. 70], $D(s)^{-1}N(s)$ can be expressed by the following observer-form realization $\{A, B, C\}$ [1, p. 413]:

$$D(s)^{-1}N(s) = C(sI - A)^{-1}B \quad (7)$$

where

$$A = J - D_l D_h^{-1} C_0 \quad (8)$$

$$B = N_l \quad (9)$$

$$C = D_h^{-1} C_0. \quad (10)$$

III. MAIN RESULT

Lemma: Let

$$S^T(s)\bar{X}(s) + \Psi(s)\bar{Y}(s) = 0.$$

Then the class of all polynomial solutions $\bar{X}(s) \in \mathbb{R}[s]^l$, $\bar{Y}(s) \in \mathbb{R}[s]^{n \times l}$ of (11) are given by

$$\bar{X}(s) = C_0 Q(s), \quad (12)$$

$$\bar{Y}(s) = -(sI_n - J)Q(s) \quad (13)$$

where $Q(s) \in \mathbb{R}[s]^{n \times l}$ is an arbitrary polynomial matrix.

Proof: It can be easily checked that $(S(s), \Psi(s))$ is left coprime, $(C_0, sI_n - J)$ is right coprime, and

$$S(s)C_0 = \Psi(s)(sI_n - J).$$

Therefore (12) and (13) hold ([2, p. 186] and [3, p. 46]). \square

Let $\delta[\cdot]$ denote the highest degree of all entries of a polynomial matrix. Define

$$F(s) = L_l - D_l D_h^{-1} L_h(s),$$

$$f = \delta F(s).$$

Theorem: Given an integer $r \geq \max(f, n)$, define

$$W_r = [B \ AB \ \cdots \ A^r B] \in \mathbb{R}^{n \times m(r+1)}$$

$$F(s) = \sum_{i=0}^r F_i s^i \in \mathbb{R}[s]^{n \times l} \quad (14)$$

where $F_i \in \mathbb{R}^{n \times l}$. Then the class of all polynomial solutions $X(s) \in \mathbb{R}[s]^{n \times l}$ and $Y(s) \in \mathbb{R}[s]^{m \times l}$ of (1) with $\delta Y(s) \leq r$ are given by

$$X(s) = D_h^{-1} L_h(s) + U(s) + R(s)Z, \quad (15)$$

$$Y(s) = V(s) + P(s)Z \quad (16)$$

where $Z \in \mathbb{R}^{m(r+1) \times l}$ is an arbitrary real matrix and

$$U(s) = \sum_{i=0}^{r-1} U_i s^i \in \mathbb{R}[s]^{n \times l},$$

$$V(s) = \sum_{i=0}^r V_i s^i \in \mathbb{R}[s]^{m \times l},$$

$$R(s) = \sum_{i=0}^{r-1} R_i s^i \in \mathbb{R}[s]^{n \times m(r+1)},$$

$$P(s) = \sum_{i=0}^r P_i s^i \in \mathbb{R}[s]^{m \times m(r+1)}.$$

$$U_j = (A^j B)^T (W_r W_r^T)^{-1} \left(\sum_{i=0}^r A^i F_i \right) \in \mathbb{R}^{n \times l}, \quad j = 0 \cdots r$$

$$P_j = \left[\underbrace{0}_{m \times j} \ I_m \ 0 \right] - (A^j B)^T (W_r W_r^T)^{-1} W_r \in \mathbb{R}^{m \times m(r+1)},$$

$$U_j = C \left(\sum_{i=0}^{r-j-1} A^i F_{i+j+1} - \sum_{i=0}^{r-j-1} A^i B V_{i+j+1} \right) \in \mathbb{R}^{n \times l},$$

$$R_j = -C \sum_{i=0}^{r-j-1} A^i B P_{i+j+1} \in \mathbb{R}^{n \times m(r+1)}, \quad j = 0 \cdots r-1.$$

Proof: Substituting (4), (5), and (6) into (1) leads to

$$\begin{aligned} D(s)X(s) + N(s)Y(s) - L(s) \\ = S(s)\{D_h X(s) - L_h(s)\} \\ + \Psi(s)\{D_l X(s) + B Y(s) - L_l\} \\ = 0. \end{aligned} \quad (17)$$

From the Lemma, it follows that

$$\begin{aligned} X(s) &= D_h^{-1}\{L_h(s) + C_0 Q(s)\} \\ &= D_h^{-1} L_h(s) + C' Q(s) \end{aligned} \quad (18)$$

$$(sI_n - A)Q(s) + B Y(s) = F(s). \quad (19)$$

Letting

$$Q(s) = \sum_{i=0}^{r-1} Q_i s^i, \quad (20)$$

$$Y(s) = \sum_{i=0}^{r-1} Y_i s^i, \quad (21)$$

and substituting into (19), it follows that

$$\left. \begin{aligned} Q_{r-1} + B Y_r &= 0 \\ Q_{r-2} + B Y_{r-1} - A Q_{r-1} &= 0 \\ \vdots & \\ Q_{j-1} + B Y_j - A Q_j &= F_j \\ \vdots & \\ Q_0 + B Y_1 - A Q_1 &= F_1 \end{aligned} \right\} \quad (22)$$

$$B Y_0 - A Q_0 = F_0. \quad (23)$$

From (22)

$$\begin{aligned} Q_j &= \sum_{i=0}^{j-1} A^i F_{i+j+1} - \sum_{i=0}^{j-1} A^i B Y_{i+j+1} \in \mathbb{R}^{n \times l}, \\ 0 \leq j &\leq r-1. \end{aligned} \quad (24)$$

Substituting into (23) gives

$$W_r [Y_0^T \ Y_1^T \ \cdots \ Y_{r-1}^T]^T = \sum_{i=0}^{r-1} A^i F_i. \quad (25)$$

Since (A, B, C) is minimal [1, p. 439, Theorem 6.5-1], $W_r W_r^T$ is nonsingular. Hence, the general solution is given by

$$\begin{aligned} [Y_0^T \ Y_1^T \ \cdots \ Y_{r-1}^T]^T \\ = W_r^T (W_r W_r^T)^{-1} \sum_{i=0}^{r-1} A^i F_i + \{I_{m(r+1)} - W_r^T (W_r W_r^T)^{-1} W_r\} Z \\ = [Y_0^T \ Y_1^T \ \cdots \ Y_{r-1}^T]^T + [P_0^T \ P_1^T \ \cdots \ P_{r-1}^T]^T Z \end{aligned} \quad (26)$$

where $Z \in \mathbb{R}^{m(r+1) \times l}$ is arbitrary. Therefore, (16) holds. Substituting (24) and (26) into (18) gives (15). The proof is completed. \square

Remark: The theorem presents a simple algorithm for obtaining the class of all solutions with lower degree than a specified number $r+1$ in terms of $Y(s)$. The contribution of this algorithm is that the solutions can be computed easily by only basic matrix operations such as inversion of $W_r W_r^T$, whose size is $n \times n$, independent of a specified number r .

For a matrix M , let $[M]_j$ and $[M]_-$ be the j th column vector of M and a matrix satisfying

$$M[M]_- = M \quad (27)$$

respectively. $[M]_-$ is termed as the generalized inverse matrix of M . The solutions $\{X(s), Y(s)\}$ whose $\delta_i Y(s)$, $i = 1 \cdots l$ are minimum among all solutions of (1) are called the solutions with the minimum column degree in terms of $Y(s)$. The following corollary provides both the minimum possible number of r in the Theorem and the class of all solutions with the minimum column degree in terms of $Y(s)$.

Corollary: Let $f_j = \delta_{r_j} F(s)$ and

$$r_j^* = \min \left\{ k \geq 0 : \text{rank} \left[W_k, \sum_{i=0}^{l_j} A^i [F_i]_{i,j} \right] = \text{rank } W_k \right\}, \quad j = 1 \cdots l. \quad (28)$$

Given a set of integers $\{r_j, j = 1 \cdots l\}$ such that $r_j \geq r_j^*$, the class of all polynomial solutions $X(s) \in \mathbb{R}[s]^{n \times l}$ and $Y(s) \in \mathbb{R}[s]^{m \times l}$ of (1) with $\delta_i Y(s) \leq r_j, j = 1 \cdots l$ are given by

$$[X(s)]_{i,j} = D_h^{-1} [L_h(s)]_{i,j} + u_j^*(s) + R_j^*(s) z_j, \quad j = 1 \cdots l \quad (29)$$

$$[Y(s)]_{i,j} = v_j^*(s) + P_j^*(s) z_j, \quad j = 1 \cdots l \quad (30)$$

where $z_j \in \mathbb{R}^{m(r_j+1)}$, $j = 1 \cdots l$ are arbitrary real vectors and

$$u_j^*(s) = \sum_{i=0}^{\max(l_j, r_j)-1} u_{j,i}^* s^i \in \mathbb{R}[s]^n,$$

$$v_j^*(s) = \sum_{i=0}^{r_j} v_{j,i}^* s^i \in \mathbb{R}[s]^m,$$

$$R_j^*(s) = \sum_{i=0}^{\max(l_j, r_j)-1} R_{j,i}^* s^i \in \mathbb{R}[s]^{n \times m(r_j+1)},$$

$$P_j^*(s) = \sum_{i=0}^{r_j} P_{j,i}^* s^i \in \mathbb{R}[s]^{m \times m(r_j+1)}.$$

$$[(v_{j0}^*)^T (v_{j1}^*)^T \cdots (v_{j,r_j}^*)^T]^T = [W_{r_j}]_- \left(\sum_{i=0}^{l_j} A^i [F_i]_{i,j} \right) \in \mathbb{R}^n,$$

$$[(P_{j0}^*)^T (P_{j1}^*)^T \cdots (P_{j,r_j}^*)^T]^T = I_{m(r_j+1)} - [W_{r_j}]_- W_{r_j}^T \in \mathbb{R}^{m(r_j+1) \times m(r_j+1)}.$$

$$u_{j,i}^* = C' \left(\sum_{k=0}^{l_j-i-1} A^k [F_{i+k+1}]_{i,j} - \sum_{k=0}^{r_j-i-1} A^k B v_{j,i+k+1}^* \right) \in \mathbb{R}^n, \quad i = 0 \cdots \max(f_j, r_j) - 1,$$

$$R_{j,i}^* = -C' \sum_{k=0}^{l_j-i-1} A^k B P_{j,i+k+1}^* \in \mathbb{R}^{n \times m(r_j+1)}, \quad i = 0 \cdots \max(f_j, r_j) - 1.$$

With the choice of $\{r_j = r_j^*, j = 1 \cdots l\}$, (29) and (30) provide the class of all solutions with the minimum column degree in terms of $Y(s)$.

Proof. Without loss of generality, we consider the equations of the j th column in (18) and (19), i.e.,

$$[X(s)]_{i,j} = D_h^{-1} [L_h(s)]_{i,j} + C' [Q(s)]_{i,j}, \quad (31)$$

$$(sI_n - A)[Q(s)]_{i,j} + B[Y(s)]_{i,j} = [F(s)]_{i,j}. \quad (32)$$

Letting

$$[Q(s)]_{rj} = \sum_{i=0}^{\max(f_j, r_j)-1} q_{ji} s^i$$

$$[Y(s)]_{rj} = \sum_{i=0}^{r_j} y_{ji} s^i,$$

and substituting into (32), it follows that

$$q_{ji} = \sum_{k=0}^{f_j-i-1} A^k [F_{i+k+1}]_{rj} - \sum_{k=0}^{r_j-i-1} A^k B y_{j, i+k+1} \in \mathbf{R}^p,$$

$$i = 0 \cdots \max(f_j, r_j) - 1 \quad (33)$$

and

$$W_{rj} [y_{j0}^T \ y_{j1}^T \ \cdots \ y_{j, r_j}^T]^T = \sum_{i=0}^{f_j} A^i [F_i]_{rj}. \quad (34)$$

There exists a $[y_{j0}^T y_{j1}^T \cdots y_{j, r_j}^T]^T \in \mathbf{R}^{m(r_j+1)}$ satisfying (34) for a given number r_j if and only if

$$\text{rank} \left[W_{rj}, \sum_{i=0}^{f_j} A^i [F_i]_{rj} \right] = \text{rank} [W_{rj}]$$

[10, p. 29]. Then the class of all solutions satisfying (34) is given by

$$[y_{j0}^T \ y_{j1}^T \ \cdots \ y_{j, r_j}^T]^T$$

$$= [W_{rj}]^{-1} \left\{ \sum_{i=0}^{f_j} A^i [F_i]_{rj} \right\} + \{I_{m(r_j+1)} - [W_{rj}]^{-1} W_{rj}\} z_j$$

$$= [(y_{j0}^*)^T (y_{j1}^*)^T \cdots (y_{j, r_j}^*)^T]^T$$

$$+ [(P_{j0}^*)^T (P_{j1}^*)^T \cdots (P_{j, r_j}^*)^T]^T z_j \quad (35)$$

where $z_j \in \mathbf{R}^{m(r_j+1)}$, $j = 1 \cdots l$ are arbitrary real vectors. Hence, (30) holds. Substituting (33) and (35) into (31) leads to (29). \square

Remark: In [4] and [9], algorithms for the minimum degree solutions are proposed. The algorithm of [4] presents a solution in which the rows of $Y(s)$ has minimum degree. That of [9] results in a solution in which the columns of $[X(s)^T \ Y(s)^T]^T$ has minimal degree. Therefore, our algorithm proposes the minimum degree solution in a different sense from those of [4] and [9].

IV. NUMERICAL EXAMPLES

A. Example 1

Consider the following polynomial matrices.

$$D(s) = \begin{bmatrix} s+1 & s+2 \\ 0 & s+3 \end{bmatrix}, \quad N(s) = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix},$$

$$L(s) = I_2.$$

The observer-form realization of $D(s)^{-1}N(s)$ is given by

$$A = \begin{bmatrix} -1 & -1 \\ 0 & -3 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}.$$

We choose $r = n - 1 = 1$. Then

$$W = \begin{bmatrix} 0 & 1 & -1 & -2 \\ 1 & 1 & -3 & -3 \end{bmatrix}.$$

From the Theorem, the general solutions of (1) under the constraint of $\delta X(s) = 0$ and $\delta Y(s) \leq 1$ are shown in the equation found at the bottom of the page, where $Z \in \mathbf{R}^{1 \times 2}$ is arbitrary.

B. Example 2

In this example, we compare our algorithm with that of [9] from the viewpoint of the minimum degree solution.

Consider the following polynomial matrices.

$$D(s) = \begin{bmatrix} s^2 + s + 1 & s \\ s^2 & 2 \end{bmatrix}, \quad N(s) = \begin{bmatrix} s+1 & s^2 \\ s & s+1 \end{bmatrix},$$

$$L(s) = \begin{bmatrix} s^3 + 1 & s \\ 3s + 2 & s^2 + 1 \end{bmatrix}.$$

Thus, $D(s)$ and $N(s)$ are the same as those of example in [9]. By using the column searching algorithm of [9], the minimum degree solution is obtained as follows:

$$X(s) = \begin{bmatrix} 1 & 3 \\ s+1 & 4s+3 \end{bmatrix}, \quad Y(s) = \begin{bmatrix} -2s & -2s-3 \\ s & -5 \end{bmatrix}.$$

Second, our algorithm is applied. By our Corollary, we have $r_1^* = 0$ and $r_2^* = 1$. Then the class of all solutions with the minimum column degree in terms of $Y(s)$ is obtained as follows:

$$X(s) = \begin{bmatrix} -2 & -0.3 - 3z \\ s^2 - 2s - 1 & 1.1s^2 + 0.7s + 0.8 + (s^2 - 3s - 2)z \end{bmatrix},$$

$$Y(s) = \begin{bmatrix} 3 & (2s+3)(0.1+z) \\ 4 & -1.1s - 0.6 - (s-4)z \end{bmatrix},$$

where $z \in \mathbf{R}$ is arbitrary.

Therefore, it is seen that the algorithm of [9] can produce the solution with lower column degree in terms of $[X(s)^T \ Y(s)^T]^T$ than ours and, on the other hand, ours can produce the class of all lower column degree solutions in terms of $Y(s)$ than that of [9].

V. CONCLUSION

This note presents two results, the Theorem and Corollary. Theorem shows a simple algorithm for obtaining the class of all solutions with lower degree than a specified number $r+1$ in terms of $Y(s)$, where r is an arbitrary integer $r \geq \max(f, n)$. The contribution is that the class of solutions can be computed easily by only basic matrix operations such as inversion of W, W_r^T , whose size is $n \times n$, independent of a specified number r . Corollary provides the minimum possible number of r in the Theorem. So the class of all solutions with the minimum column degree in terms of $Y(s)$ can be also obtained. The necessary computation is a generalized inverse matrix of W_{rj} in the Corollary, that is simple linear equations of (27).

In also [4] and [9], simple methods are proposed. However, the procedure in [4] needs controllability indexes and observability indexes of a realization of $D(s)^{-1}N(s)$ and the division of a polynomial matrix. In [9], it is required to find l linearly dependent

$$X(s) = \begin{bmatrix} 0.5 & -0.4 \\ 0 & 0.3 \end{bmatrix} + \begin{bmatrix} 0.4 & -0.1 & 0.3 & -0.2 \\ -0.3 & -0.3 & -0.1 & -0.1 \end{bmatrix} Z$$

$$Y(s) = \begin{bmatrix} 0.5s - 0.5 & -0.4s + 0.3 \\ -0.5s + 0.5 & 0.1s - 0.2 \end{bmatrix} + \begin{bmatrix} 0.4s + 0.7 & -0.1s + 0.2 & 0.3s + 0.4 & -0.2s - 0.1 \\ -0.1s + 0.2 & 0.4s + 0.7 & -0.2s - 0.1 & 0.3s + 0.4 \end{bmatrix} Z$$

columns in a real matrix, whose size is $(N + K + 1)p \times \{(K + 1)p + (K + 2)l\}$, where

$$N = \max \{\delta D(s), \delta L(s)\},$$

$$K = \max [n, \delta L(s), \delta \{N(s) \text{adj } D(s)\}] \geq n.$$

Thus, the computational efforts of our algorithm are much reduced compared with the previous ones.

APPENDIX

In this Appendix, the assumption of $\delta_i D(s) > \delta_i N(s)$ $i = 1 \cdots p$, is removed. That is, we consider the case of $\delta_i D(s) \leq \delta_i N(s)$ for some i . In this case, $N(s)$ can be represented as follows [1]–[3]:

$$N(s) = D(s)Q_N(s) + R_N(s)$$

where $Q_N(s) \in \mathbb{R}[s]^{p \times m}$, $R_N(s) \in \mathbb{R}[s]^{p \times m}$, and $\delta_i D(s) > \delta_i R_N(s)$, $i = 1 \cdots p$. In particular, if $\delta_i D(s) \geq \delta_i N(s)$ for $i = 1 \cdots p$, i.e., $D(s)^{-1}N(s)$ is proper, then $N(s)$ can be represented by $N_h \in \mathbb{R}^{p \times m}$ and $N_l \in \mathbb{R}^{p \times m}$ as follows:

$$N(s) = S(s)N_h + \Psi(s)N_l.$$

Hence Q_N and $R_N(s)$ can be obtained easily as

$$Q_N = D_h^{-1}N_h,$$

$$R_N(s) = \Psi(s)(N_l - D_l D_h^{-1}N_h).$$

The theorem can provide polynomial solutions $X_N(s)$ and $Y_N(s)$ satisfying

$$D(s)X_N(s) + R_N(s)Y_N(s) = L(s).$$

Then, by using the $X_N(s)$ and $Y_N(s)$, polynomial solutions $X(s)$ and $Y(s)$ of (1) are given by

$$\begin{aligned} X(s) &= X_N(s)Q_N(s)Y_N(s), \\ Y(s) &= Y_N(s). \end{aligned}$$

This can be readily verified by substituting into (1) as follows:

$$\begin{aligned} D(s)X(s) + N(s)Y(s) &= D(s)\{X_N(s) - Q_N(s)Y_N(s)\} \\ &+ \{D(s)Q_N(s) + R_N(s)\}Y_N(s) \\ &= L(s). \end{aligned}$$

Nonlinear Versus Linear Control in the Absolute Stabilizability of Uncertain Systems with Structured Uncertainty

Andrey V. Savkin and Ian R. Petersen

Abstract—This note considers a stabilization problem for a class of uncertain linear systems containing structured uncertainty described by a certain Integral Quadratic Constraint. The notion of stabilizability considered is that of absolute stabilizability. The main result gives a necessary and sufficient condition for the absolute stabilizability of this class of uncertain systems in terms of the existence of a solution to a corresponding "diagonally scaled" H^∞ control problem. It follows from this result that absolute stabilizability via nonlinear control implies absolute stabilizability via linear control.

1. INTRODUCTION

In recent years, a number of results have appeared showing that certain classes of uncertain linear systems have the property that if they can be stabilized via a nonlinear controller, then they can also be stabilized via a linear controller; see [1]–[4]. These results are concerned with problems of robust stabilization in which the underlying uncertain system contains "unstructured" uncertainty. This note establishes a corresponding result for a class of uncertain linear system containing structured uncertainty. The uncertain systems under consideration allow for nonlinear, time-varying, dynamic, noncausal uncertainties. This class of uncertainties is described by an "Integral Quadratic Constraint" such as found in the work of Yakubovich; e.g., see [5], [6]. The notion of stability considered is that of absolute stability which can also be found in the work of Yakubovich; e.g., see [5], [6]. Our main result is a necessary and sufficient condition for the absolute stabilizability of such an uncertain system. This condition is given in terms of the existence of a solution to a corresponding "diagonally scaled" H^∞ control problem. A corollary to this result is the fact that if an uncertain system is absolutely stabilizable via nonlinear (but time-invariant) control, then it will be absolutely stabilizable via linear control.

The launching point for this note is a recent result developed in [7]. This result is a convexity result for a collection of integral quadratic forms defined over the space of solutions to a stable linear time-invariant system; a related result can also be found in [8]. The result of [7] is referred to as an "S-procedure." In this note, we extend the S-procedure result of [7] to a collection of integral functionals defined over the space of solutions to a nonlinear time-invariant system. This

IEEE Log Number 9407024.

enables us to consider the absolute stabilization problem for the case in which nonlinear controllers are allowed. We can summarize our approach as a three-step procedure for robust stabilization based on the following three steps:

- the S-procedure theorem;
- H^∞ control;
- the Kalman–Yakubovich–Popov (KYP) lemma.

The remaining sections of the note proceed as follows. Section II introduces the class of uncertain systems under consideration and defines the notion of absolute stabilizability. Section III presents our “S-procedure” for nonlinear systems. Section IV presents our main results.

II. PROBLEM STATEMENT

We consider a class of uncertain linear systems described by state equations of the form

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t) + \sum_{s=0}^k D_s \xi_s(t) \\ y(t) &= Cx(t) + \sum_{s=0}^k H_s \xi_s(t) \\ z_s(t) &= K_s x(t) + G_s u(t); \quad s = 0, 1, \dots, k\end{aligned}\quad (2.1)$$

where $x(t) \in \mathbf{R}^n$ is the state, $u(t) \in \mathbf{R}^m$ is the control input, $y(t) \in \mathbf{R}^l$ is the measured output, $z_0(t) \in \mathbf{R}^{h_0}, \dots, z_k(t) \in \mathbf{R}^{h_k}$ are the uncertainty outputs, and $\xi_0(t) \in \mathbf{R}^{r_0}, \dots, \xi_k(t) \in \mathbf{R}^{r_k}$ are the uncertainty inputs.

System Uncertainty: The uncertainty in the above system is described by equations of the form

$$\begin{aligned}\xi_0(t) &= \phi_0(t, z_0(\cdot)|_0^t), \xi_1(t) = \phi_1(t, z_1(\cdot)|_0^t), \\ &\dots, \xi_k(t) = \phi_k(t, z_k(\cdot)|_0^t)\end{aligned}\quad (2.2)$$

where the following Integral Quadratic Constraint is satisfied. This uncertainty description allows for nonlinear, time-varying, dynamic, noncasual uncertainties.

Definition 2.1: (Integral Quadratic Constraint; see [5], [6].) An uncertainty of the form (2.2) is an admissible uncertainty for the system (2.1) if the following conditions hold. Given any locally square integrable control input $u(\cdot)$ and any corresponding solution to (2.1), (2.2) defined on an existence interval¹ $(0, t_*)$, then there exists a sequence $\{t_i\}_{i=1}^\infty$ and constants $d_0 \geq 0, d_1 \geq 0, \dots, d_k \geq 0$ such that $t_i \rightarrow t_*, t_i \geq 0$ and

$$\int_0^{t_i} \|\xi_s(t)\|^2 dt \leq \int_0^{t_i} \|z_s(t)\|^2 dt + d_s, \quad \forall t_i \text{ and } \forall s = 0, 1, \dots, k. \quad (2.3)$$

Here $\|\cdot\|$ denotes the standard Euclidean norm. Also, note that t_* and t_i may be equal to infinity.

We will consider the problem of absolute stabilization via a nonlinear output feedback controller

$$\dot{x}_c(t) = \Lambda(x_c(t), y(t)); \quad u(t) = \lambda(x_c(t), y(t)) \quad (2.4)$$

where $\Lambda(\cdot, \cdot)$ and $\lambda(\cdot, \cdot)$ are continuous vector functions.

Notation: Throughout this note, $L_2[0, \infty)$ denotes the Hilbert space of square integrable vector valued functions defined on $[0, \infty)$. Also $\|\cdot\|_2$ denotes the corresponding $L_2[0, \infty)$ norm.

¹That is, t_* is the upper limit of the time interval over which the solution exists.

Definition 2.2: The uncertain system (2.1), (2.2) is absolutely stabilizable via nonlinear control if there exists a controller of the form (2.4) and a constant $c > 0$ such that

- for any initial condition $[x(0) \ x_c(0)] = [x_0 \ x_{c0}]$ and any admissible $\xi(\cdot) = [\xi_0(\cdot) \ \dots \ \xi_k(\cdot)] \in L_2[0, \infty)$, the closed-loop system defined by (2.1) and (2.4) has a unique solution which remains bounded on $[0, \infty)$;
- the closed-loop system (2.1), (2.4) with $\xi(t) \equiv 0$ is globally uniformly asymptotically stable;
- for any initial condition $[x(0) \ x_c(0)] = [x_0 \ x_{c0}]$ and any admissible $\xi(\cdot) = [\xi_0(\cdot) \ \dots \ \xi_k(\cdot)]$, then $[x(\cdot) \ x_c(\cdot) \ u(\cdot) \ \xi_0(\cdot) \ \dots \ \xi_k(\cdot)] \in L_2[0, \infty)$, (hence, $t_* = \infty$) and

$$\begin{aligned}\|x(\cdot)\|_2^2 + \|x_c(\cdot)\|_2^2 + \|u(\cdot)\|_2^2 + \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2 \\ \leq c \left[\|x(0)\|^2 + \|x_c(0)\|^2 + \sum_{s=0}^k d_s \right];\end{aligned}\quad (2.5)$$

- for any $\epsilon > 0$, there exists a $\delta > 0$ such that the following condition holds: for any vector $[x_0' \ x_{c0}']' \in \{h: \|h\| \leq \delta\}$ and any $\xi(\cdot) = [\xi_0(\cdot) \ \xi_1(\cdot) \ \dots \ \xi_k(\cdot)] \in L_2[0, \infty)$, let $[x^{(1)}(t)' \ x_c^{(1)}(t)']'$ be the corresponding solution to the closed-loop system defined by (2.1) and (2.3) with initial condition $x^{(1)}(0) = x_0, x_c^{(1)}(0) = x_{c0}$. Also let $[x^{(2)}(t)' \ x_c^{(2)}(t)']'$ denote the solution to the closed-loop system with initial condition $x^{(2)}(0) = 0, x_c^{(2)}(0) = 0$; then $\|x^{(1)}(\cdot) - x^{(2)}(\cdot)\|_2^2 + \|x_c^{(1)}(\cdot) - x_c^{(2)}(\cdot)\|_2^2 + \|u^{(1)}(\cdot) - u^{(2)}(\cdot)\|_2^2 < \epsilon$.

Note, condition iv) in the above definition is a technical stability condition which is needed in order to establish the results of this note.

Observation 2.1: If the uncertain system (2.1), (2.3) is absolutely stabilizable, then the corresponding closed-loop uncertain system (2.1), (2.3), (2.4) will have the property that $x(t) \rightarrow 0$ as $t \rightarrow \infty$ for any admissible uncertainty $\xi(\cdot)$. Indeed, since $\{x(\cdot), u(\cdot), \xi(\cdot)\} \in L_2[0, \infty)$, we can conclude from (2.1) that $\dot{x}(\cdot) \in L_2[0, \infty)$. However, using the fact that $x(\cdot) \in L_2[0, \infty)$ and $\dot{x}(\cdot) \in L_2[0, \infty)$, it now follows that $x(t) \rightarrow 0$ as $t \rightarrow \infty$. Furthermore, if the controller (2.4) is linear, then also $x_c(t) \rightarrow 0$ as $t \rightarrow \infty$.

III. S-PROCEDURE FOR NONLINEAR SYSTEMS

In this section, we present a result which extends the “S-Procedure” of [7]. The main result of this section applies to a nonlinear, time-invariant system of the form

$$\dot{h}(t) = \Pi(h(t), v(t)) \quad (3.1)$$

where $h(t) \in \mathbf{R}^n$ is the state and $v(t) \in \mathbf{R}^p$ is the input. Associated with the system (3.1) is the following set of functionals: $f_0(h(\cdot), v(\cdot)) = \int_0^\infty \nu_0(h(t), v(t)) dt, \dots, f_k(h(\cdot), v(\cdot)) = \int_0^\infty \nu_k(h(t), v(t)) dt$.

Assumptions: The system (3.1) and associated set of functionals satisfy the following assumptions.

- 1) The function $\Pi(\cdot, \cdot)$ is continuous.
- 2) For all $\{h(\cdot), v(\cdot)\} \in L_2[0, \infty)$, the quantities $f_0(h(\cdot), v(\cdot)), \dots, f_k(h(\cdot), v(\cdot))$ are finite.
- 3) Given any $\epsilon > 0$, there exists a constant $\delta > 0$ such that the following condition holds. For any input function $v_0(\cdot) \in L_2[0, \infty)$ and any $h_0 \in \{h_0 \in \mathbf{R}^n: \|h_0\| \leq \delta\}$, let $h_1(t)$ denote the corresponding solution to (3.1) with initial condition $h(0) = h_0$ and let $h_2(t)$ denote the corresponding solution to (3.1) with initial condition $h(0) = 0$. Then

both $h_1(t)$ and $h_2(t)$ are defined on $[0, \infty)$ and both functions belong to $L_2[0, \infty)$. Furthermore, $|f_s(h_1(\cdot), \psi(\cdot)) - f_s(h_2(\cdot), \psi(\cdot))| < \epsilon$ for $s = 0, 1, \dots, k$.

Note, Assumption 3.3) is a stability-type assumption on the system (3.1).

Notation: For the system (3.1) satisfying the above assumptions, we define $\Omega \subset L_2[0, \infty)$ as follows. Ω is the set of $\{h(\cdot), \psi(\cdot)\}$ such that $\psi(\cdot) \in L_2[0, \infty)$ and $h(\cdot)$ is the corresponding solution to (3.1) with $h(0) = 0$.

Theorem 3.1: Consider the system (3.1) and associated functionals and suppose the Assumptions 3.1)–3.3) are satisfied. If $f_0(h(\cdot), \psi(\cdot)) \geq 0$ for all $\{h(\cdot), \psi(\cdot)\} \in \Omega$ such that $f_1(h(\cdot), \psi(\cdot)) \geq 0, \dots, f_k(h(\cdot), \psi(\cdot)) \geq 0$, then there exist constants $\tau_0 \geq 0, \tau_1 \geq 0, \dots, \tau_k \geq 0$ such that $\sum_{s=0}^k \tau_s > 0$ and

$$\tau_0 f_0(h(\cdot), \psi(\cdot)) \geq \tau_1 f_1(h(\cdot), \psi(\cdot)) + \tau_2 f_2(h(\cdot), \psi(\cdot)) + \dots + \tau_k f_k(h(\cdot), \psi(\cdot)) \quad (3.2)$$

for all $\{h(\cdot), \psi(\cdot)\} \in \Omega$.

In order to prove this theorem, we will use the following convex analysis result (the proof of which was given in the preliminary version of this note [9]). However, we first introduce some notation.

Notation: Given $S \subset \mathbb{R}^n$ and $T \subset \mathbb{R}^n$ and $\lambda \in \mathbb{R}$, then $S + T := \{x + y: x \in S, y \in T\}$, $\lambda S := \{\lambda x: x \in S\}$, and $\text{cone}(S) := \{\alpha x: x \in S, \alpha \geq 0\}$. Also, $\text{cl}(S)$ denotes the closure of the set S .

Lemma 3.1: (See [9] for proof.) Consider a set $M \subset \mathbb{R}^{k+1}$ with the property that $a + b \in \text{cl}(M)$ for all $a, b \in M$. If $x_0 \geq 0$ for all vectors $[x_0 \dots x_k] \in M$ such that $x_1 \geq 0, \dots, x_k \geq 0$, then there exist constants $\tau_0 \geq 0, \dots, \tau_k \geq 0$ such that $\sum_{s=0}^k \tau_s > 0$ and $\tau_0 x_0 \geq \tau_1 x_1 + \tau_2 x_2 + \dots + \tau_k x_k$ for all $[x_0 \dots x_k] \in M$.

Proof of Theorem 3.1: Suppose $f_0(h(\cdot), \psi(\cdot)) \geq 0$ for all $\{h(\cdot), \psi(\cdot)\} \in \Omega$ such that $f_1(h(\cdot), \psi(\cdot)) \geq 0, \dots, f_k(h(\cdot), \psi(\cdot)) \geq 0$ and let $M := \{[f_0(h(\cdot), \psi(\cdot)) \dots f_k(h(\cdot), \psi(\cdot))] \in \mathbb{R}^{k+1}: \{h(\cdot), \psi(\cdot)\} \in \Omega\}$. It follows from the assumption on the set Ω that $x_0 \geq 0$ for all vectors $[x_0 \dots x_k] \in M$ such that $x_1 \geq 0, \dots, x_k \geq 0$. Now let $\{h_a(\cdot), \psi_a(\cdot)\} \in \Omega$ and $\{h_b(\cdot), \psi_b(\cdot)\} \in \Omega$ be given. Since $h_a(\cdot) \in L_2[0, \infty)$, there exists a sequence $\{T_i\}_{i=1}^\infty \subset \mathbb{R}$ such that $T_i \rightarrow \infty$ and $h_a(T_i) \rightarrow 0$. Now consider the corresponding sequence $\{h_i(\cdot), \psi_i(\cdot)\}_{i=1}^\infty \subset \Omega$, where

$$\psi_i(t) = \begin{cases} \psi_a(t) & t < T_i \\ \psi_b(t - T_i) & t \geq T_i. \end{cases}$$

We will establish that $f_s(h_i(\cdot), \psi_i(\cdot)) \rightarrow f_s(h_a(\cdot), \psi_a(\cdot)) + f_s(h_b(\cdot), \psi_b(\cdot))$ for $s = 0, 1, \dots, k$. Indeed, let $s \in \{0, 1, \dots, k\}$ be given and fix i . Now suppose $\hat{h}_i(\cdot)$ is the solution to (3.1) with input $\psi(\cdot) = \psi_b(\cdot)$ and $h(0) = h_a(T_i)$. It follows from the time invariance of the system (3.1) that $h_i(t) \equiv \hat{h}_i(t - T_i)$. Hence,

$$\begin{aligned} f_s(h_i(\cdot), \psi_i(\cdot)) &= \int_0^\infty \nu_s(h_i(t), \psi_i(t)) dt \\ &= \int_0^{T_i} \nu_s(h_a(t), \psi_a(t)) dt \\ &\quad + \int_{T_i}^\infty \nu_s(h_i(t), \psi_b(t - T_i)) dt \\ &= \int_0^{T_i} \nu_s(h_a(t), \psi_a(t)) dt + f_s(\hat{h}_i(t), \psi_b(t)). \end{aligned}$$

Using the fact that $h_a(T_i) \rightarrow 0$, Assumption 3.3 implies $f_s(\hat{h}_i(t), \psi_b(t)) \rightarrow f_s(h_b(\cdot), \psi_b(\cdot))$ as $i \rightarrow \infty$. Also, $\int_0^{T_i} \nu_s(h_a(t), \psi_a(t)) dt \rightarrow \int_0^\infty \nu_s(h_a(t), \psi_a(t)) dt \rightarrow f_s(h_a(\cdot), \psi_a(\cdot))$. Hence, $f_s(h_i(\cdot), \psi_i(\cdot)) \rightarrow f_s(h_a(\cdot), \psi_a(\cdot)) + f_s(h_b(\cdot), \psi_b(\cdot))$.

From the above, it follows that the set M has the property that $a + b \in \text{cl}(M)$ for all $a, b \in M$. Hence, Lemma 3.1 implies that there exist constants $\tau_0 \geq 0, \dots, \tau_k \geq 0$ such that $\sum_{s=0}^k \tau_s > 0$ and $\tau_0 x_0 \geq \tau_1 x_1 + \dots + \tau_k x_k$ for all $[x_0 \dots x_k] \in M$. That is, condition (3.2) is satisfied. \square

Note a feature of the proof of this result is to exploit the “fading memory” property of a nonlinear system satisfying Assumptions 3.1)–3.3).

IV. THE MAIN RESULT

Our main results require that the uncertain system (2.1), (2.3) satisfies the following assumptions.

Assumptions. Let matrices \hat{D} , \hat{K} , E_1 , and \hat{E}_2 be defined by $\hat{D} := [D_0 \dots D_k]$, $\hat{K} := [K'_0 \dots K'_k]'$, $\hat{E}_1 = \sum_{s=0}^k G'_s G_s$, $\hat{E}_2 = \sum_{s=0}^k H_s H'_s$. Then, we assume

- 4.1) The pair (A, B) is stabilizable.
- 4.2) The pair (A, K) is observable.
- 4.3) $E_1 > 0$.
- 4.4) The pair (A, C) is detectable.
- 4.5) The pair (A, D) is controllable.
- 4.6) $\hat{E}_2 > 0$.

Assumptions 4.1) and 4.4) are necessary for the “nominal system” to be stabilizable and hence can be made without loss of generality. Assumptions 4.2), 4.3), 4.5), and 4.6) are technical assumptions required to ensure that the underlying H^∞ problem is “nonsingular;” e.g., see [10]. This underlying “diagonally scaled” H^∞ control problem is defined as follows. Let $\tau_1 > 0, \dots, \tau_k > 0$ be given constants and consider the system

$$\dot{x}(t) = Ax(t) + Du(t) + Bw(t)$$

$$y(t) = Cx(t) + Dw(t)$$

$$z(t) = Kx(t) + Gu(t) \quad (4.1)$$

where $u(t)$ is the disturbance input, $z(t)$ is the controlled output,

$$K := \begin{bmatrix} K_0 \\ \sqrt{\tau_1} K_1 \\ \vdots \\ \sqrt{\tau_k} K_k \end{bmatrix}, \quad G := \begin{bmatrix} G_0 \\ \sqrt{\tau_1} G_1 \\ \vdots \\ \sqrt{\tau_k} G_k \end{bmatrix}.$$

$$H := [H_0 \quad \frac{1}{\sqrt{\tau_1}} H_1 \quad \dots \quad \frac{1}{\sqrt{\tau_k}} H_k],$$

$$D := [D_0 \quad \frac{1}{\sqrt{\tau_1}} D_1 \quad \dots \quad \frac{1}{\sqrt{\tau_k}} D_k]. \quad (4.2)$$

Also, consider the following induced norm bound condition:

$$J \triangleq \sup_{u(\cdot) \in L_2[0, \infty), \|u(\cdot)\|_2 = 1} \frac{\|z(\cdot)\|_2^2}{\|w(\cdot)\|_2^2} < 1. \quad (4.3)$$

The H^∞ control problem corresponding to the system (4.1) is said to have a solution if there exists a controller mapping from y to u such that the closed-loop system satisfies condition (4.3); e.g., see [10].

Theorem 4.1: Consider the uncertain system (2.1), (2.3) and suppose that Assumptions 4.1)–4.6) are satisfied. Then the following statements are equivalent.

- i) The uncertain system (2.1), (2.3) is absolutely stabilizable via a nonlinear controller of the form (2.4).

- ii) There exist constants $\tau_1 > 0, \dots, \tau_k > 0$ such that the H^∞ control problem (4.1), (4.3) is solved by a linear controller of the form

$$\dot{x}_c(t) = A_c x_c(t) + B_c y(t); \quad u(t) = C_c x_c(t). \quad (4.4)$$

If condition ii) holds, then the uncertain system (2.1), (2.3) is absolutely stabilizable via the linear controller (4.4).

In order to prove this result, we first establish the following preliminary lemma.

Lemma 4.1: Suppose that the uncertain system (2.1), (2.3) is absolutely stabilizable via a controller of the form (2.4). Then, there exist constants $\tau_1 > 0, \dots, \tau_k > 0$ and $\delta > 0$ such that

$$\begin{aligned} & \|z_0(\cdot)\|_2^2 - \|\xi_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s (\|z_s(\cdot)\|_2^2 - \|\xi_s(\cdot)\|_2^2) \\ & \leq -\delta \left(\|x(\cdot)\|_2^2 + \|x_c(\cdot)\|_2^2 + \|u(\cdot)\|_2^2 + \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2 \right) \end{aligned} \quad (4.5)$$

for all the solutions to the closed-loop system with the initial condition $x(0) = 0, x_c(0) = 0$.

Proof: Suppose that the uncertain system (2.1), (2.3) is absolutely stabilizable via a control of the form (2.4) and consider the corresponding closed-loop system. This system is described by the state equations

$$\begin{aligned} \dot{x}(t) &= A x(t) B \lambda(x_c(t), y(t)) + \sum_{s=0}^k D_s \xi_s(t) \\ \dot{x}_c(t) &= \Lambda(x_c(t), y(t)). \end{aligned} \quad (4.6)$$

This system can be regarded as a system of the form (3.1) with the associations: $h(t) \sim [x(t)' \ x_c(t)']'$ and $v(t) \sim \xi(t)$ where $\xi(\cdot) = [\xi_0(\cdot) \ \dots \ \xi_k(\cdot)]$. The corresponding set $\Omega \subset L_2[0, \infty)$ defined in Section III is as follows: Ω is the set of vector functions $\{x(\cdot), x_c(\cdot), \xi(\cdot)\}$ such that $\xi(\cdot) \in L_2[0, \infty)$ and $[x(\cdot)' \ x_c(\cdot)']'$ is the corresponding solution to (2.1), (2.4) with initial condition $x(0) = 0, x_c(0) = 0$. Also associated with the above system is the following set of integral functionals $f_0(\cdot), \dots, f_k(\cdot)$:

$$\begin{aligned} f_0(x(\cdot), x_c(\cdot), \xi(\cdot)) &:= \int_0^\infty (\|\xi_0(t)\|^2 - \|K_0 x(t) + G_0 \lambda(x_c(t), y(t))\|^2) dt \\ &\quad - \delta_0 \int_0^\infty (\|x(t)\|^2 + \|x_c(t)\|^2 \\ &\quad + \|\lambda(x_c(t), y(t))\|^2 + \|\xi(t)\|^2) dt \\ f_1(x(\cdot), x_c(\cdot), \xi(\cdot)) &:= \int_0^\infty (\|K_1 x(t) + G_1 \lambda(x_c(t), y(t))\|^2 - \|\xi_1(t)\|^2) dt \\ &\quad + \delta_0 \int_0^\infty (\|x(t)\|^2 + \|x_c(t)\|^2 \\ &\quad + \|\lambda(x_c(t), y(t))\|^2 + \|\xi(t)\|^2) dt \\ &\vdots \\ f_k(x(\cdot), x_c(\cdot), \xi(\cdot)) &:= \int_0^\infty (\|K_k x(t) + G_k \lambda(x_c(t), y(t))\|^2 - \|\xi_k(t)\|^2) dt \\ &\quad + \delta_0 (\|x(t)\|^2 + \|x_c(t)\|^2 \\ &\quad + \|\lambda(x_c(t), y(t))\|^2 + \|\xi(t)\|^2) dt \end{aligned} \quad (4.7)$$

where $\delta_0 = 1/2(k+1)c$ and c is as defined in (2.1). Definition 2.2. Thus, using (2.1), we can write

$$\begin{aligned} f_0(x(\cdot), x_c(\cdot), \xi(\cdot)) &= -(\|z_0(\cdot)\|_2^2 - \|\xi_0(\cdot)\|_2^2 \\ &\quad + \delta_0 (\|x(\cdot)\|_2^2 + \|x_c(\cdot)\|_2^2 \\ &\quad + \|\xi(\cdot)\|_2^2 + \|u(\cdot)\|_2^2)) \end{aligned}$$

$$\begin{aligned} f_1(x(\cdot), x_c(\cdot), \xi(\cdot)) &= \|z_1(\cdot)\|_2^2 - \|\xi_1(\cdot)\|_2^2 + \delta_0 (\|x(\cdot)\|_2^2 \\ &\quad + \|x_c(\cdot)\|_2^2 + \|\xi(\cdot)\|_2^2 + \|u(\cdot)\|_2^2) \end{aligned}$$

\vdots

$$\begin{aligned} f_k(x(\cdot), x_c(\cdot), \xi(\cdot)) &= \|z_k(\cdot)\|_2^2 - \|\xi_k(\cdot)\|_2^2 + \delta_0 (\|x(\cdot)\|_2^2 \\ &\quad + \|x_c(\cdot)\|_2^2 + \|\xi(\cdot)\|_2^2 + \|u(\cdot)\|_2^2). \end{aligned} \quad (4.8)$$

We wish to apply Theorem 3.1 to the system (4.6) and associated functionals (4.7). However, we must first show that Assumptions 3.1)–3.3) are satisfied. The satisfaction of Assumption 3.1 follows directly from the continuity of the functions $\Lambda(\cdot, \cdot)$ and $\lambda(\cdot, \cdot)$. Assumption 3.2 follows directly from part iii) of Definition 2.2 and equations (4.8). To establish Assumption 3.3, let $\epsilon > 0$ be given and consider an uncertainty input $\xi(\cdot) \in L_2[0, \infty)$. Let $[x^{(1)}(t)' \ x_c^{(1)}(t)']'$ be the corresponding solution to the closed-loop system (4.6) with $[x^{(1)}(0) \ x_c^{(1)}(0)]' = [x_0 \ x_{c0}]$, and let $[x^{(2)}(t)' \ x_c^{(2)}(t)']'$ be the solution to (4.6) with $x^{(2)}(0) = 0, x_c^{(2)}(0) = 0$. Now consider the quantity $|f_0(x^{(1)}(\cdot), x_c^{(1)}(\cdot), \xi(\cdot)) - f_0(x^{(2)}(\cdot), x_c^{(2)}(\cdot), \xi(\cdot))|$ where the functional $f_0(\cdot, \cdot, \cdot)$ is defined in (4.7). Using the triangle inequality and the Cauchy-Schwarz inequality, it follows that

$$\begin{aligned} & |f_0(x^{(1)}(\cdot), x_c^{(1)}(\cdot), \xi(\cdot)) - f_0(x^{(2)}(\cdot), x_c^{(2)}(\cdot), \xi(\cdot))| \\ & \leq \delta_0 (\|x^{(1)}(\cdot) - x^{(2)}(\cdot)\|_2^2 + \|x_c^{(1)}(\cdot) - x_c^{(2)}(\cdot)\|_2^2 \\ & \quad + \|u^{(1)}(\cdot) - u^{(2)}(\cdot)\|_2^2 + \|z_0^{(1)}(\cdot) - z_0^{(2)}(\cdot)\|_2^2) \\ & \leq \delta_0 (\|x^{(1)}(\cdot) - x^{(2)}(\cdot)\|_2^2 \\ & \quad + \|x_c^{(1)}(\cdot) - x_c^{(2)}(\cdot)\|_2^2 + \|u^{(1)}(\cdot) - u^{(2)}(\cdot)\|_2^2) \\ & \quad + \|[K_0 \ D_0]\|^2 (\|x^{(1)}(\cdot) - x^{(2)}(\cdot)\|_2^2 \\ & \quad + \|u^{(1)}(\cdot) - u^{(2)}(\cdot)\|_2^2) \end{aligned} \quad (4.9)$$

where $\|[K_0 \ D_0]\|$ denotes the induced matrix norm of the matrix $[K_0 \ D_0]$. However, it follows from part iv) of Definition 2.2 that given any $\epsilon > 0$, there exists a constant $\delta > 0$ such that $\|x_0\|^2 + \|x_{c0}\|^2 \leq \delta^2$ implies $\|x^{(1)}(\cdot) - x^{(2)}(\cdot)\|_2^2 + \|x_c^{(1)}(\cdot) - x_c^{(2)}(\cdot)\|_2^2 + \|u^{(1)}(\cdot) - u^{(2)}(\cdot)\|_2^2 < \epsilon$. Now using inequality (4.9), it follows that $|f_0(x^{(1)}(\cdot), x_c^{(1)}(\cdot), \xi(\cdot)) - f_0(x^{(2)}(\cdot), x_c^{(2)}(\cdot), \xi(\cdot))| \leq (\delta_0 + \|[K_0 \ D_0]\|)\epsilon$. A similar inequality holds for the quantities $|f_1(x^{(1)}(\cdot), x_c^{(1)}(\cdot), \xi(\cdot)) - f_1(x^{(2)}(\cdot), x_c^{(2)}(\cdot), \xi(\cdot))|, \dots, |f_k(x^{(1)}(\cdot), x_c^{(1)}(\cdot), \xi(\cdot)) - f_k(x^{(2)}(\cdot), x_c^{(2)}(\cdot), \xi(\cdot))|$. Thus, by choosing

$$\epsilon = \min \left\{ \frac{\epsilon}{(\delta_0 + \|[K_s \ D_s]\|)} : s = 0, 1, \dots, k \right\}$$

and letting δ equal the corresponding value of δ , it follows that Assumption 3.3 is satisfied.

To apply Theorem 3.1, we must show that $f_0(x(\cdot), x_c(\cdot), \xi(\cdot)) \geq 0$ for all $\{x(\cdot), x_c(\cdot), \xi(\cdot)\} \in \Omega$ such that $f_s(x(\cdot), x_c(\cdot), \xi(\cdot)) \geq 0$ for $s = 1, \dots, k$. If this is not true, then there exists a $\{x^0(\cdot), x_c^0(\cdot), \xi^0(\cdot)\} \in \Omega$ such that $f_0(x^0(\cdot), x_c^0(\cdot), \xi^0(\cdot)) < 0$ and

$f_s(x^0(\cdot), x^0(\cdot), \xi^0(\cdot)) \geq 0$ for $s = 1, \dots, k$. However, the input $\xi^0(\cdot)$ satisfies the integral quadratic constraint (2.3) with $t_r = \infty$ and $d_s = \delta_0(\|x^0(\cdot)\|_2^2 + \|x^0(\cdot)\|_2^2 + \|\xi^0(\cdot)\|_2^2 + \|u^0(\cdot)\|_2^2)$ for $s = 0, 1, \dots, k$. Hence, condition iii) of Definition 2.2 implies that

$$\begin{aligned} & \|x^0(\cdot)\|_2^2 + \|x^0(\cdot)\|_2^2 + \|\xi^0(\cdot)\|_2^2 + \|u^0(\cdot)\|_2^2 \\ & \leq c \sum_{s=0}^k \delta_0(\|x^0(\cdot)\|_2^2 + \|x^0(\cdot)\|_2^2 + \|\xi^0(\cdot)\|_2^2 + \|u^0(\cdot)\|_2^2) \\ & \leq c(k+1)\delta_0(\|x^0(\cdot)\|_2^2 + \|x^0(\cdot)\|_2^2 + \|\xi^0(\cdot)\|_2^2 + \|u^0(\cdot)\|_2^2) \\ & \leq \frac{1}{2}(\|x^0(\cdot)\|_2^2 + \|x^0(\cdot)\|_2^2 + \|\xi^0(\cdot)\|_2^2 + \|u^0(\cdot)\|_2^2) \end{aligned}$$

which yields the desired contradiction.

We now apply Theorem 3.1 to the system (4.6) and functionals (4.7). It follows that there exist $\tau_0 \geq 0, \tau_1 \geq 0, \dots, \tau_k \geq 0$ such that $\sum_{s=0}^k \tau_s > 0$ and $\tau_0 f_0(x(\cdot), x(\cdot), \xi(\cdot)) \geq \sum_{s=1}^k \tau_s f_s(x(\cdot), x(\cdot), \xi(\cdot))$ for all $\{x(\cdot), x(\cdot), \xi(\cdot)\} \in \Omega$. We now prove that $\tau_s > 0$ for all $s = 0, 1, \dots, k$. If we let $\delta := \delta_0 \sum_{s=0}^k \tau_s > 0$, then

$$\begin{aligned} & \sum_{s=0}^k \tau_s (\|z_s(\cdot)\|_2^2 - \|\xi_s(\cdot)\|_2^2) \\ & \leq -\delta \left(\|x(\cdot)\|_2^2 + \|x(\cdot)\|_2^2 + \|u(\cdot)\|_2^2 + \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2 \right) \quad (4.10) \end{aligned}$$

for all $\{x(\cdot), x(\cdot), \xi(\cdot)\} \in \Omega$. Now if $\tau_j = 0$ for some $j \in \{0, \dots, k\}$, then we can let $\xi_j(\cdot) \equiv 0$ for all $s \neq j$ and choose any nonzero $\xi_j(\cdot) \in L_2[0, \infty)$. However, this leads to a contradiction with (4.10) since the left side of (4.10) is nonnegative and the right side of (4.10) is negative. Therefore, we must have, $\tau_s > 0$ for $s = 0, 1, \dots, k$. Furthermore, observe that in this case, we may take $\tau_0 = 1$ without loss of generality. Moreover, with $\tau_0 = 1$, inequality (4.10) leads directly to (4.5). \square

Proof of Theorem 4.1: i) \Rightarrow ii) Consider an uncertain system (2.1), (2.3) satisfying Assumptions 4.1)–4.6) and suppose that the system is absolutely stabilizable via a nonlinear controller of the form (2.4). It follows from Lemma 4.1 that there exist constants $\tau_1 > 0, \tau_2 > 0, \dots, \tau_k > 0$ such that inequality (4.5) is satisfied. Now the system (2.1) is equivalent to the system (4.1) where $w(\cdot) = [\xi_0(\cdot), \sqrt{\tau_1}\xi_1(\cdot), \dots, \sqrt{\tau_k}\xi_k(\cdot)]$, $\hat{z}(\cdot) = [z_0(\cdot), \sqrt{\tau_1}z_1(\cdot), \dots, \sqrt{\tau_k}z_k(\cdot)]$, and the matrices D, K, G , and H are defined as in (4.2). It follows from inequality (4.5) that there exists a constant $\delta > 0$ such that if $x(0) = 0$, then $\|\hat{z}(\cdot)\|_2^2 - \|w(\cdot)\|_2^2 = \|z_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s \|z_s(\cdot)\|_2^2 - \|\xi_0(\cdot)\|_2^2 - \sum_{s=1}^k \tau_s \|\xi_s(\cdot)\|_2^2 \leq -\delta \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2$ for all $w(\cdot) \in L_2[0, \infty)$. Hence, there exists a $\delta_1 > 0$ such that if $x(0) = 0$, then $\|\hat{z}(\cdot)\|_2^2 - \|w(\cdot)\|_2^2 \leq -\delta_1(\|\xi_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s \|\xi_s(\cdot)\|_2^2) = -\delta_1 \|w(\cdot)\|_2^2$ for all $w(\cdot) \in L_2[0, \infty)$. That is, condition (4.3) is satisfied. Therefore, the controller (2.4) solves the standard H^∞ control problem (4.1), (4.3). Furthermore, it follows from Assumptions 4.1)–4.6) that the system (4.1) satisfies the assumptions required by Theorems 5.5 and 5.6 of [10]. Hence, using this theorem, it follows that there exists a linear controller of the form (4.4) which solves the H^∞ control problem (4.1), (4.3).

ii) \Rightarrow i) Consider an uncertain system (2.1), (2.3) satisfying Assumptions 4.1)–4.6) and suppose there exist constants $\tau_1 > 0, \tau_2 > 0, \dots, \tau_k > 0$ such that the H^∞ control problem (4.1), (4.3) is solved by a linear controller of the form (4.4). The closed-loop system defined by (4.1) and (4.4) is described by the state equations

$$\dot{\bar{x}}(t) = P\bar{x}(t) + Qw(t); \quad \hat{z}(t) = T\bar{x}(t) \quad (4.11)$$

where

$$\bar{x} = \begin{bmatrix} x \\ x_r \end{bmatrix}, \quad P = \begin{bmatrix} A & BC_r \\ B_r C & A_r \end{bmatrix},$$

$$Q = \begin{bmatrix} D \\ D_r H \end{bmatrix}, \quad T = [K \quad GC_r].$$

Since the controller (4.4) solves the H^∞ control problem mentioned above, the matrix P will be stable; e.g., see [10]. Also, if we apply the control (4.4) to the uncertain system (2.1), (2.3), the resulting closed-loop uncertain system can be described by the state equations (4.11) where $w(t)$ is now interpreted as an uncertainty input and $\hat{z}(t)$ is interpreted as an uncertainty output.

We will consider an uncertain system described by the state equations (4.11) where the uncertainty is required to satisfy the following integral quadratic constraint analogous to (2.3):

$$\int_0^{t_1} \|T\bar{x}(t)\|^2 dt \leq \int_0^{t_1} \|w(t)\|^2 dt + d \quad \forall t_1. \quad (4.12)$$

Note that any admissible uncertainty for the closed-loop uncertain system (2.1), (2.3), (4.4) will also be an admissible uncertainty for the uncertain system (4.11), (4.12) with $d = d_0 + \sum_{s=1}^k \tau_s d_s \geq 0$.

We will now show that the uncertain system (4.11), (4.12) is absolutely stable; see [5], [6] for the definition of absolute stability. First, recall that the system (4.11) is such that (4.3) is satisfied. Hence, there exists a constant $\delta_1 > 0$ such that if $x(0) = 0$, then $\|\hat{z}(\cdot)\|_2^2 - \|w(\cdot)\|_2^2 \leq -\delta_1 \|w(\cdot)\|_2^2$ for all $w(\cdot) \in L_2[0, \infty)$. Therefore, if $x(0) = 0$, then $\int_0^\infty (\|T\bar{x}(t)\|^2 - \|w(t)\|^2) dt \leq -\delta_1 \int_0^\infty \|w(t)\|^2 dt$ for all $w(\cdot) \in L_2[0, \infty)$. Furthermore, the stability of the matrix P implies that there exists a constant $\mu > 0$ such that if $x(0) = 0$, then $\int_0^\infty \|x(t)\|^2 dt \leq \mu \int_0^\infty \|w(t)\|^2 dt$ for all $w(\cdot) \in L_2[0, \infty)$. Hence, the constant $\delta = \delta_1/(\mu + 1) > 0$ is such that

$$\int_0^\infty (\|T\bar{x}(t)\|^2 - \|w(t)\|^2) dt \leq -\delta \int_0^\infty (\|x(t)\|^2 + \|w(t)\|^2) dt \quad (4.13)$$

for all $\{x(\cdot), w(\cdot)\} \in L_2[0, \infty)$ connected by (4.11) with $x(0) = 0$. Using a version of the KYP Lemma (Theorem 1 of [6]), condition (4.13) and the stability of the matrix P now imply that the uncertain system (4.11), (4.12) is absolutely stable.

We will now show that the closed-loop uncertain system (2.1), (2.3), (4.4) satisfies the conditions for absolute stabilizability given in Definition 2.2. Condition i) of Definition 2.2 follows directly from the absolute stability of the uncertain system (4.11), (4.12). Moreover, the absolute stability of this uncertain system implies that there exists a constant $c_0 > 0$ such that for any initial condition $x(0) = x_0$ and any admissible uncertainty input $w(\cdot)$ described by (4.12), then $\{x(\cdot), w(\cdot)\} \in L_2[0, \infty)$ and $\|x(\cdot)\|_2^2 + \|w(\cdot)\|_2^2 \leq c_0[\|x_0\|^2 + d]$. Now equation (4.4) implies that there exists a constant $c_1 > 0$ such that $\|u(t)\| \leq c_1 \|x(t)\|$ for all solutions to the closed-loop system (2.1), (4.4). Furthermore, given any admissible $\xi(\cdot) = [\xi_0(\cdot) \dots \xi_k(\cdot)]$ for the closed-loop system (2.1), (2.3), (4.4), then $w(\cdot) = [\xi_0(\cdot), \sqrt{\tau_1}\xi_1(\cdot), \dots, \sqrt{\tau_k}\xi_k(\cdot)]$ is an admissible uncertainty input for the uncertain system (4.11), (4.12) with $d = d_0 + \sum_{s=1}^k \tau_s d_s$. Hence, we can conclude that

$$\begin{aligned} & \frac{1}{2c_1} \|u(\cdot)\|_2^2 + \frac{1}{2} \|x(\cdot)\|_2^2 + \|\xi_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s \|\xi_s(\cdot)\|_2^2 \\ & \leq \|x(\cdot)\|_2^2 + \|\xi_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s \|\xi_s(\cdot)\|_2^2 \\ & \leq c_0 \left[\|x_0\|^2 + d_0 + \sum_{s=1}^k \tau_s d_s \right]. \quad (4.14) \end{aligned}$$

However, it is straightforward to verify that there exist constants $\sigma_1 > 0$ and $\sigma_2 > 0$ such that we can write $\sigma_1(\|u(\cdot)\|_2^2 + \|x(\cdot)\|_2^2 + \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2) \leq (1/2\sigma_1)\|u(\cdot)\|_2^2 + \frac{1}{2}\|x(\cdot)\|_2^2 + \|\xi_0(\cdot)\|_2^2 + \sum_{s=1}^k \tau_s \|\xi_s(\cdot)\|_2^2$, and moreover, $c_0[\|x_0\|^2 + d_0 + \sum_{s=1}^k \tau_s d_s] \leq \sigma_2[\|x_0\|^2 + \sum_{s=0}^k d_s]$. Hence, by combining these inequalities with (4.14), it follows that $\|u(\cdot)\|_2^2 + \|x(\cdot)\|_2^2 + \sum_{s=0}^k \|\xi_s(\cdot)\|_2^2 \leq \sigma_2/\sigma_1[\|x_0\|^2 + \sum_{s=0}^k d_s]$. That is, condition iii) of Definition 2.2 is satisfied. Conditions ii) and iv) of Definition 2.2 follows directly from the stability of the matrix P . Thus, we can now conclude that the system (2.1), (2.3) is absolutely stabilizable via the control (4.4). \square

Remark: The above theorem gives a necessary and sufficient condition for absolute stabilizability in terms of the solution to a corresponding H^∞ control problem. It is well known that such an H^∞ control problem can be solved in terms of two algebraic Riccati equations; e.g., see [10].

The following corollary is an immediate consequence of the above theorem.

Corollary 4.1: If the uncertain system (2.1), (2.3) satisfies Assumptions 4.1)–4.6) and is absolutely stabilizable via nonlinear control, then it will be absolutely stabilizable via a linear controller of the form (4.4).

A Linear Algebraic Framework for Dynamic Feedback Linearization

E. Aranda-Bricaire, C. H. Moog, and J.-B. Pomet

Abstract—To any accessible nonlinear system we associate a set of infinitesimal Brunovsky form. This gives an algebraic criterion for strong accessibility as well as a generalization of Kronecker controllability indices. An output function which defines a right-invertible system without zero dynamics is shown to exist if and only if the basis of the Brunovsky form can be transformed into a system of exact differential forms. This is equivalent to the system being differentially flat and hence constitutes a necessary and sufficient condition for dynamic feedback linearizability.

1. INTRODUCTION

The problem of exact linearization of a nonlinear system using static state feedback was solved in [18] and [22]. It can be shown that this problem is linked with the classification of functions (or exact one-forms) with respect to their relative degree [8]. When the linearization problem can not be solved using static state feedback, it is appealing to try to solve it using dynamic state feedback. This note emphasizes the links between this new problem and the classification of (non necessarily exact) one-forms with respect to their relative degree. The dynamic feedback linearization problem was stated in its full generality for the first time in [6]: given a nonlinear control system

$$\Sigma: \dot{x} = f(x) + g(x)u \quad (1)$$

where $x \in R^n$, $u \in R^m$, find a dynamic compensator

$$C: \begin{cases} \dot{u} = \alpha(x, \xi) + \beta(x, \xi)v \\ \xi = \gamma(x, \xi) + \delta(x, \xi)v \end{cases} \quad (2)$$

and an extended set of coordinates $z = \alpha(x, \xi)$ in which the extended system reads as a controllable linear one. Relying upon the differential geometric approach, sufficient conditions and necessary conditions have been given in [7]. In some particular cases, necessary and sufficient conditions are given there. A less general formulation of the dynamic linearization problem is as follows. Consider a nonlinear system where the output $y = h(x)$, $y \in R^m$, has been specified. If the system is right-invertible, it is always possible to construct a dynamic compensator in such a way that noninteracting control is achieved [10], [26]. The standard decoupling feedback provides also input–output linearization and if, in addition, the system has the property of having no zero dynamics, then it actually solves the dynamic linearization problem [19], [21]. Thus, the existence of such an output function is a sufficient condition for dynamic linearizability.

In [12], [13], and [24], the notions of linearizing output and endogeneous feedback were introduced. A linearizing output is a system of functions φ_i of x, u, \dot{u}, \dots which are differentially

independent and such that both x and u can be expressed as functions of the φ 's and their time derivatives. Existence of a linearizing output is called differential flatness of the system. A dynamic compensator of the form (2) such that ξ can be expressed as a function of x, u, \dot{u}, \dots , is called endogeneous. flatness is equivalent to dynamic linearizability by endogeneous feedback. Furthermore, recent results [14], [15] show that no system is linearizable by nonendogeneous feedback without being flat. An equivalence relation between systems may be defined such that differential flatness is equivalence to a linear system. This equivalence corresponds to transformations by endogeneous feedback.

In [23], the notion of a dynamic equivalence has been defined in terms of D -algebras. A system is equivalent to a controllable linear system if and only if its associated D -algebra is free. The set of generators of this D -algebra plays the role of linearizing output.

The goal of the present note is to characterize the existence of these linearizing outputs depending on x, u, \dot{u}, \dots , defined in a new algebraic approach which can be recovered from the early notions of zero dynamics and infinite zero structure [9], [19], [20], [26]. This characterization is equivalent to the system's property of being differentially flat, and hence constitutes, from the results in [14] and [15], a necessary and sufficient condition for dynamic feedback linearizability.

It will be shown that to any nonlinear system, one can associate a so-called infinitesimal Brunovsky form which may be viewed as a time-varying Brunovsky form of the first-order approximation of Σ [11]. The construction of this Brunovsky form provides an accessibility criterion, as well as a generalization of linear Kronecker indices. This form singles out a family of m elements of the formal vector space of differential forms, and it is shown that a linearizing output exists if, and only if, this family can be transformed into a system of exact one-forms via some invertible transformation. A preliminary version of this work was presented in [28], where the infinitesimal Brunovsky form was defined (it was called nonexact instead of infinitesimal), and was shown to provide a tool to characterize linearizing outputs in the sense of [12], [13], [24]. Let us also mention that a more "differential geometric" presentation of the present material may be found in [2] and [29].

Section II is devoted to some preliminaries from [9], and to a problem statement of dynamic linearization in terms of the infinite zero structure, as in [19]. The infinitesimal Brunovsky form is introduced in Section III with an algorithmic construction. An accessibility criterion is given which involves purely algebraic computations. In Section IV, existence of a linearizing output is characterized in terms of the infinitesimal Brunovsky form. The above theory is illustrated in Section V by the study of various particular cases. Concluding remarks are offered in Section VI.

II. PRELIMINARIES

A. The Infinite Zero Structure [9], [26]

Consider the nonlinear control system Σ , where $f(\cdot)$ and the columns of $g(\cdot)$ are meromorphic vector fields. Throughout the note it is assumed that $\text{rank } g(x) = m$. Let \mathcal{K} denote the field of meromorphic functions of x, u, \dot{u}, \dots . The time derivative of a function $\varphi \in \mathcal{K}$ is defined by

$$\frac{d}{dt}\varphi = \dot{\varphi} = \frac{\partial \varphi}{\partial x}(f(x) + g(x)u) + \sum_{j \geq 0} \frac{\partial \varphi}{\partial u^{(j)}} u^{(j+1)}.$$

Clearly, \mathcal{K} is closed under time-differentiation. Let \mathcal{E} denote the \mathcal{K} -vector space spanned by $dx, du, d\dot{u}, \dots$. The elements of \mathcal{E} are called

differential forms of degree one, or simply one-forms. d/dt induces a derivation on \mathcal{E} in the following way $d/dt: \omega = \sum_j a_j dv_j \mapsto \dot{\omega} = \sum_j (\dot{a}_j dv_j + a_j d\dot{v}_j)$. The relative degree of a one-form $\omega \in \text{span}_{\mathcal{K}}\{dx\}$ is defined as the smallest integer r such that $\omega^{(r)} \notin \text{span}_{\mathcal{K}}\{dx\}$. If such an integer does not exist, set $r = \infty$.

Now, consider the system Σ and suppose that the output function $y = h(x)$, $y \in \mathbb{R}^m$, has been specified. Introduce the chain of subspaces $\mathcal{E}_0 \subset \mathcal{E}_1 \subset \dots \subset \mathcal{E}_n$ of \mathcal{E} , defined by

$$\mathcal{E}_k := \text{span}_{\mathcal{K}}\{dx, dy, \dots, dy^{(k)}\}. \quad (3)$$

The number of zeros at infinity of order less than or equal to k , for $1 \leq k \leq n$, is

$$\sigma_k = \dim \frac{\mathcal{E}_k}{\mathcal{E}_{k-1}}. \quad (4)$$

The infinite zero structure can be given either by the list $\{\sigma_k\}$ or by the list $\{n'_i\}$ of the orders of the zeros at infinity. Σ is said to be (right) invertible if $\sigma_n = m$. Following [9], one has the following.

Lemma 2.1: Assume that Σ is invertible. Let $\mathcal{X} := \text{span}_{\mathcal{K}}\{dx\}$, $\mathcal{Y} := \text{span}_{\mathcal{K}}\{dy^{(k)}, k \geq 0\}$. Then $\dim(\mathcal{X} \cap \mathcal{Y}) = \Sigma, n'_i$.

Remark 2.2: Note that although \mathcal{Y} is, in general, infinite dimensional, the intersection of subspaces $\mathcal{X} \cap \mathcal{Y}$ is, at most, of dimension n . The subspace $\mathcal{X} \cap \mathcal{Y}$ has been first considered in [5] for studying minimality in dynamic decoupling.

B. Dynamic Feedback Linearization Problem Statement

Any nonlinear system with outputs and which is right-invertible can be fully linearized whenever it has no zero dynamics, in the sense of the dynamics of the reduced inverse system [20]. Thus, the absence of zero dynamics is a sufficient condition for dynamic feedback linearization [19], [21]. This is equivalent to $\Sigma, n'_i = n$. This yields (more precisely) the following.

Problem Statement 1: Given Σ , find, if possible, an m -dimensional output function $y = h(x)$ such that the system is right-invertible and $\Sigma, n'_i = n$. ■

Solvability of this problem is not necessary for dynamic feedback linearizability. A more general approach to the dynamic feedback linearization problem, which originates in [12], [13], [24], where it is instrumental to define differential flatness, consists of allowing the output function to explicitly depend on the input u as well as on a finite number, say, $\nu - 1$, of its time derivatives. From Lemma 2.1, this situation may be stated as the existence of an m -dimensional output function $y = h(x, u, \dots, u^{(\nu-1)})$ such that the system is right-invertible and $\dim(\mathcal{X}_\nu \cap \mathcal{Y}) = n + m\nu$, where $\mathcal{X}_\nu := \text{span}_{\mathcal{K}}\{dx, du, \dots, du^{(\nu-1)}\}$. For square invertible systems, one has $\mathcal{X}_\nu + \mathcal{Y} = \mathcal{X} + \mathcal{Y}$ and consequently $\dim(\mathcal{X}_\nu \cap \mathcal{Y}) = \dim(\mathcal{X} \cap \mathcal{Y}) + m\nu$. So, the more general problem is stated as follows.

Problem Statement 2: Given Σ , find, if possible, an integer ν and an m -dimensional output function $y = h(x, u, \dots, u^{(\nu-1)})$ such that the system is right-invertible and

$$\dim(\mathcal{X} \cap \mathcal{Y}) = n. \quad (5)$$

If such an output exists, it is called a *linearizing output*. ■

C. Differential Flatness

In [12], [13], and [24], the notions of linearizing output, differential flatness, endogeneous and exogeneous feedback were introduced. In [12] and [13], this is done within a differential algebraic framework, whereas in [24] the analytic case is also considered.

Roughly speaking, a linearizing output [12], [13] is a system of differentially independent functions φ , of x, u, \dot{u}, \dots , such that x, u

can in turn be expressed as functions of the φ 's and a finite number of their time derivatives. This definition is equivalent to the one in Problem Statement 2 because condition (5) means that one is able to recover the variables x, u as functions of the outputs y , and their time derivatives, and on the other hand, right invertibility ensures that the outputs y are differentially independent in the sense that they do not satisfy any differential equation independent of u . We refer the reader to [16] for an exhaustive discussion of differential flatness and its link with an equivalence relation between systems.

A system Σ is said to be differentially flat (or simply flat) if it admits a system of linearizing outputs. It is proved in [12], [13] and [24] that differential flatness for a system Σ is equivalent to linearizability via a dynamic compensator C which has the property of being endogeneous (this may be defined as the possibility to express the variables ξ as functions of $x, u, u^{(1)}, \dots$). Recent results [14], [15] show that flatness is in fact equivalent to dynamic linearizability without any restriction on the nature of compensators.

III. THE INFINITESIMAL BRUNOVSKY FORM

A. A Flag for the Differential Vector Space \mathcal{E}

We shall construct a sequence of subspaces of \mathcal{E} in the following manner. Define

$$\mathcal{H}_0 = \text{span}_{\mathcal{K}} \{dx, du\}$$

$$\mathcal{H}_k = \{ \omega \in \mathcal{H}_{k-1} \mid \omega \in \mathcal{H}_{k-1} \} \quad (6)$$

It is clear that $\mathcal{E} \supset \mathcal{H}_0 \supset \mathcal{H}_1 \supset \mathcal{H}_2 \supset \dots$ and that at the first step the above induction yields $\mathcal{H}_1 = \text{span}_{\mathcal{K}} \{dx\}$. Proposition 3.1 is a simple consequence of the construction. Feedback invariance comes from the fact that the relative degree of a one-form is obviously invariant under regular static state feedback. Existence of the integer l comes from the fact that each \mathcal{H}_k is a finite dimensional \mathcal{K} -vector space so that at each step either its dimension decreases or $\mathcal{H}_{k+1} = \mathcal{H}_k$.

Proposition 3.1 \mathcal{H}_k is the space of one-forms which have relative degree greater than or equal to k . Both the subspaces \mathcal{H}_k and the integers $\rho_k = \dim \mathcal{H}_k$ are invariant under regular static state feedback. There exists an integer $k^* > 0$ such that $\mathcal{H}_{k+1} = \mathcal{H}_k$ for $k \geq k^*$.

The following algorithm allows us to explicitly construct bases for the subspaces \mathcal{H}_k .

Step 1 Take $\{dx_1, \dots, dx_{l_1}, du_1, \dots, du_{l_2}\} \cup \{dx_1, \dots, dx_{l_1}\}$ as bases of \mathcal{H}_0 and \mathcal{H}_1 .

Step $k+1$ Suppose that $\{\eta_1, \dots, \eta_{l_{k-1}}, \mu_1, \dots, \mu_{l_k}\} \cup \{\eta_1, \dots, \eta_{l_{k-1}}\}$ are bases respectively of \mathcal{H}_{k-1} and \mathcal{H}_k and let us construct a basis for \mathcal{H}_{k+1} . The elements of \mathcal{H}_{k+1} are the one-forms $\omega \in \mathcal{H}_k$ such that $\omega \in \mathcal{H}_k$. Let $\omega = \sum_i \lambda_i \eta_i \in \mathcal{H}_k$ then $\omega = \sum_i (\lambda_i \eta_i + \lambda_j \eta_j)$. It is clear that $\omega \in \mathcal{H}_k$ if and only if $\sum_i \lambda_i \eta_i \in \mathcal{H}_k$. Now note that since $\eta_i \in \mathcal{H}_k$, η_j must be in \mathcal{H}_{k-1} so $\sum_i \lambda_i \eta_i$ may be written in the following form

$$\sum_i \lambda_i \eta_i = \sum_i \lambda_i \left(\sum_j \sigma_{ij} \eta_j + \sum_j \tau_{ij} \mu_j \right)$$

Thus $\omega \in \mathcal{H}_k$ if and only if the coefficients λ_j satisfy the following system of linear equations

$$\sum_j \tau_{ij} \lambda_j = 0 \quad 1 \leq i \leq \rho_{k-1} - \rho_k \quad (7)$$

This system of equations has $\rho_k - \rho$ linearly independent solutions being the rank of the matrix $[\tau_{ij}]$. Thus $\dim \mathcal{H}_{k+1}$ can be computed as

$$\alpha_k = \sum_{i=1}^{\rho_k} \lambda_i \eta_i \quad 1 \leq k \leq l$$

where $(\lambda_1', \dots, \lambda_{\rho_k}')^T$ are the ρ_{k+1} independent solutions of (7). The algorithm stops after a finite number k^* of steps when $\rho_{k+1} = 0$. In fact it is not difficult to show that $k^* \leq n - m + 1$.

Remark 3.2 In general the subspaces \mathcal{H}_k may depend on x, u in the following sense: the elements α built using the above algorithm can be written as linear combinations of dx, du and the coefficients being functions of $x, u, u^{(1)}, \dots$. However, a careful inspection of the construction shows that at the l th step these coefficients may be chosen to depend at most on u and its first $k-2$ time derivatives.

B. Accessibility Criteria

Proposition 3.3

1) \mathcal{H}_∞ is the largest subspace of $\mathcal{H}_l = \text{span}_{\mathcal{K}} \{dx, du\}$ which is invariant under time differentiation. It is also for any $k \geq 1$ the largest subspace of $\mathcal{H}_{l-1} = \text{span}_{\mathcal{K}} \{dx, du^{(1)}, \dots, du^{(k)}\}$ which is invariant under time differentiation.

2) Let $\{\alpha_1, \dots, \alpha_{l_\infty}\}$ be a basis for \mathcal{H}_∞ . Then the Frobenius condition $d\alpha_i \wedge \alpha_1 \wedge \dots \wedge \alpha_{l_\infty} = 0$, $1 \leq i \leq \rho_\infty$ is satisfied.

Proof Point 1 is a consequence of the construction (it is clear that starting from \mathcal{H}_{l-1} instead of \mathcal{H}_l in (6) one finds \mathcal{H}_∞ after k steps). The proof of point 2 is given in the Appendix. ■

In point 2 of Proposition 3.3 \wedge indicates the exterior product of differential forms. These conditions imply integrability of the Pfaffian system $\{\alpha_1, \dots, \alpha_{l_\infty}\}$ around regular points according to the dual version of Frobenius theorem. The reader who is not familiar with these matters is referred to [1].

Subspace \mathcal{H}_∞ may be interpreted as a codistribution on $\mathbb{R}^n \times \mathbb{R}^{m-1}$ where $k-1$ is the maximum number of input time derivatives necessary to write a basis of \mathcal{H}_∞ . Proposition 3.3 implies that this codistribution is locally integrable around any point where it has constant rank. This implies that \mathcal{H}_∞ is locally spanned by ρ_∞ exact one-forms $dx_1, \dots, dx_{l_\infty}$ where x_1, \dots, x_{l_∞} are functions defined around such regular points. These functions do not depend on u and its time derivatives because $\mathcal{H}_\infty \subset \text{span}_{\mathcal{K}} \{dx\}$ so \mathcal{H}_∞ may be interpreted as a codistribution on \mathbb{R}^n . Since for a function $v(x)$, $dv \in \mathcal{H}_\infty$ is equivalent to v being constant along all the vector fields $\text{ad}_j^{l_k}(f)$ with $j \geq 0$ and g_k the control vector fields (i.e. to be constant along the strong accessibility distribution) \mathcal{H}_∞ is around regular points the annihilator of the strong accessibility distribution. This leads to the following

Proposition 3.4 (Accessibility Criteria) The following statements are equivalent

- 1) System Σ satisfies the strong accessibility rank condition
- 2) Any nonzero one-form has finite relative degree
- 3) $\mathcal{H}_\infty = \{0\}$

Proposition 3.4 is one key result of this note since it allows the following construction which we then relate to linearizing outputs if these exist.

C. The Infinitesimal Brunovsky Form

Theorem 3.5 Suppose $\mathcal{H}_\infty = \{0\}$. There exists a list of integers $\{r_1, \dots, r_l\}$ invariant under regular static state feedback and m one-forms $\omega_1, \dots, \omega_m$ with relative degrees r_1, \dots, r_l such that

- 1) $\text{span}_\Lambda \{\omega_i^{(j)}, 1 \leq i \leq m, 0 \leq j \leq r_i - 1\} = \text{span}_\Lambda \{dx\}$;
 - 2) $\text{span}_\Lambda \{\omega_i^{(j)}, 1 \leq i \leq m, 0 \leq j \leq r_i\} = \text{span}_\Lambda \{dx, du\}$;
 - 3) the forms $\{\omega_i^{(j)}, 1 \leq i \leq m, j \geq 0\}$ are linearly independent.
- In particular, $\sum_{i=1}^m r_i = n$.

Proof: Let \mathcal{W}_k be a basis for \mathcal{H}_k . By definition, \mathcal{W}_k and $\dot{\mathcal{W}}_k$ are in \mathcal{H}_{k+1} . Note that \mathcal{W}_k and $\dot{\mathcal{W}}_k$ are linearly independent. For, let $\mathcal{W}_k = \{\eta_1, \dots, \eta_{p_k}\}$ —then $\dot{\mathcal{W}}_k = \{\dot{\eta}_1, \dots, \dot{\eta}_{p_k}\}$ —and suppose that there exist some coefficients $\{\lambda_i, \mu_i\}$ such that $\sum_i (\lambda_i \eta_i + \mu_i \dot{\eta}_i) = 0$. The linear independence of the η_i 's implies that not all the μ_i 's vanish. Now consider the one-form $\omega = \sum_i \mu_i \eta_i$ whose time derivative is $\dot{\omega} = \sum_i \dot{\mu}_i \eta_i - \sum_i \lambda_i \eta_i$. This implies that ω is in \mathcal{H}_{k+1} , which is a contradiction. Hence, it is always possible to choose a set \mathcal{W}_{k+1} (possibly empty) such that $\mathcal{W}_k, \dot{\mathcal{W}}_k, \mathcal{W}_{k+1}$ is a basis for \mathcal{H}_{k+1} . This procedure is repeated k^* times, so the sequence $\{\mathcal{H}_k\}$ is shown to have the following structure:

$$\mathcal{H}_k = \text{span}_\Lambda \{\omega_i^{(j)}, k \leq i \leq k^*, 0 \leq j \leq i-k, 0 \leq k \leq k^*.$$

$\mathcal{H}_1 = \text{span}_\Lambda \{dx\}$ and $\text{rank } g(x) = m$ imply that $\mathcal{W}_0 = \emptyset$. It can be proved by induction that, for $0 \leq k \leq k^*$, the set $\{\mathcal{W}_k, \dots, \mathcal{W}_{k^*}^{(k^*-k)}, \dots, \mathcal{W}_k\}$ is linearly independent. Finally, set $\{\omega_1, \dots, \omega_m\} = \{\mathcal{W}_k, \dots, \mathcal{W}_1\}$. The invariance of the list of relative degrees is rather obvious from the construction. It can also be seen from the fact that the number of r_i 's which are equal to k is given by $\kappa_k = \text{card } \mathcal{W}_k = \dim \mathcal{H}_k / (\mathcal{H}_{k+1} + \dot{\mathcal{H}}_{k+1})$. ■

The following (straightforward) corollary of Theorem 3.5 is the reason for the name infinitesimal Brunovsky form: the ω_k 's provide a basis of one-forms in which the first-order approximation of Σ looks like a linear Brunovsky canonical form [11]. If these forms were integrable, then they would yield a true Brunovsky canonical form for system Σ (for this reason, the term infinitesimal is preferred to "non-exact," used in [28]). In any case, the integers r_i are nice candidates for generalizing to nonlinear systems the notion of linear Kronecker controllability indices.

Corollary 3.6 (The Infinitesimal Brunovsky form): Suppose $\mathcal{H}_\infty = \{0\}$. Then the basis $\{\omega_i^{(j)}, 1 \leq i \leq m, 1 \leq j \leq r_i\}$ of $\text{span}_\Lambda \{dx\}$ defined by $\omega_i^{(j)} = \omega_i^{(j-1)}$ yields

$$\begin{aligned} \dot{\omega}_{i-1} &= \omega_{i-2} \\ &\vdots \\ \dot{\omega}_{i-1} &= \omega_{i-1} \\ \dot{\omega}_{i-1} &= \sum_{j=1}^n a_{i,j} dx_j + \sum_{j=1}^m b_{i,j} du_j \end{aligned} \quad (1 \leq i \leq m)$$

where $a_{i,j}, b_{i,j} \in \mathcal{K}$ and $[b_{i,j}]$ has an inverse in the ring of $m \times m$ matrices with entries in \mathcal{K} .

IV. MAIN RESULTS

A. Some Preliminaries

An Algebra of Polynomial Operators: Let $\mathcal{K}[d/dt]$ denote the (noncommutative) algebra of polynomials in the operator d/dt with coefficients in \mathcal{K} . The addition and external multiplication are the usual ones. The internal multiplication corresponds to operators composition: $(d/dt)(p) = p(d/dt) + \dot{p}$, $\forall p \in \mathcal{K}$. The only invertible elements in $\mathcal{K}[d/dt]$ are the nonzero elements of \mathcal{K} (i.e., nonzero polynomials of degree zero). Let $\mathcal{K}^{m \times m}[d/dt]$ denote the algebra of $m \times m$ matrices with entries in $\mathcal{K}[d/dt]$. Let \mathcal{E}^m be the differential \mathcal{K} -vector space spanned by m -tuples of one-forms. Each $P \in \mathcal{K}^{m \times m}[d/dt]$ defines a differential operator in \mathcal{E}^m : $P \cdot \Omega = \sum_i P_i \Omega_i^{(i)}$ for all $\Omega = (\omega_1, \dots, \omega_m)^T \in \mathcal{E}^m$, where $\Omega_i^{(i)} = (\omega_1^{(i)}, \dots, \omega_m^{(i)})^T$ and $P_i := \sum_j P_{ij}(d/dt)^j \in \mathcal{K}^{m \times m}[d/dt]$.

Invertible elements of $\mathcal{K}^{m \times m}[d/dt]$ play an important role; they are elements $P \in \mathcal{K}^{m \times m}[d/dt]$ such that there exists $Q \in \mathcal{K}^{m \times m}[d/dt]$ such that $P \cdot Q = Q \cdot P = I_m$.

Definition 4.1 (Structure at Infinity for One-Forms): $\Omega = (\omega_1, \dots, \omega_m)^T$ is said to have $\sigma_k = \dim(\text{span}_\Lambda \{dx, \Omega, \dots, \Omega^{(k)}\} / \text{span}_\Lambda \{dx, \Omega, \dots, \Omega^{(k-1)}\})$ zeros at infinity of order less than or equal to k .

For exact one-forms ($\omega_i = dh_i$), Definition 4.1 coincides with (3) and (4), since exterior differentiation and time-differentiation commute, so that the notations of Section II may be adopted verbatim. In particular, Lemma 2.1 is also valid for systems of one-forms.

Proposition 4.2: Consider the system of m one-forms $\Omega := (\omega_1, \dots, \omega_m)^T$, and the polynomial matrix operator $P \in \mathcal{K}^{m \times m}[d/dt]$. Let $\tilde{\Omega} := P \cdot \Omega$. Then

$$\dim(\mathcal{N}_\nu \cap \text{span}_\Lambda \{\Omega^{(k)}, k \geq 0\}) \leq \dim(\mathcal{N}_\nu \cap \text{span}_\Lambda \{\tilde{\Omega}^{(k)}, k \geq 0\})$$

where ν is an integer large enough such that Ω and $\tilde{\Omega}$ belong to \mathcal{N}_ν .

Proof: Suppose P has degree α . Straightforward computations show that $\tilde{\Omega}^{(k)}$, for $k \geq 0$, can be written as a linear combination of the following form $\tilde{\Omega}^{(k)} = R_0 \Omega + R_1 \dot{\Omega} + \dots + R_{k+\alpha} \Omega^{(k+\alpha)}$. Thus, $\text{span}_\Lambda \{\tilde{\Omega}^{(k)}, k \geq 0\} \subseteq \text{span}_\Lambda \{\Omega^{(k)}, k \geq 0\}$ and the result follows. ■

B. The Results

Our main result is the following. It is an easy consequence of Theorem 3.5 and Proposition 4.2.

Theorem 4.3 (Problem Statement 2): Suppose $\mathcal{H}_\infty = \{0\}$. There exists a system of linearizing outputs if and only if there exists an invertible polynomial operator $P \in \mathcal{K}^{m \times m}[d/dt]$ such that $d(P\Omega) = 0$, where $\Omega = (\omega_1, \dots, \omega_m)^T$ is a system of one-forms characterized by Theorem 3.5.

Proof:

Necessity: Suppose $y = h(x, u, \dots, u^{(\nu-1)})$ is a linearizing output. Problem Statement 2 implies that $\mathcal{E} = \mathcal{Y}$. Theorem 3.5 implies that $\mathcal{E} = \text{span}_\Lambda \{\Omega^{(k)}, k \geq 0\}$. Thus, there exist polynomial matrix operators P, Q such that $dy = P\Omega$ and $\Omega = Q dy$. Clearly, $PQ = QP = I_m$ and hence P is invertible. Moreover, $d(P\Omega) = d(dy) = 0$.

Sufficiency: Let $N = \dim(x_\nu \cap \text{span}_\Lambda \{\Omega^{(k)}, k \geq 0\})$, $\tilde{N} = \dim(\mathcal{N}_\nu \cap \text{span}_\Lambda \{\Omega^{(k)}, k \geq 0\})$, where $\Omega = P\Omega$. Theorem 3.5 implies that $N = n + m\nu$. Existence of the operator P implies $N \leq \tilde{N}$. Invertibility of P implies the existence of an operator Q such that $\Omega = Q\tilde{\Omega}$, i.e., $N \leq \tilde{N}$ and hence $N = \tilde{N}$. The result follows because one can assume, without loss of generality, that $\Omega = d(x, u, \dots, u^{(\nu-1)})$, y is a linearizing output. ■

Theorem 4.3 relates linearizing outputs, if they exist, to the set of differential one-forms built in Theorem 3.5 for arbitrary accessible systems. It provides an alternative way to tackle the problem of deciding whether linearizing outputs exist, i.e., whether a given system is linearizable by endogeneous dynamic feedback, by looking for an invertible matrix P meeting the above conditions. This does not provide a practically checkable criterion because the degree (in the operator d/dt) of the matrix P is not known *a priori*, which prevents the condition of the theorem from being finitely checkable. By forcing P to have degree zero (i.e., to be an invertible matrix with entries in \mathcal{K}), the problem is made finite, and one obtains the following sufficient condition.

Corollary 4.4: A sufficient condition for the existence of a system of linearizing outputs is that a system of one-forms $\Omega = (\omega_1, \dots, \omega_m)^T$ satisfying the conditions of Theorem 3.5 satisfy the Frobenius condition

$$d\omega_i \wedge \omega_1 \wedge \dots \wedge \omega_m = 0, \quad 1 \leq i \leq m. \quad (8)$$

The relative degrees of $\omega_1, \dots, \omega_m$ coincide with the orders of the zeros at infinity of the linearizing outputs.

Proof: The Frobenius condition implies that there exists a basis composed of exact one-forms for the codistribution spanned by $\{\omega_1, \dots, \omega_m\}$, and hence that there exists an invertible matrix (with entries in \mathcal{K}) relating this basis to $\{\omega_1, \dots, \omega_m\}$. ■

The condition (8) is obviously finitely (and easily) checkable once some ω_i 's have been constructed. It is of course not a necessary condition, and it should be noted that, in general, it depends on the choice of the ω_i 's: some systems of one-forms satisfying the conditions of Theorem 3.5 may satisfy the Frobenius condition (8), whereas some others do not. Even for a linear system, a wrong choice of the one-forms $\omega_1, \dots, \omega_m$ prevents condition (8) from being satisfied. However, in many practical cases (see the proofs of the results in Section V or [28, Section 3.2]), it is not difficult to round this difficulty and check whether (8) is met for one of the possible choices of the ω_i 's.

A way for bounding the degree of P is to look for linearizing outputs depending on x only, as illustrated by the following result.

Theorem 4.5 (Problem Statement 1): Suppose $\mathcal{H}_\infty = \{0\}$. Then there exists a system of linearizing outputs which depend only on x if and only if the conditions of Theorem 4.3 are satisfied and, in addition, $\deg(P_{ij}(d/dt)) \leq r_j - 1$, $1 \leq i, j \leq m$.

Proof: Sufficiency is obvious. Conversely, suppose that one of the polynomial elements of the matrix $P(d/dt)$, say $P_{ij}(d/dt)$ has degree equal to r_j . Thus, dh_i contains a term which depends on du and that cannot be eliminated by the remaining terms since, by construction, all the $\omega_i^{(k)}$ are linearly independent. This is a contradiction. ■

Note that it is very easy to write down some similar criteria for the existence of linearizing outputs depending on x , u , and any finite number of time derivatives of u . Such types of conditions as the ones given in Theorem 4.5 can be restated as existence of a finite number of functions—the coefficients of the polynomial entries of P —meeting some differential conditions, namely, $d(P\Omega) = 0$ and P invertible. A possible way to avoid writing the relations on the entries of P for it to be invertible is to write P as a finite product of elementary invertible matrices and taking the coefficients of these elementary matrices as unknowns instead of the entries of P itself; this is exploited in [27]. Checking whether there exist some linearizing outputs depending on x , u , and any finite number of time derivatives of u therefore amounts to checking whether a finite set of PDE's in a finite number of unknown functions has a solution.

This is not new since it is easy (although tedious) to write down the PDE's which have to be satisfied by the linearizing outputs themselves, if they are restricted to depend on x only. This is the underlying idea of the characterizations given in some particular cases (see, for instance, [25]). We, however, believe that looking for the invertible matrix P once the ω_k 's have been constructed is more natural and more tractable. This is illustrated by the very short proofs of the theorems of next section, which are known but usually not so natural to prove, and by results like the ones obtained in [28, Section 3.2], [27], [3, Theorem 5.4], which work out some nontrivial particular cases.

V. PARTICULAR CASES

In this section we recover some classical results using the infinitesimal Brunovsky form.

Theorem 5.1 (Static State Feedback Linearization): System Σ is linearizable by static state feedback if, and only if, $\mathcal{H}_\infty = \{0\}$ and, for $k = 1, \dots, k^*$, \mathcal{H}_k is completely integrable.

This is, of course, equivalent to the early characterization [17] and [22], or to the more recent one given in [17] and [22]. The infinitesimal Brunovsky form provides a very short proof.

Proof: If each \mathcal{H}_k is completely integrable, one may choose forms, say, $\omega_i = dq_i(x)$, $i = 1, \dots, m$ in Theorem 3.5 whose m functions $q_i(x)$ whose relative degrees satisfy $\sum_{i=1}^m r_i = n$ whose decoupling matrix [21] is nonsingular because the ω_i 's and their time derivatives are linearly independent, this completes the first part. The converse is obvious since the \mathcal{H}_k 's are invariant by static feedback, and are integrable for a linear system. ■

Theorem 5.2 (Single-Input Systems). Let Σ be a single-input system and suppose $\mathcal{H}_\infty = \{0\}$. Then there is only one differential form ω_1 in Theorem 3.5, and the following statements are equivalent:

1) Σ is linearizable by static state feedback; 2) Σ is linearizable by dynamic state feedback; 3) $d\omega_1 \wedge \omega_1 = 0$, where ω_1 is such that $\mathcal{H}_0 = \text{span}_{\mathcal{K}} \{\omega_1\}$.

This result (equivalence between 1 and 2) was first obtained in [6] and [7]. The infinitesimal Brunovsky form—note that ω_1 is invariant up to a nonzero multiplicative function—allows us to give the simple characterization 3 and the following very simple proof.

Proof: It is obvious from Theorem 5.1 and Theorem 4.3 because the only invertible elements of $\mathcal{K}[d/dt]$ are those having degree 0. In turn, multiplication by a nonzero function does not change the rank of the differential form $d\omega_1 \wedge \omega_1$.

Theorem 5.3 (Systems with $m = n - 1$ inputs [7]): A system Σ with $m = n - 1$ inputs is linearizable by dynamic state feedback if, and only if, $\mathcal{H}_\infty = \{0\}$.

Proof: \mathcal{H}_2 is generated by a single nonzero one-form ω_1 which is orthogonal to the distribution spanned by the vector fields g_1, \dots, g_{n-1} , and thus can be chosen independent of u . $\omega_2, \dots, \omega_{n-1}$ can be chosen arbitrarily, linearly independent of $\{\omega_1, \omega_2\}$ and belonging to $\text{span}_{\mathcal{K}} \{dx\}$: they can also be chosen independent of u . Then, the differential forms $d\omega_i \wedge \omega_1 \wedge \dots \wedge \omega_{m-1}$, $i = 1, \dots, m$, are zero because they are $(n+1)$ -forms in n variables. The converse is obvious. ■

VI. CONCLUSION

We have built a so-called infinitesimal Brunovsky form which exhibits m controllable blocks whose dimensions play the role of Kronecker controllability indices in the linear case. This extension to the nonlinear case is innovative since, to our best knowledge, it is the only available one with the property that the sum of these indices equals the dimension of the strong accessibility distribution. This result on nonlinear accessibility was used to derive a necessary and sufficient condition for existence of a linearizing output, and the early results in (either static or dynamic) feedback linearization have been shown to fit naturally in our formalism. Static feedback linearization was shown to be a matter of exact one-forms whereas dynamic feedback linearization is a matter of possibly nonexact one-forms.

APPENDIX

PROOF OF PROPOSITION 3.3, POINT 2

Define \mathcal{E}^* to be the dual vector space of \mathcal{E} (topology induced by $\|\sum a_j dv_j\|^2 = \sum a_j^2$, dv_j 's taken among the dx_i 's or the $du_k^{(j)}$'s, both sums are finite), whose elements—"vector fields"—are of the form

$$X = \sum_{i=1}^n a_i \frac{\partial}{\partial x_i} + \sum_{k=1}^m \sum_{j \geq 0} b_{j,k} \frac{\partial}{\partial u_k^{(j)}}$$

where $a_i, b_{j,k}$ are in \mathcal{K} and $\partial/\partial x_i, \partial/\partial u_k^{(j)}$ are defined by $\langle \partial/\partial x_i, dx_i \rangle = \delta_{i,i'}$, $\langle \partial/\partial u_k^{(j)}, du_k^{(j')} \rangle = \delta_{j,j'} \delta_{k,k'}$, $\langle \partial/\partial u_k^{(j)}, \dots \rangle$

$d\epsilon_i = \langle \partial/\partial x_i, du_k^{(j)} \rangle = 0$. Note that the above linear combination need not be finite, but does define an element of \mathcal{E}^* because, for all $\omega \in \mathcal{E}$, $\langle X, \omega \rangle$ may be written as a sum with only finitely many nonzero terms. Define the "time-derivative" of $X \in \mathcal{E}$ by

$$\langle \dot{X}, \omega \rangle = \langle \dot{X}, \omega \rangle - \langle X, \dot{\omega} \rangle. \quad (9)$$

The interior product (or hook) $i(X)$ is defined, for a differential form of degree two $\mu = \sum_{i,j} a_{i,j} dv_i \wedge dv_j$, by $i(X)\mu = \sum_{i,j} a_{i,j} (\langle X, dv_i \rangle dv_j - \langle X, dv_j \rangle dv_i)$. Clearly, taking the time-derivative of both sides in this identity yields, from (9),

$$\dot{i(X)\mu} = i(\dot{X})\mu + i(X)\dot{\mu}. \quad (10)$$

Let $\alpha_1, \dots, \alpha_{p_\infty}$ be a basis of \mathcal{H}_∞ , and define the following subspace of \mathcal{E}^*

$$\mathcal{G}_\infty = \{X \in \mathcal{E}^* \mid \forall \omega \in \mathcal{H}_\infty, \langle X, \omega \rangle = 0 \text{ and } \alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega = 0\}$$

whose elements are sometimes called [4] the "Cauchy characteristic vector fields" of \mathcal{H}_∞ . The "characteristic system" (or "retracting space" according to [4]) of \mathcal{H}_∞ is defined as its annihilator: $\mathcal{C}(\mathcal{H}_\infty) = \mathcal{G}_\infty^\perp$. For a certain $K \geq 0$, the elements $\alpha_1, \dots, \alpha_{p_\infty}$ of the chosen basis for \mathcal{H}_∞ can be written as linear combinations of dx_1, \dots, dx_n with coefficients function of $x, u, \dot{u}, \dots, u^{(K)}$ only, hence all the α_i 's are linear combinations of elements of the form $dx_j \wedge dx_l$ or $dx_j \wedge du_k^{(l)}$ with $l \leq K$, so that all the elements $\partial/\partial u_k^{(j)}$ are in \mathcal{G}_∞ for $j \geq K+1$, and finally that $\mathcal{C}(\mathcal{H}_\infty)$ is a subspace of $\text{span}_K \{dx, du, \dot{u}, \dots, u^{(K)}\}$. Furthermore, we have the following.

Lemma: $\mathcal{C}(\mathcal{H}_\infty)$ is invariant by time-differentiation.

From point 1 of Proposition 3.3, this implies $\mathcal{C}(\mathcal{H}_\infty) \subset \mathcal{H}_\infty$, and hence, from standard exterior algebra, $\alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega = 0$ for $i = 1, \dots, p_\infty$.

Proof of the Lemma: Consider $X \in \mathcal{G}_\infty$, $\omega \in \mathcal{H}_\infty$. We have [compare (9) and (10)]

$$\langle \dot{X}, \omega \rangle = \langle \dot{X}, \omega \rangle - \langle X, \dot{\omega} \rangle$$

$$\begin{aligned} & \alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(\dot{X})d\omega \\ &= \overline{\alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega} - \alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega - \dots \\ & - \alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega - \alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega. \end{aligned}$$

Since $\langle X, \omega \rangle$ and $\alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(X)d\omega$ are identically zero, and $\dot{\alpha}_1, \dots, \dot{\alpha}_{p_\infty}$ and $\dot{\omega}$ are in \mathcal{H}_∞ (because \mathcal{H}_∞ is invariant by time-differentiation), all the terms on the right-hand sides above are zero, which implies $\langle \dot{X}, \omega \rangle = 0$ and $\alpha_1 \wedge \dots \wedge \alpha_{p_\infty} \wedge i(\dot{X})d\omega = 0$. Hence, \dot{X} is in \mathcal{G}_∞ because this is true for all $\omega \in \mathcal{H}_\infty$. Now, take η

in $\mathcal{C}(\mathcal{H}_\infty)$. For all $X \in \mathcal{G}_\infty$, $\langle X, \eta \rangle = \langle \dot{X}, \eta \rangle - \langle X, \dot{\eta} \rangle = 0$ where $\langle \dot{X}, \eta \rangle$ is zero because $\langle X, \eta \rangle$ is identically zero, and $\langle \dot{X}, \eta \rangle$ is zero because \dot{X} is in \mathcal{G}_∞ . This proves $\eta \in \mathcal{C}(\mathcal{H}_\infty) \Rightarrow \dot{\eta} \in \mathcal{C}(\mathcal{H}_\infty)$, and therefore the lemma. ■

Design of a Class of Luenberger Observers for Descriptor Systems

M. Hou and P. C. Müller

Abstract—A new approach to the design of a class of Luenberger observers for descriptor systems is presented. The design is performed in a straightforward manner. The conditions required in the design are given in terms of the original system matrices. The relationship among these and other well-known conditions is highlighted.

I. INTRODUCTION

The design of Luenberger-type observers for descriptor systems has obtained considerable attention in the past decade, see, e.g., [1]–[11].

Descriptor systems under consideration have the following form:

$$E\dot{x} = Ax + Bu \quad (1)$$

$$y = Cx + Du \quad (2)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^r$, $y \in \mathbb{R}^m$ are the descriptor variables, control, and measurement vectors, respectively. E , $A \in \mathbb{R}^{n \times n}$, B , C , and D are known real matrices of appropriate dimensions. $\text{rank } E = r$, $0 < r < n$.

Mostly, the matrices E and A are assumed to be square, i.e., $q = n$, and the matrix pencil $\lambda E - A$ is required to be regular. However, as shown in [3] and [10], concerning observer design this kind of assumption is not needed. Therefore, no assumption on $\lambda E - A$ is made in this note.

We accept piecewise continuous distributions as solutions [12]. It is well known that arbitrary initial conditions $E x(0_-)$ and inputs $u(t)$ are admissible for a descriptor system with a regular matrix pencil. However, since no assumption on $\lambda E - A$ has been made in (1), we should assume that u and a certain but unknown initial condition $E x(0_-)$ are admissible, i.e., they do not result in contrary equations in (1). More precisely, $E x(0_-)$ and $u(t)$ are said to be admissible if they satisfy $\text{rank} [-sE + A] E x(0_-) B U(s) = \text{rank} (sE - A)$ for some $s \in \mathbb{C}$, where $U(s)$ is the Laplace transformation of $u(t)$. Thus, there exists at least one trajectory obeying (1) and (2). It is worth pointing out that the admissibility and consistency of the initial condition $E x(0_-)$ are two different concepts. The former implies the existence of solution(s), while the latter guarantees further the impulse-free behavior of the solution(s).

Certainly, if $\lambda E - A$ is not of full column rank, i.e., for any $\lambda \in \mathbb{C}$ $\text{rank}(\lambda E - A) < n$, then there exist more than one trajectory satisfying (1). Here, we emphasize the difference between the description of a system, e.g., (1), and the real system. Although the description (1) is of course assumed to be correct, it may be incomplete. The column singularity of $\lambda E - A$ reflects incompleteness of the description. In such a case, one cannot answer the question of uniqueness of trajectories only from (1). However, if

$$\begin{bmatrix} -\lambda E + A \\ C \end{bmatrix}$$

is column regular, i.e., there exists $\lambda \in \mathbb{C}$ such that this extended matrix pencil has rank n , then the solution $x(t)$ satisfying (1)

Manuscript received August 26, 1993; revised November 18, 1993, March 14, 1994, and May 29, 1994.

IEEE Log Number 9407026.

and (2) for any given admissible initial condition are unique. By treating y formally as some passive inputs, this can be proven following the analysis by, for example, Gantmacher and Flether [14].

In the observer design for descriptor systems, the condition

$$\text{rank} \begin{bmatrix} -\lambda E + A \\ C \end{bmatrix} = n$$

for any $\lambda \in \mathbb{C}$, $\text{Re}(\lambda) > 0$ is needed at any rate. This condition implies column regularity of

$$\begin{bmatrix} -\lambda E + A \\ C \end{bmatrix}$$

and therefore uniqueness of the trajectory. This means that once an observer for a descriptor system is obtained, the observer supplies the estimation of a trajectory, and this trajectory of the underlying system has to be unique even if uniqueness of the trajectory may not be recognized from (1) alone before.

Efforts have been made to design observers for descriptor systems under different conditions using various techniques. A series of results of Paraskevopoulos *et al.* [7], [8], [15] devote to the design of a class of Luenberger observers of the form

$$\dot{z} = E_1 z + E_2 y + E_3 u, \quad z \in \mathbb{R}^p \quad (3)$$

$$x = F_1 z + F_2 y \quad (4)$$

where $\hat{x}(t)$ goes to $x(t)$ as t tends to infinity for any initial condition $z(0)$ and arbitrary admissible $E x(0_-)$. The underlying descriptor systems in [7] and [8] are of the form (1), (2) with the assumptions $|\lambda E - A| \neq 0$ and $D = 0$.

The more general Luenberger observer has the same form as (3) and (4) except that (4) also contains the input term $F_3 u$. Generally, this kind of observer needs less restrictive conditions than that of the above class of Luenberger observers as shown in [16]. The research is progressing toward achievement of necessary and sufficient existence conditions as well as design procedures of Luenberger observers for descriptor systems. Although for the class of Luenberger observers of the form (3), (4) an effort has been made in [7], [8] to approach this goal, the resulted existence conditions can be proved to be sufficient only [10], [16]. On the other hand, the design in [7], [8] is rather involved.

The aim of this note is to propose a straightforward design of the observers described by (3) and (4), and to provide the corresponding conditions in terms of the original system matrices. The treatment in this note permits the general descriptor systems like (1), (2) to be taken into consideration. The existence conditions in the simple form enable us to compare them to the existing ones.

Finally, it is worth noting that a natural choice of observer form may be

$$E\dot{\hat{x}} = A\hat{x} + Bu + L(y - C\hat{x} - Du). \quad (5)$$

Thus, the design of Luenberger observers can be addressed as finding L such that in the error equation $E\dot{e} = (A + LC)e$, where $e = x - \hat{x}$, e is free of impulsive behavior and goes to zero as t tends to infinity. This goal is nevertheless not reachable if E and A have fewer rows than columns. Therefore, the form (5) is not recommended for dealing with the observer design for descriptor systems of the type (1), (2).

II. EXISTENCE CONDITIONS AND DESIGN PROCEDURE

The main result of this note is as follows. Its proof provides a design procedure.

Theorem 2.1: There exists an observer of the type (3), (4) if the following two conditions are fulfilled:

$$\text{rank} \begin{bmatrix} -\lambda E + A \\ C \end{bmatrix} = n, \quad \forall \lambda \in \mathbb{C}, \quad \text{Re}(\lambda) \geq 0, \quad (6)$$

$$\text{rank} \begin{bmatrix} E & A & B \\ 0 & C & D \\ 0 & E & 0 \end{bmatrix} = n + \text{rank} \begin{bmatrix} E & B \\ 0 & D \end{bmatrix}. \quad (7)$$

Proof: Using the singular value decomposition technique [18], one can always find two nonsingular orthogonal matrices $\tilde{P} \in \mathbb{R}^{n \times n}$ and $\tilde{Q} \in \mathbb{R}^{n \times n}$ such that $\tilde{P}E\tilde{Q} = \text{diag}(\Sigma, 0)$, where Σ , is nonsingular. Thus, by choosing $P = \text{diag}(\Sigma^{-1}, I_{q-m})\tilde{P}$, one has

$$\begin{aligned} \text{diag}(P, I_m) \begin{bmatrix} E & A & B \\ 0 & C & D \end{bmatrix} \text{diag}(\tilde{Q}, \tilde{Q}, I_s) \\ = \begin{bmatrix} I_r & 0 & A_{11} & A_{12} & B_{11} \\ 0 & 0 & A_{21} & A_{22} & B_{21} \\ 0 & 0 & C_{11} & C_{22} & D \end{bmatrix}. \end{aligned} \quad (8)$$

We can further find an orthogonal matrix $P_1 \in \mathbb{R}^{(q-m) \times (q-m)}$ such that

$$P_1 \begin{bmatrix} B_{21} \\ D \end{bmatrix} = \begin{bmatrix} B_2 \\ 0 \end{bmatrix}$$

where $B_2 \in \mathbb{R}^{(q-m) \times s}$ has full row rank with

$$\gamma = \text{rank} \begin{bmatrix} E & B \\ 0 & D \end{bmatrix}.$$

Write

$$P_1 \begin{bmatrix} A_{21} & A_{22} & B_{21} \\ C_{11} & C_{22} & D \end{bmatrix} = \begin{bmatrix} A_2 & A_3 & B_2 \\ A_4 & A_5 & 0 \end{bmatrix} \quad (9)$$

$\tilde{P} = \text{diag}(I_r, P_1) \text{diag}(\tilde{P}, I_m)$ and $\tilde{Q} = \text{diag}(\tilde{Q}, \tilde{Q}, I_s)$. In view of (8) and (9), we get

$$\tilde{P} \begin{bmatrix} E & A & B \\ 0 & C & D \end{bmatrix} \tilde{Q} = \begin{bmatrix} I_r & 0 & A_{11} & A_{12} & B_{11} \\ 0 & 0 & A_2 & A_3 & B_2 \\ 0 & 0 & A_4 & A_5 & 0 \end{bmatrix}. \quad (10)$$

This means that the system (1), (2) can be rewritten as

$$\dot{\xi}_1 = A_{11}\xi_1 + A_{12}\xi_2 + B_{11}u - P_{1,2}y \quad (11)$$

$$0 = A_2\xi_1 + A_3\xi_2 + B_2u - P_{2,2}y \quad (12)$$

$$0 = A_4\xi_1 + A_5\xi_2 - P_{3,2}y \quad (13)$$

where $\xi = [\xi_1^T \ \xi_2^T \ \xi_3^T]^T = \tilde{Q}^T x$; $[P_{1,2}^T \ P_{2,2}^T \ P_{3,2}^T]^T$ is the last $(q+m)$ columns of \tilde{P} . Due to the special structure of \tilde{P} , it is easy to verify that $P_{12} = 0$. The row partition of the last $(q+m)$ columns of \tilde{P} is obvious according to (11)–(13).

Since

$$\text{diag}(\tilde{P}, P_1) \begin{bmatrix} E & A & B \\ 0 & C & D \\ 0 & E & 0 \end{bmatrix} \tilde{Q} = \begin{bmatrix} I_r & 0 & A_{11} & A_{12} & B_{11} \\ 0 & 0 & A_2 & A_3 & B_2 \\ 0 & 0 & A_4 & A_5 & 0 \\ 0 & 0 & I_r & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (14)$$

and

$$\tilde{P} \begin{bmatrix} E & B \\ 0 & D \end{bmatrix} \text{diag}(\tilde{Q}, I_s) = \begin{bmatrix} I_r & 0 & B_{11} \\ 0 & 0 & B_2 \\ 0 & 0 & 0 \end{bmatrix} \quad (15)$$

it is easy to verify that the condition (7) holds if and only if A_5 has full column rank $n-r$.

Solving (13) for ξ_2 , substituting the solution into (11) and (12), and premultiplying (13) by $(I_\beta - A_5 A_5^+)$, where $\beta = q+m-r$, we get

$$\dot{\xi}_1 = \bar{A}_1 \xi_1 + B_{11}u + G_1 y \quad (16)$$

$$\bar{y} = \bar{C}_1 \xi_1 + \bar{B}_2 u \quad (\bar{y} = Hy) \quad (17)$$

$$\xi_2 = -A_5^+ A_4 \xi_1 + A_5^+ P_{3,2} y \quad (18)$$

where $\bar{A}_1 = A_{11} - A_{12} A_5^+ A_4$, $G_1 = A_{12} A_5^+ P_{3,2}$, $A_5^+ = (A_5^T A_5)^{-1} A_5^T$,

$$\bar{C}_1 = \begin{bmatrix} A_2 - A_3 A_5^+ A_4 \\ (I_\beta - A_5 A_5^+) A_4 \end{bmatrix}, \quad \bar{B}_2 = \begin{bmatrix} B_2 \\ 0 \end{bmatrix}.$$

$$H = \begin{bmatrix} P_{2,2} - A_3 A_5^+ P_{3,2} \\ (I_\beta - A_5 A_5^+) P_{3,2} \end{bmatrix}. \quad (19)$$

Now it is clear if the pair $\{\bar{A}_1, \bar{C}_1\}$ is detectable, one can design a full-order observer for the subsystem described by (16), (17) using the standard techniques. Then, combining the observer with (18) and considering the relation $x = \tilde{Q}\xi$, one finishes the observer design. The observer has the form (3), (4) with the order r .

In the following, we prove that under the condition (7), the pair $\{\bar{A}_1, \bar{C}_1\}$ is detectable if and only if the condition (6) holds.

Consider only

$$\begin{aligned} \text{rank} \begin{bmatrix} -\lambda E + A \\ C \end{bmatrix} &= \text{rank} \begin{bmatrix} -\lambda I_r + A_{11} & A_{12} \\ A_2 & A_3 \\ A_4 & A_5 \end{bmatrix} \\ &= \text{rank} \begin{bmatrix} -\lambda I_r + A_{11} & A_{12} \\ A_2 & A_3 \\ (I_\beta - A_5 A_5^+) A_4 & 0 \\ A_5^+ A_4 & I_{n-r} \end{bmatrix} \\ &= \text{rank} \begin{bmatrix} -\lambda I_r + (A_{11} - A_{12} A_5^+ A_4) & 0 \\ A_2 - A_3 A_5^+ A_4 & 0 \\ (I_\beta - A_5 A_5^+) A_4 & 0 \\ A_5^+ A_4 & I_{n-r} \end{bmatrix} \end{aligned} \quad (20)$$

where the second equality is obtained by premultiplying the line block $[A_4 \ A_5]$ in the first equality by the column nonsingular matrix

$$\begin{bmatrix} I_\beta - A_5 A_5^+ \\ A_5^+ \end{bmatrix}. \quad \square$$

The above observer is of order r . Noting the special structure of \bar{B}_2 , one knows that the second part of the measurement \bar{y} in (17) is free of inputs. Hence, it is easy to design a reduced-order observer in the form (3), (4) for the subsystem (16), (17) following, for instance a similar technique in [23]. The resulting observer will have the order p

$$\begin{aligned} p &= r - \text{rank}(I_\beta - A_5 A_5^+) A_4 \\ &= r - \{\text{rank}[A_4 \ A_5] - \text{rank} A_5\} \\ &= r - \left\{ \text{rank} \begin{bmatrix} E & A & B \\ 0 & C & D \end{bmatrix} - \text{rank} \begin{bmatrix} E & B \\ 0 & D \end{bmatrix} - (n-r) \right\} \\ &= n + \text{rank} \begin{bmatrix} E & B \\ 0 & D \end{bmatrix} - \text{rank} \begin{bmatrix} E & A & B \\ 0 & C & D \end{bmatrix} \end{aligned} \quad (21)$$

which is directly obtainable by using the form (16)–(18).

In the next section we shall prove that the conditions (6), (7) and the order (21) are equivalent to those given in [8] provided $\lambda E - A$ is regular and $D = 0$. Nevertheless, the condition (7) combining with the condition (6) is still only sufficient for the design of observers

of the type (3), (4), and the order (21) is not minimal generally. These can be shown by constructing counterexamples. For instance, Example 2 in [10] serves as a counterexample showing nonnecessity of (7) for the design of observers of the type (3), (4).

III. RELATIONSHIP AMONG EXISTING DESIGN CONDITIONS

In [7] and [8], the condition corresponding to (7) is

$$\text{rank} \left\{ \begin{bmatrix} E \\ C \end{bmatrix} J^T \begin{bmatrix} I \\ \Lambda \end{bmatrix} \right\} = n \quad (22)$$

where $n = \text{rank}[F \ B]$, J is the permutation matrix such that

$$J(\mu F + I)^{-1}[F \ B] = \begin{bmatrix} F_I & B_I \\ E_{II} & B_{II} \end{bmatrix} \quad (23)$$

where $[E_I \ B_I]$ has full row rank n , and Λ is the unique solution of the equation $[E_{II} \ B_{II}] = \Lambda[E_I \ B_I]$, μ is an arbitrary number such that $\mu I + I$ is nonsingular. Obviously the matrix pencil $\Lambda F - I$ is assumed to be regular. Since the condition (7) does not imply this assumption and the matrix D in (7) is generally nonzero, the following proposition indicates that the condition (7) is a generalization of the condition (22).

Proposition 3.1 Provided the matrix pencil $\Lambda F - I$ is regular, the following conditions are equivalent

$$a) \text{rank} \left\{ \begin{bmatrix} I \\ C \end{bmatrix} J^T \begin{bmatrix} I \\ \Lambda \end{bmatrix} \right\} = \text{rank}[I \ B] \quad (24)$$

$$b) \text{rank} \left\{ \begin{bmatrix} I \\ C \end{bmatrix} (\mu F + I)^{-1} [I \ B] [F \ B] \right\} = \text{rank}[F \ B] \quad (25)$$

$$c) \text{rank} \begin{bmatrix} I & A & B \\ 0 & C & 0 \\ 0 & F & 0 \end{bmatrix} = n + \text{rank}[F \ B] \quad (26)$$

where the notation $(\)$ represents an arbitrary generalized inverse of $(\)$ satisfying $(\)(\)(\) = (\)$.

Proof First we prove the equivalence between a) and b).

Since

$$\begin{aligned} &\text{rank} \left\{ \begin{bmatrix} I \\ C \end{bmatrix} (\mu F + I)^{-1} [F \ B] [I^* \ B] \right\} \\ &= \text{rank} \left\{ \begin{bmatrix} I \\ C \end{bmatrix} J^T S S^{-1} J (\mu L + I)^{-1} \right. \\ &\quad \left. [F \ B] [I^* \ B] (\mu F + I)^T S \right\} \end{aligned} \quad (27)$$

for any permutation matrix J and any nonsingular matrix S , by choosing J as in (23) and

$$S = \begin{bmatrix} I & 0 \\ \Lambda & I \end{bmatrix}$$

one has

$$\begin{aligned} S^{-1} J (\mu F + I)^{-1} [F \ B] &= \begin{bmatrix} I_I & 0 \\ -\Lambda & I_{II} \end{bmatrix} \begin{bmatrix} F_I & B_I \\ E_{II} & B_{II} \end{bmatrix} \\ &= \begin{bmatrix} E_I & B_I \\ 0 & 0 \end{bmatrix} \end{aligned} \quad (28)$$

which leads to

$$\begin{aligned} S^{-1} J (\mu F + I)^{-1} [F \ B] [I^* \ B] (\mu F + I)^T S \\ &= \{ S^{-1} J (\mu F + I)^{-1} [F \ B] \} \{ S^{-1} J (\mu F + I)^{-1} [F \ B] \}^* \\ &= \begin{bmatrix} E_I & B_I \\ 0 & 0 \end{bmatrix} \begin{bmatrix} F_I & B_I \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} I_I & 0 \\ 0 & 0 \end{bmatrix} \end{aligned} \quad (29)$$

This, in view of (27), confirms the equivalence between a) and b).

Now we prove the equivalence between b) and c). To verify

$$\begin{aligned} &\begin{bmatrix} S^{-1} J (\mu F + I)^{-1} & 0 & 0 \\ 0 & 0 & I_r \\ 0 & I_n & 0 \end{bmatrix} \begin{bmatrix} I & A & B \\ 0 & C & 0 \\ 0 & F & 0 \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & I \\ 0 & 0 \end{bmatrix} \\ &= \begin{bmatrix} I_I & I & 0 & 0 \\ 0 & 0 & I & 0 \\ 0 & H_1 & H & 0 \end{bmatrix} \end{aligned}$$

where

$$H_1 = \begin{bmatrix} I \\ C \end{bmatrix} J^T \begin{bmatrix} I_I \\ \Lambda \end{bmatrix}, \quad H = \begin{bmatrix} F \\ C \end{bmatrix} J^T \begin{bmatrix} 0 \\ I \end{bmatrix}$$

Then, due to the full row rank of $[F_I \ B_I]$ the conclusion is obvious. \square

In order to design Luenberger observers, different conditions are adopted in various design techniques. As shown by Dai [5] the condition (6) is necessary (but generally not sufficient) for any Luenberger type observer which provides the estimation of the descriptor vector x . We need only to compare the conditions which are additionally required for designing Luenberger observers. In the following, we outline these existing additional conditions which are given in terms of the original system matrices, and for reference we cite some corresponding works in which these conditions are used to design Luenberger observers.

$$a) \text{rank} \begin{bmatrix} I \\ C \end{bmatrix} = n \quad (\text{see [2], [19], [21]})$$

$$b) \text{rank} \begin{bmatrix} F & A & B \\ 0 & C & 0 \\ 0 & E & 0 \end{bmatrix} = n + \text{rank}[I \ B]$$

(see this note and [7], [8])

$$c) \text{rank} \begin{bmatrix} F & A \\ 0 & C \\ 0 & E \end{bmatrix} = n + \text{rank } F \quad (\text{see [4], [9], [22]})$$

$$d) \text{rank} \begin{bmatrix} I & A & B & 0 \\ 0 & F & 0 & A \\ 0 & 0 & 0 & C \\ 0 & 0 & 0 & F \end{bmatrix} = n + \text{rank} \begin{bmatrix} I & A & B \\ 0 & I & 0 \end{bmatrix}$$

(see [10])

Remark 3.1 For the convenience of comparison, $D = 0$ is assumed in (2). Thus, the condition (7) now has the form b).

Remark 3.2 In a recent paper [11] the necessary and sufficient conditions are provided for the Luenberger observer design in terms of the Weierstrass form of a transformed descriptor system. Therefore, the underlying descriptor systems are assumed to be regular. As a matter of fact, in terms of the Kronecker form [13], the same can be done for arbitrary descriptor systems.

It is known that, provided the necessary condition (6) holds under either conditions a) or b), the class of Luenberger observers of the form (3)–(4) can be designed. But under neither c) nor d) can this be guaranteed. It is also known that a general Luenberger observer, i.e., in (4), the input term may exist, can be designed under each of the conditions a)–d) combining with the condition (6). Since all these conditions a)–d) with (6) are known to be sufficient for the corresponding cases, it is interesting to know what kind of relationship exists among these conditions. The following proposition gives the answer.

Proposition 3.2 There exists the relation $a) \Rightarrow b) \Rightarrow c) \Rightarrow d)$ but, in general, $a) \Leftarrow b) \Leftarrow c) \Leftarrow d)$. Here, for instance $a) \Rightarrow b)$ represents that b) can be deduced from a).

Proof: On account of (10), without loss of generality, the matrices E , A , B , and C are assumed to be in the forms

$$E = \begin{bmatrix} I_1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} A_{11} & A_{12} \\ A_2 & A_4 \\ A_4 & A_5 \end{bmatrix},$$

$$B = \begin{bmatrix} B_{11} \\ B_2 \\ 0 \end{bmatrix}, \quad C = [C_{11} \quad C_{12}] \quad (31)$$

where B_2 has full row rank. By using these forms it is easy to prove the conclusion. \square

Proposition 3.2 shows that d) is the weakest condition among a)–d).

Finally, we provide a conclusion about the order of the observers. This result is parallel to Proposition 3.1, and its proof is analogous to that of Proposition 3.1.

Proposition 3.3: Provided the matrix pencil $\lambda E - A$ is regular and $D = 0$, the reduced order (21) of the designed observer can be expressed in the following different ways:

$$a) \quad p = \text{rank} [E \quad B] - \text{rank} \left\{ C^T J^T \begin{bmatrix} I_2 \\ N \end{bmatrix} \right\} \quad (32)$$

$$b) \quad p = \text{rank} [E \quad B] - \text{rank} \{ C(\mu E + A)^{-1} [E \quad B] [E \quad B]^{-1} \} \quad (33)$$

$$c) \quad p = \text{rank} [E \quad B] - \text{rank} \begin{bmatrix} E & A & B \\ 0 & C & 0 \end{bmatrix} + n. \quad (34)$$

Remark 3.3: The expression (32) was given in [8].

IV. CONCLUSION

A class of Luenberger observers in [7] and [8] can easily be designed under two simple conditions. The conditions in terms of the original system matrices are shown to be equivalent to those in [7] and [8]. Furthermore, the present design is available for the more general class of linear descriptor systems. However, in contrast with the claim in [7] and [8], the design conditions are known to be sufficient in usual cases. The exact relationship among the different design conditions in literature which are given in terms of the original system matrices is shown.

ACKNOWLEDGMENT

The authors appreciate the inspired comments of a reviewer on uniqueness of trajectories of arbitrary descriptor systems.

Comments on "On the Robust Popov Criterion for Interval Lur'e Systems"

T. Mori, T. Nishimura, Y. Kuroe, and H. Kokame

Abstract—This correspondence supplements the remarks made in a paper by Dahleh *et al.* as to the Popov sector of Lur'e systems with interval plants. A numerical example is provided to show that strict inequalities hold among three sectors: those obtained by the theorem of the paper,¹ by applying Popov theorem to each member system, and by applying that to each of the systems with Kharitonov plants. This counterexample negates a tempting conjecture on "strong" robust Popov criterion.

In the above paper,¹ Dahleh, Tesi and Vicino derived the robust Popov criterion for a Lur'e system including a sector-type nonlinearity and a family of interval plants. Hereafter, we mostly employ

Fig. 1. Popov loci and Popov lines for the interval plant family

Fig. 2. Critical Popov lines and corresponding sectors.

the notations of the paper.¹ In particular, by "sector k ," we mean the sector $[0, k]$. In short, the criterion says that we have only to test absolute stability with Popov theorem for 16 Lur'e systems that correspond to Kharitonov plants. The caveat is, however, that we should choose a fixed multiplier constant θ_l for all these systems. This leads to a lower bound k_l for the sector k_0 which is obtainable by applying the Popov theorem to each member Lur'e system with the multiplier depending upon the member plant. If we need to apply the Popov theorem to only the 16 extreme systems with possibly different multipliers, then we have the sector k_u which is larger than or equal to k_0 . Thus, we have, in general, $k_l \leq k_0 \leq k_u$, as remarked in the paper.¹

Here, what we are intrigued by is the question: can the last inequality always be equality? If so, we would be able to obtain the "strong" robust Popov criterion, which we can afford most using the original Popov theorem. This tempting conjecture was also posed in [1]. Unfortunately, a counterexample has been found by an extensive search.

Setting $C(s) \equiv 1$, as in the paper,¹ we consider a stable interval plant,

$$g(s) = \frac{0.01s + 1}{s^5 + 5s^4 + a_1s^3 + 41s^2 + a_1s + 1} \quad (1)$$

where $a_1 \in [8, 11]$, $a_3 \in [10, 12]$. For this family, we have the following two Kharitonov plants:

$$\begin{aligned} g_{11}(s) &= g_{14}(s) = N_1(s)/D_1(s) = N_1(s)/D_1(s) \\ &= \frac{0.01s + 1}{s^5 + 5s^4 + 10s^3 + 41s^2 + 11s + 1} \end{aligned} \quad (2)$$

$$\begin{aligned} g_{12}(s) &= g_{13}(s) = N_1(s)/D_2(s) = N_1(s)/D_3(s) \\ &= \frac{0.01s + 1}{s^5 + 5s^4 + 12s^3 + 41s^2 + 8s + 1} \end{aligned} \quad (3)$$

Other than these plants, we pick a non-Kharitonov plant

$$g_{00}(s) = \frac{0.01s + 1}{s^5 + 5s^4 + 10s^3 + 41s^2 + 9s + 1} \quad (4)$$

Fig. 1 shows the Popov loci for $g_{11}(s)$ and $g_{12}(s)$ (using a solid curve) and that for $g_{00}(s)$ (using a dashed curve). We can draw the line l_1 touching both of the Kharitonov loci, and this determines the sector obtained by "weak" robust Popov criterion. For $k = K = 7.363 \dots$ (corresponds to $-1/K$ in Fig. 1), the criterion is no more effective, but we can still draw the lines, l_{11} and l_{12} , in whose right-hand side the Kharitonov loci are located. However, it is impossible to draw the Popov line for g_{00} at the point $(-1/K, 0)$. This indicates that the "strong" robust Popov criterion fails to hold.

In order to obtain k_0 , we have to resort to partitioning the intervals into evenly spaced grids. For each coefficient value at the grid, the existence of the multiplier is examined. For this task, a symbolic computation approach is available [2]. Fig. 2 illustrates three critical Popov lines for the above interval plant. These lines determine the Popov sectors: $k_l = K_l = 4.826 \dots$, $k_0 = K_0 = 5.774 \dots$, and $k_u = K_u = 7.363 \dots$. The plant $g_{00}(s)$ which gives K_0 in this figure is slightly different from $g_{00}(s)$ in Fig. 1, in that the coefficient 9 of the first degree term in the denominator in (4) is changed to 8. We see, from this example, that the inequalities among the sectors can be actually strict: $k_l < k_0 < k_u$.

An Output Feedback Globally Stable Controller for Induction Motors

Gerardo Espinosa-Pérez and Romeo Ortega

Abstract—We present here a globally stable nonlinear dynamic output feedback controller for torque tracking and flux regulation of induction motors. The control law is globally defined (even in startup), requires only measurement of stator variables and rotor speed, and does not rely on cancellation of the systems nonlinearities. Our work extends in several directions the result of the paper by Ortega *et al.*, where the torque tracking problem was solved for a model where the variables are expressed in a frame rotating at an arbitrary angular frequency (dq model). First, we obviate the need to transfer the dq control signals of the paper by Ortega *et al.* to the physical input variables in the stator frame, hence providing a directly implementable control law. Second, besides the torque tracking objective, we include the practically important rotor flux regulation task. Third, by choosing a more suitable representation of the motor model, we simplify the controller structure and provide a better understanding of its derivation and behavior.

I. INTRODUCTION

It is widely recognized that induction motors, which have been extensively utilized in industrial controls, offer a very promising alternative for future applications like electrical vehicles and robotics, see, e.g., [21] and [1]. Among the advantages of the ac induction motor over dc types: they pack more power into less space, they have no need for failure-prone brushes, they are more rugged, and they have flatter efficiency-versus-speed curves. Also, with the continuous drop in the cost of electronics, the ac system is becoming more cost-effective. To match the higher quality standards of wider drive ranges and higher reliability requires the development of new robust control techniques—a challenging task that has attracted the attention of control theoreticians.

Induction motors can be described [22] by a fifth-order nonlinear differential equation with four electrical coordinates (stator and rotor currents or fluxes) and one mechanical coordinate (rotor speed). There are two physical inputs to the motor (stator voltages), and only three state variables are typically available for measurement (stator currents and the rotor speed). Furthermore, the motor parameters vary considerably during operation and the generated torque is perturbed by an unknown torque load. In typical industrial drives, the controlled variables are rotor position and speed, which are indirectly regulated via nested PI loops around the fundamental torque control loop [11]. With an eye on electric vehicles and robotic applications, we center here directly in torque tracking.¹

A globally stable output feedback controller for torque regulation of a complete induction motor model with unknown torque load was recently presented in [16]. These results were further extended to torque tracking in [17]. The control algorithms in both papers are derived based on the so called dq model of the motor. This model is obtained applying two coordinate transformations to the basic $\alpha\beta$

model. First, we refer to rotor variables to the stator coordinate frame² to obtain the so-called ab model. Then, an additional projection of all signals to an arbitrarily rotating frame is applied. In the industrial electronics community, where the focus is on steady-state operation at constant speed, these transformations are well understood, see, e.g., [8], [12]. However, as pointed out in Section II-B, there seems to be some confusion among the control workers as to how these dynamical models and corresponding controllers are related. One of our objectives in writing this paper is to clarify these relationships.

Since the controllers in [16] and [17] are derived for the dq model, an additional step to transfer the control signals to the physical input variables in the stator frame is needed for its implementation. In this note we show that, contrary to some incorrect statements made in the literature [13], this transformation does not require the measurement of rotor variables. To enhance the readability of the note, instead of deriving the implementable control law “reverse transforming” the control of [17], we directly obtain the control in the $\alpha\beta$ model. We then show how the scheme of [17] can be obtained by transforming the present control law. In summary, our main contribution is then to provide the first directly implementable³ globally stable nonlinear dynamic output feedback controller for torque tracking and flux regulation of an induction motor.

The difficulty of torque control is that, in contrast with dc motors, torque is a nonlinear function of fluxes and currents. It has been shown in [3] that the full induction motor model (including the mechanical dynamics) is not exactly linearizable if we select torque as the output. It is, however, input-output linearizable (modulo singularity problems) with respect to velocity and rotor flux norm [9]. This theoretically interesting property has motivated several authors to study the velocity tracking problem, e.g., [10], [9], [3], [14], [2]. In [18] it is shown how to achieve global speed regulation from our torque tracking controller. It is worth pointing out that, in contrast with our control law which is globally defined, even in start up, in the aforementioned results (see also [6]) various singularity problems appear.

The remainder of the note is organized as follows. First, we derive in Section II the induction motor basic $\alpha\beta$ model, establish some key properties, and present the torque tracking and flux regulation problem. Section III contains the proposed control law, derived directly from the $\alpha\beta$ model, hence implementable without further transformations. The proof of the main stability result is deferred to the Appendix. In Section IV we explain the different transformations of the motor model, and using these transformations rederive the controller of [17]. The performance of the proposed algorithm is illustrated via simulations in Section V. Finally, we present some concluding remarks.

II. MODEL AND PROBLEM FORMULATION

In this section we derive first the basic motor model ($\alpha\beta$ model) from the total energy function and Lagrange's equations, and establish its key *passivity* property.⁴ Also, we present some fundamental relationships of the motor that are used in the sequel for the controller derivation.

²This is a classical approach that simplifies the analysis of the machine removing from the electrical equations the dependence on position.

³To obtain the 3ϕ equivalent controller, it is only necessary to apply the inverse Blondel's transformation [15].

⁴It is clear that passivity, being an input-output property, is independent of the system coordinates thus valid in all motor representations.

A Basic $\alpha\beta$ Model

We consider a standard three phase single pole pair induction motor represented with a two-phase model known as the $\alpha\beta$ model⁵.

It considers two coils for the stator and two coils for the rotor in pairs in two orthogonal $\alpha\beta$ axes. The axes for the stator have a fixed position, while those corresponding to the rotor are rotating at the rotor angular velocity q . We make the usual basic assumptions about the mechanical structure, balanced energy distribution and linear relationship between the flux vector $\lambda = [\lambda_s^T \lambda_r^T]^T = [\lambda_1 \lambda_2 \lambda_3 \lambda_4]^T \in \mathbb{R}^4$ and the current vector $q = [q_s^T q_r^T]^T = [q_1 q_2 q_3 q_4]^T \in \mathbb{R}^4$

$$\lambda = D(q)q \quad (2.1)$$

where the subscripts (\cdot) , (\cdot) , (\cdot) are used throughout the note to denote electrical, stator, and rotor variables respectively. The superscript $(\cdot)^T$ denotes transposition. $D(q) = D^T(q) > 0$ is the 4×4 inductance matrix of the windings given by

$$D(q) = \begin{bmatrix} I_s & I_m & I_s e^{j\theta} \\ I_s e^{-j\theta} & I_r & I_m \\ I_m & I_m & I_r \end{bmatrix}$$

where $I_s, I_r, I_m > 0$ are the stator, rotor, and mutual inductances respectively. I is the 2×2 identity matrix and $e^{j\theta}$ is the rotation matrix

$$e^{j\theta} = \begin{bmatrix} \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & \cos(\theta) \end{bmatrix}$$

with J the 2×2 antisymmetric matrix

$$J = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$$

If we neglect shaft compliance, the generalized coordinates are the electrical charges in each of the coils q and the angular position of the rotor q . Since under this assumption there is no potential energy, the Lagrangian function coincides with the kinetic and the total energies and is given by

$$\mathcal{L}(q, \dot{q}) = \frac{1}{2} \dot{q}^T D(q) \dot{q} = \frac{1}{2} \dot{q}^T \begin{bmatrix} D(q) & 0 \\ 0 & D \end{bmatrix} \dot{q} \quad (2.2)$$

where $q = [q^T \dot{q}^T]^T \in \mathbb{R}^5$ and $D > 0$ is the rotor inertia.

Applying Euler-Lagrange equations, we get the state equations of the $\alpha\beta$ model describing both the electrical and mechanical subsystems as

$$D(q)\dot{q} + W_1(q)\dot{q}q + Rq = Mu \quad (2.3)$$

$$D\ddot{q} - \frac{1}{2}q^T W_1(q)\dot{q} + Rq = -\tau_l \quad (2.4)$$

where $R = \text{diag}\{R_s, R_s, R_r, R_r\} > 0$, $M = [I_2 \ 0]^T$, $W_1(q) = \partial D(q)/\partial q$, the control signals $u = [u_1 \ u_2]^T$ are the stator voltages, $R_s, R_r > 0$ are the stator and rotor resistances, $R > 0$ is the motor damping coefficient and τ_l is the load torque. The regulated outputs are the generated torque and the rotor flux which are given by

$$\tau = \frac{1}{2}q^T W_1(q)\dot{q}, \quad \lambda = L e^{-j\theta} q_s + I_r q_r \quad (2.5)$$

B Torque Tracking and Flux Regulation Problem

We consider the induction motor model (2.3)–(2.4) with outputs stator currents q_s and rotor speed \dot{q} . Control is subject to disturbance⁶ τ_l and regulated signals τ and λ . The torque reference τ_l is a bounded differentiable function with known first derivative. Our objective is then to design a control law that will ensure global asymptotic torque and flux regulation, that is $\lim_{t \rightarrow \infty} (\tau - \tau_l) = 0$, $\lim_{t \rightarrow \infty} \|\lambda - \lambda_d\| = 0$ for all initial conditions and with all internal signals uniformly bounded. Furthermore, we require that the motor in steady state operates in a balanced regime, i.e., sinusoidal stator voltage with three phases (one shifted 90° with respect to the other) with equal amplitude and frequency.

Remark 2.1 In [18] it is shown how from the torque tracking objective above we can solve the speed/position tracking problem. It essentially amounts to selecting the desired torque as a function of the desired speed.

C Motor Properties

1) Passivity. The proposition below reveals the fundamental energy dissipation property of the induction motor.

Proposition 2.1 (Passivity). The motor model (2.3)–(2.4) with zero load torque defines an output strictly passive operator $u \mapsto q$ that is there exists $\epsilon_1 > 0$, $\epsilon_2 \in \mathbb{R}$ such that $\int_0^t q^T u d\tau \geq \epsilon_1 \int_0^t \|q_s\|^2 d\tau + \epsilon_2$ (with $\|\cdot\|$ the Euclidean norm) holds for all $t > 0$ and all locally square integrable stator voltages. Furthermore, the workless forces may be factored as

$$\begin{bmatrix} W_1(q)\dot{q}q \\ -\frac{1}{2}q^T W_1(q)\dot{q} \end{bmatrix} = C(q, \dot{q})\dot{q} \\ = \begin{bmatrix} 0 & 0 & I J e^{j\theta} I \\ -L J e^{j\theta} I e^{-j\theta} q & 0 & 0 \\ I q^T J e^{j\theta} I e^{-j\theta} q & 0 & 0 \end{bmatrix} \dot{q}$$

where $D(q) = C(q, \dot{q}) + C^T(q, \dot{q})$.

Proof. Taking the time derivative of the system's total energy we get

$$\begin{aligned} \dot{\mathcal{L}} &= \dot{q}^T \left[\frac{1}{2} D(q)\dot{q} + \begin{bmatrix} -W_1(q)\dot{q}q \\ \frac{1}{2}q^T W_1(q)\dot{q} \end{bmatrix} - Rq + Mu + \xi \right] \\ &= \dot{q}^T (-Rq + Mu + \xi) \end{aligned}$$

where $R = \text{diag}\{R_s, R_s, R_r, R_r\}$, $M = [M^T \ 0]^T$, $\xi = [0 \ -\tau_l]^T$. From the integration of the last equation we get the energy balance equation

$$\underbrace{\mathcal{L}(t) - \mathcal{L}(0)}_{\text{stored energy}} = - \underbrace{\int_0^t \dot{q}^T Rq d\tau}_{\text{dissipated energy}} + \underbrace{\int_0^t \dot{q}^T (Mu + \xi) d\tau}_{\text{input energy}}$$

Noting that $\mathcal{L}(t) \geq 0$ and setting $\epsilon_1 = \lambda_{\min}\{R\}$ and $\epsilon_2 = -\mathcal{L}(0)$ proves the first part of the proposition. The second part of the proof is established via direct substitution of the terms. $\square\square\square$

The importance of the passivity property for our tracking problem is best appreciated with the following corollary that will be instrumental for the subsequent stability analysis. Its proof follows trivially from the derivative of the desired total energy function $\mathcal{L}_l = \frac{1}{2}C^T D(q)\dot{q}$ and the skew symmetry property

⁶For the sake of brevity we restrict our attention to the case of known disturbance. The extension to the unknown but linearly parameterized disturbance case follows verbatim from [17].

⁵For further details and generalizations see [15] and [4].

Corollary 2.1: For all locally square integrable q_s, \dot{q}_s and all $\mathcal{K} \in \mathcal{R}^{5 \times 5}$, the system

$$\mathcal{D}(q_s)\dot{e} + [\mathcal{C}(q_s, \dot{q}_s) + (\mathcal{R} + \mathcal{K})]e = \psi \quad (2.6)$$

satisfies the dissipation inequality $\int_0^t e^T \psi d\tau \geq c_3 \int_0^t \|e\|^2 d\tau + c_4 \|e(t)\|^2 - c_5 \|e(0)\|^2$, where $c_3 = \lambda_{\min}\{\mathcal{R} + \mathcal{K}\}$, $c_4 = \lambda_{\min}\{\mathcal{D}(q_s)\} > 0$, $c_5 = \lambda_{\max}\{\mathcal{D}(q_s)\} > 0$. Consequently, if $\psi \equiv 0$ and $\mathcal{R} + \mathcal{K} > 0$, then $\lim_{t \rightarrow \infty} e = 0$. $\square\square\square$

Remark 2.2: The factorization of the workless forces is not unique, but there always exists a suitable selection of $\mathcal{C}(q, \dot{q})$ to enforce the key skew-symmetry property [20]. It should be remarked that in the factorization of Proposition 2.1, the third and fourth row of $\mathcal{C}(q, \dot{q})$ are independent of \dot{q}_r . This feature will be used in the sequel.

2) Torque and Rotor Flux: In the remaining part of this subsection, we derive a key relationship between the rotor flux λ_r and the generated torque τ . To this end, we first notice from (2.3) that the rotor flux vector given in (2.1) satisfies the differential equation

$$\dot{\lambda}_r + R_r \dot{q}_r = 0. \quad (2.7)$$

Now, from the definition of rotor flux angle $\rho = \arctan\{\lambda_1/\lambda_3\}$, we have

$$\dot{\rho} = \frac{-1}{\|\lambda_r\|^2} \lambda_r^T \mathcal{J} \dot{\lambda}_r = \frac{R_r}{\|\lambda_r\|^2} \lambda_r^T \mathcal{J} \dot{q}_r,$$

where the last equation was obtained using (2.7). Noting that $\tau = \lambda_r^T \mathcal{J} \dot{q}_r$, we establish the fundamental fact that the rotor flux vector rotates at an angular speed

$$\dot{\rho} = \frac{R_r}{\|\lambda_r\|^2} \tau. \quad (2.8)$$

Our interest in presenting the relations above stems from the fact that we can express the torque tracking and flux regulation problem in terms of regulation of rotor current and flux as shown below.

Proposition 2.2 (Rotor Flux Regulation): Given a smooth bounded function $\tau_d(t)$ and a positive constant $\beta > 0$, let

$$\lambda_{r,d} := \beta \begin{bmatrix} \cos(\rho_d) \\ \sin(\rho_d) \end{bmatrix}, \quad \dot{\rho}_d := \frac{R_r}{\beta^2} \tau_d, \quad \rho_d(0) = 0. \quad (2.9)$$

Assume $\lim_{t \rightarrow \infty} \lambda_r = \lambda_{r,d}$ and $\lim_{t \rightarrow \infty} \dot{\lambda}_r = \dot{\lambda}_{r,d}$, then $\lim_{t \rightarrow \infty} \|\lambda_r\| = \beta$, $\lim_{t \rightarrow \infty} \tau = \tau_d$. $\square\square\square$

III. CONTROLLER DESIGN

From Proposition 2.2 and (2.7), we see that the control objective is attained if we ensure that the rotor flux converges to the solution of

$$\dot{\lambda}_{r,d} = \frac{R_r \tau_d}{\beta^2} \mathcal{J} \lambda_{r,d}, \quad \lambda_{r,d}(0) = \begin{bmatrix} \beta \\ 0 \end{bmatrix} \quad (3.1)$$

and \dot{q}_r converges to

$$\dot{q}_{r,d} := -\frac{\tau_d}{\beta^2} \mathcal{J} \lambda_{r,d}. \quad (3.2)$$

Using (2.1), we can express these two conditions in terms of currents by requiring \dot{q}_s to converge to

$$\dot{q}_{s,d} := \left(\frac{1}{L_s} \mathcal{I}_2 + \frac{L_r}{L_s \beta^2} \tau_d \mathcal{J} \right) e^{\mathcal{J} q_s} \lambda_{r,d}. \quad (3.3)$$

In other words, $\dot{q}_{s,d}, \dot{q}_{r,d}$ above define a *desired behavior* for the motor currents that delivers the required torque and insures rotor flux regulation.

On the other hand, if we define the difference between the actual and the desired behavior as $e := [e_1^T, e_2^T, e_3^T]^T := \dot{q} - \dot{q}_d$, from Corollary 2.1 we see that if (for the given $\dot{q}_{s,d}, \dot{q}_{r,d}$) we can find $\dot{q}_{s,d}$ and u such that the following system is satisfied for all q_s, \dot{q}_s :

$$\mathcal{D}(q_s)\ddot{q}_d + \mathcal{C}(q_s, \dot{q}_s)\dot{q}_d + \mathcal{R}\dot{q}_d = \mathcal{M}u + \xi \quad (3.4)$$

with $\dot{q}_d := [\dot{q}_{s,d}^T, \dot{q}_{r,d}^T, \dot{q}_{s,d}^T]^T$, then we have convergence to the desired current behavior.

It is easy to see that this is achieved with (3.2), (3.3), and

$$u = L_s \ddot{q}_{s,d} + L_s e^{\mathcal{J} q_s} \ddot{q}_{r,d} + L_s \mathcal{J} e^{\mathcal{J} q_s} \dot{q}_{r,d} + R_s \dot{q}_{s,d} \quad (3.5)$$

$$D_m \ddot{q}_{s,d} + L_s \dot{q}_r^T \mathcal{J} e^{-\mathcal{J} q_s} \dot{q}_{s,d} + R_m \dot{q}_{s,d} = -\tau_L. \quad (3.6)$$

From Corollary 2.1, it can easily be shown that this control law ensures global asymptotic torque tracking and flux regulation; however, it requires the measurement of the rotor current. To overcome this problem, we propose below a scheme where we use instead its estimate, add to the desired "energy function" \mathcal{L}_d a term that depends on the observation errors, and use the damping term \mathcal{K} to achieve a sign definite derivative. These derivations are summarized in the proposition below.

Proposition 3.1 (Main Result). Consider the induction motor model (2.3), (2.4) with measurable outputs stator currents \dot{q}_s and rotor speed \dot{q}_s . Assume the load torque τ_L is a known bounded function and that the motor parameters are also known. The torque reference τ_d is a bounded differentiable function with known first derivative. Let the control law be defined as

$$u = \Gamma(\tau_d, \dot{\tau}_d) \mathcal{J} e^{-\mathcal{J} q_s} \lambda_{r,d} + L_s \mathcal{J} e^{-\mathcal{J} q_r} \dot{q}_{r,d} - K_1(\dot{q}_{s,d}) e_s \quad (3.7)$$

with

$$\begin{aligned} \Gamma(\tau_d, \dot{\tau}_d) &= \frac{L_s \sigma}{L_{sr} \beta^2} \dot{\tau}_d \mathcal{I}_2 + \frac{L_s}{L_{sr}} \left(\frac{L_r \tau_d}{\beta^2} \mathcal{J} + \mathcal{I}_2 \right) \\ &+ \frac{\tau_d}{L_{sr} \beta^2} \left(L_s \mathcal{I}_2 + \frac{L_r \sigma}{\beta^2} \mathcal{J} \right) R_r \\ &+ \frac{1}{L_{sr}} \left(\frac{\tau_d L_r}{\beta^2} \mathcal{I}_2 - \mathcal{J} \right) R_s \end{aligned} \quad (3.8)$$

$\sigma := L_s - L_{sr}^2/L_r$ and controller dynamics (3.1) and

$$\ddot{q}_{s,d} = -\frac{1}{D_m} [L_{sr} \dot{q}_r^T \mathcal{J} e^{-\mathcal{J} q_s} \dot{q}_{r,d} + R_m \dot{q}_{s,d} + \tau_L + K_2(\dot{q}_d) e_s];$$

$$\dot{q}_{s,d}(0) = \dot{q}_{s,d0}. \quad (3.9)$$

The gains $K_1(\dot{q}_{s,d})$ and $K_2(\dot{q}_d)$ are given as

$$K_1(\dot{q}_{s,d}) = \frac{L_{sr}^2}{4\epsilon} \dot{q}_{s,d}^2, \quad K_2(\dot{q}_d) = \frac{L_{sr}^2}{4\epsilon} (\dot{q}_{1,d}^2 + \dot{q}_{2,d}^2), \quad 0 < \epsilon < R, \quad (3.10)$$

while the state estimator is

$$D_s(q_s)\ddot{\hat{q}}_s + W_1 \dot{q}_s \dot{\hat{q}}_s + R_s \dot{\hat{q}}_s = \mathcal{M}u - L(q_s, \dot{q}_s) \dot{\hat{q}}_s \quad (3.11)$$

with $\dot{\hat{q}}_s := \dot{\hat{q}}_s - \dot{q}_s$ the observation error and

$$L(q_s, \dot{q}_s) = \begin{bmatrix} 0 & 0 \\ \mathcal{J}_2 e^{-\mathcal{J} q_s} & 0 \end{bmatrix} \dot{q}_s.$$

Under these conditions, the closed-loop system achieves global asymptotic torque tracking and flux norm regulation with balanced operation.

Remark 3.1 We should recall that we have posed here a *torque* control problem where the given desired torque automatically determines [via the relationship (2.4)] the rotor speed. In this sense q_{1i} is the rotor speed that corresponds to the desired torque. Notice from (3.6) that actually this is the case if q converges to q_i . In the case where we are given a rotor speed or position control objective, τ_i should be chosen as proposed in [18].

IV. COORDINATE TRANSFORMATIONS: *ab* AND *dq* MODELS

In this section, we introduce the coordinate transformations that give us the *ab* and *dq* models. Our objective in studying in detail these transformations is twofold: first, to clearly establish the relationship between the various models studied in the control literature, second, to prove that the control law of [17] can be obtained by transforming the present controller (or vice versa) and that this transformation does not require measurement of the rotor variables.

To obtain the *ab* model we follow the standard procedure of applying to the $\alpha\beta$ model a coordinate transformation that projects the rotor currents to the stator frame. This is achieved with the change of coordinates

$$q_{1i} = T_{1i}(q)q = \begin{bmatrix} I & 0 & 0 \\ 0 & e^{j\theta} & 0 \\ 0 & 0 & 1 \end{bmatrix} q$$

Further, to obtain the *dq* model we project the *ab* currents into a frame rotating at an arbitrary angular speed ω as [8]

$$q_{1i} = T_{1i}(q)q_{1i} = \begin{bmatrix} e^{j\theta} & 0 & 0 \\ 0 & e^{j\theta} & 0 \\ 0 & 0 & 1 \end{bmatrix} q_{1i}$$

where $\theta = \omega t + \theta(0) = 0$. The relationships between the various representations are easily defined with the general rotation matrix

$$T(I - \theta) = \begin{bmatrix} e^{j\theta} & 0 & 0 \\ 0 & e^{j\theta} & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

which clearly satisfies $T(q - \theta) = T(0 - \theta)T(q - 0)$. Hence, $q_{1i} = T(0 - \theta)q_{1i} = T(q - \theta)q$. To obtain the inverse transformations notice that $T^{-1}(q - \theta) = T^{-1}(q - \theta)$.

Applying the latter transformation to the $\alpha\beta$ model and premultiplying the resulting equation by $T(q - \theta)$ yields, after some simple calculations, the *dq* model studied in [16] and [17]

$$D_{1i}q_{1i} + C_{1i}(q_{1i})q_{1i} + Rq_{1i} = Mu_{1i} + \xi \quad (4.1)$$

where $Mu_{1i} = T(q - \theta)Mu$, the matrices D_{1i} and C_{1i} are given by

$$D_{1i} = \text{diag}\{D^{1i}, D\} = \text{diag}\left\{\begin{bmatrix} I & I & I \\ I_s & I_s & L \\ L & L & I_s \end{bmatrix} D\right\} \in \mathbb{R}$$

$$C_{1i}(q_{1i}, \omega) = \begin{bmatrix} \begin{bmatrix} I & \mathcal{J} & I \\ I_s & \mathcal{J} & I \end{bmatrix} (\omega - q) & C_{1i}(q_{1i}) \\ -C_{1i}^T(q_{1i}) & 0 \end{bmatrix} \in \mathbb{R}^{n \times n}$$

$$C_{1i}(q_{1i}) = [(I - \mathcal{J}q^{1i} + I_s \mathcal{J}q^{1i})^T 0]^T$$

$$\text{and } q_{1i} = [(q^{1i})^T (q^{1i})^T q]^T$$

In order to show that the control of [17] can be obtained by means of the transformation presented above, notice that

$$u_{1i} = e^{-j\theta} u = I_s e^{-j\theta} q_{s1} + I_s e^{j(\theta_s - \theta)} q_{s2} + I_s \mathcal{J} e^{-j(\theta_s - \theta)} q_{s2} + R e^{-j\theta} q_{s1} - K_1(q_{s1})e^{-j\theta} \quad (4.2)$$

where $e^{-j(\theta_s - \theta)} q_{s1} = q_{s1}^{1i}$ and

$$e^{-j\theta} q_{s2} = \begin{bmatrix} -\frac{1}{\sqrt{2}} \frac{\tau_i}{R} (R - \tau_i + \frac{1}{2} q_{s1}) \\ \frac{1}{\sqrt{2}} (R - \tau_i + \frac{1}{2} q_{s1}) + \frac{1}{2} \end{bmatrix}$$

$$e^{-j(\theta_s - \theta)} q_{s2} = \begin{bmatrix} \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \\ -\frac{1}{\sqrt{2}} \end{bmatrix}$$

$$e^{-j\theta} q_{s1} = \begin{bmatrix} \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \end{bmatrix} \quad e^{-j(\theta_s - \theta)} q_{s1} = \begin{bmatrix} 0 \\ -\frac{1}{\sqrt{2}} \end{bmatrix}$$

$$e^{-j\theta} e^{-j(\theta_s - \theta)} = \begin{bmatrix} q_{s1}^{1i} - \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \\ q_{s2}^{1i} - \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \end{bmatrix} \quad (4.3)$$

The last expressions were obtained considering that in this new reference frame the desired rotor flux will rotate at an angular speed $\theta = q_{s1}^{1i} e^{-j\theta} - \theta = q_{s1}^{1i}$ therefore $e^{-j(\theta_s - \theta)} e^{-j\theta} = [1 \ 0]^T$.

Substitution of the above expressions in (4.2) results in the following controller

$$u_{1i}^{1i} = -I_s q_{s1}^{1i} q_{s1}^{1i} + \frac{1}{2} - K_1^{1i} \left(q_{s1}^{1i} - \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \right)$$

$$u_{1i}^{1i} = -I_s q_{s2}^{1i} q_{s2}^{1i} + \frac{1}{2} - K_1^{1i} \left(q_{s2}^{1i} - \frac{1}{\sqrt{2}} \frac{\tau_i}{R} \right)$$

where $K_1^{1i} = K_1$ and

$$\frac{1}{2} = \frac{R}{L} \frac{1}{2} - \frac{R}{L} (I - I_s - L) \tau_i - \frac{1}{L} \frac{1}{2} \tau_i q$$

$$= \frac{1}{L} \frac{1}{2} [(I - R + R I) \tau_i + (I - L - I_s) \tau_i + I \frac{1}{2} q]$$

The controller state is given by

$$q_{1i} = -\frac{1}{D} [I_s (q^{1i})^T \mathcal{J} q^{1i} + R q_{s1} + K_1^{1i} e^{-j\theta} + \tau_i]$$

with $K_1^{1i} = I_s / L e^{j\theta} [(q_{s1}^{1i})^2 + (q_{s2}^{1i})^2]$. The structure of the estimator state is easily obtained by a procedure similar to the one followed to obtain the model (4.1).

We must note the fact that the above controller differs slightly from the controller in [17] since the desired behavior for the currents (4.3) in this case was chosen to obtain the norm of the rotor flux equal to $\frac{1}{2}$ instead of $I_s \frac{1}{2}$ as in that paper.

Discussion. 1) From the *dq* model (4.1) we can obtain as a particular case the classical *ab* model by choosing $\omega = 0$.

2) A key observation is the introduction of ω in the model (4.1). This variable is used in [16] and [17] as an additional control input (denoted u_3 in those papers) to solve the torque control problem. From the derivations above, it is clear that given u_{1i} and ω we can obtain the *ab* controls via $Mu_{1i} = T^{-1}(q - \theta)Mu_{1i}$. The problem is that u_{1i} and ω themselves depend on variables expressed in the rotating frame. One objective of this note is to obviate the need of all these transformations by defining the controller dynamics directly in terms of the signals q_{s1}, q_{s2}, q .

3) It is important to remark that the *dq* model above is different from the field coordinate model used in field oriented control. The latter is obtained by selecting the angular frequency ω equal to the rotation angle of the flux vector, see [11, p. 216]. See also Section III A of [14] and [3]. It is clear that to obtain the physical signals from the field coordinate model, we require knowledge of the full state vector. This is, however, not the case for our *dq* model as erroneously pointed out in [13].

Fig. 1. Generated and desired torque.

4) The ab model is sometimes given in terms of stator currents and rotor fluxes, instead of stator and rotor currents. It is straightforward to verify that applying to (4.1) the linear transformation

$$z = \begin{bmatrix} I_2 & 0 & 0 \\ L_s I_2 & L_s I_2 & 0 \\ 0 & 0 & 1 \end{bmatrix} x$$

and choosing $\omega_n = 0$, one obtains the model studied in several recent papers, e.g., [14] and [6].

V. SIMULATION RESULTS

The performance of the control scheme of Proposition 4.3 was investigated by simulations. The numerical values of the four-pole squirrel-cage induction motor used in [7] were chosen, that is, $R_s = 0.687 \Omega$, $R_r = 0.842 \Omega$, $L_s = 84 \text{ mH}$, $L_r = 85.2 \text{ mH}$, $L_{sr} = 81.3 \text{ mH}$, $J = 0.03 \text{ Kg}^2$, and $b = 0.01 \text{ kg}^2 \text{ s}^{-1}$. We present here simulations of a sinusoidal torque reference with load torque $\tau_L = (2.75 + 0.003\dot{q}_1^2) \text{sgn}(\dot{q}_1) + 0.15\dot{q}_1$.

The motor is initially in stand-still with zero initial conditions. The controller is initialized with the values $\lambda_{i,d}(0) = [1, 0]^T$, $\dot{q}_i(0) = [10, 5, -5, 10]^T$, and the parameters $\beta = 1$, $\epsilon = 0.5$. Fig. 1 shows the response of the generated and the desired torque, and in Fig. 2 the rotor currents and their observed values are depicted. Notice that although the observation error converges to zero in less than 0.3 s, output tracking takes longer because of the slower state error convergences, which are shown in Fig. 3. The required control effort is very smooth as shown in Figs. 4 and 5. As seen from the figures, and taking into account the fact that the simulation includes the motor start-up and zero crossing of the generated torque with a highly nonlinear load torque characteristic, the performance of the closed-loop system is quite remarkable.

VI. CONCLUDING REMARKS

We have solved in this note the output feedback torque tracking and flux regulation problem for an induction motor model given in physical $\alpha\beta$ frame. The controller is based on the "energy-shaping" methodology of [16]. It is shown that it can be obtained by "rotating-back" the control law of [17] or vice versa.

The following features of the proposed controller are worth emphasizing.

Fig. 2. Real and observed rotor currents.

Fig. 3. Electrical state error signals.

- In contrast with [14], we *do not* require measurement of rotor variables, typically unavailable in applications.
- The control law is *always well defined* (i.e., there are no singular points), even in start-up. This constitutes an unquestionable advantage with respect to existing results, e.g., [6], where the set of singularities is determined by the design methodology, and consequently is unrelated to the physical structure of the system and very difficult to analyze.
- Tuning and commissioning are very simple. There is essentially only one design parameter ϵ in (3.10), which reflects the confidence in our rotor resistance estimate. Since this estimate is usually bad, we essentially are required to inject some high gain in the loop.
- To overcome the need of knowing the torque load, we can use a parameter estimator as done in [16] and [17]. A more challenging problem is uncertainty in the motor resistances, for which solutions are known only with full state measurement [16], [14]. It is worth pointing out that in [4] some simulations that reveal instability of a scheme including parameter adaptation and (a globally stable) state estimator have been reported.

Fig. 4. Stator voltages.

Fig. 5. A window over the stator voltages.

For speed/position control applications, a slight modification to the present controller must be made. This has been recently reported in [18].

APPENDIX PROOF OF MAIN RESULT

First, notice that the controller (3.7) is obtained from the substitution of (3.2), (3.3) into (3.5). Now, the error equation is given by

$$D(q_5)\dot{e} + C(q_5, \dot{q}_5)e + (\mathcal{R} + \mathcal{K}(q_5, \dot{q}_5))e = S(q_5, \dot{q}_5)\dot{q}_d \quad (\text{A.1})$$

where $\mathcal{K} = \text{diag}\{K_1(\dot{q}_5)I_2, 0, K_2(\dot{q}_5)\}$ and

$$S = \begin{bmatrix} 0 & L_{sr} \mathcal{T} e^{J q_5} \dot{q}_{5,d} \\ 0 & 0 \\ 0 & L_{sr} \dot{q}_{5,d}^T \mathcal{T} e^{J q_5} \end{bmatrix} \in \mathcal{R}^{5 \times 4}.$$

On the other hand, from (3.11) and (2.3), the observation error satisfies the following equation:

$$D_r(q_5)\ddot{\hat{q}}_r + (W_1(q_5)\dot{\hat{q}}_r + L(q_5, \dot{\hat{q}}_5))\dot{\hat{q}}_r + R_r \dot{\hat{q}}_r = 0. \quad (\text{A.2})$$

Consider the quadratic function $V = \frac{1}{2}e^T D(q)e + \frac{1}{2}\dot{q}_r^T \dot{q}_r$ whose time derivative, taking into account the antisymmetry of $\dot{D} - 2C$ and $\dot{D}_r - 2(W_1\dot{q}_5 + L)$, yields

$$\dot{V} = -e^T (\mathcal{R} + \mathcal{K})e + e^T S \dot{q}_r - \dot{q}_r^T R_r \dot{q}_r = -z^T Q z$$

where we have defined $z = [e^T, \dot{q}_r^T]^T$, and

$$Q = \begin{bmatrix} \mathcal{R} + \mathcal{K} & \frac{1}{2}S \\ \frac{1}{2}S^T & R_r \end{bmatrix}.$$

Checking that (3.10) ensures positive definiteness of Q , we conclude that e and \dot{q}_r are bounded and converge to zero. Internal stability is established noting that $\lambda_{r,d}$ is bounded by construction so \dot{q}_r is bounded. Boundedness of $\dot{q}_{5,d}$ follows from the fact that $\dot{q}_{5,d}$ is the output of an asymptotically stable filter with bounded inputs (3.9). $\square\square\square$

Eigenstructure Assignment in Linear Descriptor Systems

Petr Zagalak and Vladimír Kučera

Abstract—Given a linear controllable system $E\dot{x} = Fx + Gu$, we study the limits of linear proportional feedback $u = Kx + v$ in assigning a desired finite and infinite eigenstructure of the closed-loop system $E\dot{x} = (F + GK)x + Gv$. The closed-loop system is not restricted to be regular; its rank makes part of the specifications. Necessary and sufficient conditions are established for the existence of a feedback gain K which assigns the desired eigenstructure, and a procedure is outlined to calculate one such gain.

I. INTRODUCTION

Let

$$E\dot{x} = Fx + Gu \quad (1)$$

be a linear descriptor system where E , F are $n \times n$ matrices, and G is an $n \times m$ matrix of rank m over R , the field of real numbers.

The problem of eigenstructure assignment by linear proportional feedback

$$u = Kx + v \quad (2)$$

where K is an $m \times n$ matrix over R , has had a long history. When E is nonsingular, the eigenstructure of (1) is specified by the invariant polynomials of $sE - F$, or equivalently by the position and structure of the system's finite eigenvalues. Then Rosenbrock [12] showed that a controllable system (1) with controllability indexes c_1, c_2, \dots, c_m (decreasingly ordered by magnitude) can be assigned the eigenstructure given by invariant polynomials $\psi_1(s), \psi_2(s), \dots, \psi_m(s)$ (decreasingly ordered by degree) if and only if the set of inequalities

$$\sum_{i=j}^m \deg \psi_i(s) \leq \sum_{i=j}^m c_i, \quad j = 1, 2, \dots, m \quad (3)$$

are satisfied and equality holds when $j = 1$. This famous result, commonly referred to as the fundamental theorem of state feedback, identifies the limits of feedback (2) in altering the eigenstructure of (1). Alternative proofs were given later by Dickinson [1], Flamm [2], and Kučera [5].

A more general situation arises when E is singular. Then the pencil $sE - F$ has finite as well as infinite elementary divisors, or, equivalently, the system has finite as well as infinite eigenvalues. This means that the system gives rise to exponential as well as impulsive modes. Assuming that $sE - F$ is regular, Kučera and Zagalak [6] generalized Rosenbrock's result in the situation where the desired eigenstructure is specified solely by finite elementary divisors or by invariant polynomials. The other extreme, where only infinite elementary divisors are being assigned, was considered by Zagalak and Kučera [13].

The problem of simultaneously assigning the finite and the infinite eigenstructure was solved by the same authors in [14]. The result says that a regular controllable system (1) with controllability indexes c_1, c_2, \dots, c_m (decreasingly ordered by magnitude) can be assigned

by applying feedback (2) that preserves its regularity, the eigenstructure specified by invariant polynomials $\psi_1(s), \psi_2(s), \dots, \psi_m(s)$ (decreasingly ordered by degree), and by infinite eigenvalue orders d_1, d_2, \dots, d_m (decreasingly ordered by magnitude) if and only if the set of inequalities

$$\sum_{i=j}^m \deg \psi_i(s) + d_i \leq \sum_{i=j}^m c_i, \quad j = 1, 2, \dots, m \quad (4)$$

are satisfied with equality holding when $j = 1$, and

$$d_i = 0, \quad i > m - q \quad (5)$$

where q is the number of infinite zeros of (1). The necessity of (4) was proven already by Jones, Pugh, and Hayton [3] and conditions equivalent to (4) and (5) were given, without proof, in Özçaldıran [10].

The requirement that the resulting feedback system

$$E\dot{x} = (F + GK)x + Gv \quad (6)$$

be regular is too restrictive in many situations. That is why we relax this assumption here and make the rank of $sE - (F + GK)$ a part of the specifications. This will allow for desired eigenstructures specified by a number of invariant polynomials less than n .

II. BASIC CONCEPTS

The system (1) is said to be controllable if $\text{rank } [sE - F \ G] = n$ for all complex s , finite and infinite. For details, see Lewis [8] and Verghese, Lévy, and Kailath [12], and the references given therein.

Let $N(s)$, $D(s)$ be, respectively, $n \times m$, $m \times m$ matrices over $R[s]$, the ring of polynomials in s with coefficients in R , such that

$$[sE - F \ -G] \begin{bmatrix} N(s) \\ D(s) \end{bmatrix} = 0.$$

Then $N(s)$, $D(s)$ are said to form a (right) normal external description of (1) if

i)

$$\begin{bmatrix} N(s) \\ D(s) \end{bmatrix}$$

is a decreasingly column-degree ordered, minimal polynomial basis of $\text{Ker } [sE - F \ -G]$; and

ii) $N(s)$ is a minimal polynomial basis of $A(sE - F)$, where A is a maximal annihilator of G .

See Malabre, Kučera, and Zagalak [9] for details.

Then the controllability indexes of (1) are the column degrees

$$c_i = \deg_i \begin{bmatrix} N(s) \\ D(s) \end{bmatrix}, \quad i = 1, 2, \dots, m$$

of any normal external description of (1). When $\deg_i D(s) > \deg_i N(s)$, we call c_i a proper controllability index of (1).

III. PROBLEM FORMULATION

Let (1) be a controllable system with controllability indexes $c_1 \geq c_2 \geq \dots \geq c_m$, and let q be the number of the proper controllability indexes. We are given r monic polynomials $\psi_1(s), \psi_2(s), \dots, \psi_r(s)$ in $R[s]$ such that $\psi_{i+1}(s)$ divides $\psi_i(s)$, $i = 1, 2, \dots, r-1$, and

IEEE Log Number 9407029.

positive integers $d_1 \geq d_2 \geq \dots \geq d_l$. These polynomials and integers are not arbitrary, they are assumed to satisfy

$$\sum_{i=1}^l \deg \epsilon_i(s) + \sum_{i=1}^l d_i = \sum_{i=1}^+ \epsilon_i^* \quad (7)$$

for some selection $\epsilon_1^* \geq \epsilon_2^* \geq \dots \geq \epsilon_{l+m-n}^*$ of $l+m-n$ controllability indexes of (1) that includes all the proper controllability indexes.

The problem of eigenstructure assignment is then as follows. First establish necessary and sufficient conditions under which a feedback gain K exists in (2) such that $\epsilon_i(s)$'s are the invariant polynomials and d_i 's are the infinite eigenvalue orders of the closed loop system (6). Second if the conditions are verified give a procedure to calculate one such K .

IV. FUNDAMENTAL THEOREM

The following theorem solves the existence part of the eigenstructure assignment problem.

Theorem The eigenstructure assignment problem has a solution if and only if

$$n - m + p + q \leq l \leq n \quad (8)$$

and

$$\sum_{i=1}^l \deg \epsilon_i(s) + d_i \leq \sum_{i=1}^+ \epsilon_i^* \quad i = 1, 2, \dots, l \quad (9)$$

where by convention $d_i = 0$ for $i < p$ and $\epsilon_i^* = 0$ for $i > l+m-n$.

Proof (Necessity) We suppose there exists a feedback gain K such that the eigenstructure of (6) is given by the lists $\epsilon_1(s), \dots, \epsilon_l(s)$ and d_1, \dots, d_l that satisfy (7) for some $\epsilon_1^* \geq \epsilon_2^* \geq \dots \geq \epsilon_{l+m-n}^*$. We wish to prove (8) and (9).

To handle the finite and the infinite eigenstructure in a uniform way we shall apply the conformal mapping

$$u = \frac{s}{s-a} \quad (10)$$

where $a \neq 0$ is a complex number that is not an eigenvalue of (6).

Let $\Lambda(s) = D(s)$ be a normal external description of (1). Then

$$[sI - F - G(K - G)] \begin{bmatrix} \Lambda(s) \\ D(s) - K\Lambda(s) \end{bmatrix} = 0 \quad (11)$$

so that $\Lambda(s) = D(s) - K\Lambda(s)$ is a normal external description of the closed loop system (6). Since controllability is invariant under the action of feedback (2) the systems (1) and (6) are controllable with the same controllability indexes.

We define

$$\begin{bmatrix} B(u) \\ C(u) \end{bmatrix} = \begin{bmatrix} \Lambda\left(\frac{u}{u-1}\right) \\ D\left(\frac{u}{u-1}\right) - K\Lambda\left(\frac{u}{u-1}\right) \end{bmatrix} \quad \text{diag}[(u-1)^{-1}, \dots, (u-1)^{-1}] \quad (12)$$

This is a polynomial matrix over $R[u]$ which is irreducible and column proper with column degrees $\epsilon_1, \epsilon_2, \dots, \epsilon_l$. Obviously, $C(u)$ also has column degrees $\epsilon_1, \epsilon_2, \dots, \epsilon_l$. We suppose without loss of generality that the matrix F has been brought to the form

$$E = \begin{bmatrix} E_1 \\ 0 \end{bmatrix} \quad (13)$$

with F_1 of full row rank. Say f . We define

$$P(u) = -Q(u) = \text{diag} \left[\underbrace{u-1, \dots, u-1}_f, 1, \dots, 1 \right] \left[\frac{au}{u-1} F - (F + G)K - G \right]$$

This is again a polynomial matrix over $R[u]$ which is irreducible and row proper.

It follows from (11) that

$$[P(u) - Q(u)] \begin{bmatrix} B(u) \\ C(u) \end{bmatrix} = 0$$

Lemma 1 of the Appendix implies that the rank deficiency of $P(u)$ and $Q(u)$ are the same, namely

$$\text{rank } C(u) = l + m - n$$

since $\text{rank } P(u) = l$ by assumption. Further the invariant polynomials of $B(u)$ equal those of $Q(u)$, namely

$$\epsilon_1(u) = 1, \dots, \epsilon_f(u) = 1$$

$$\epsilon_{f+1}(u) = u-1, \dots, \epsilon_{f+m-n}(u) = u-1$$

$$\epsilon_{f+m-n+1}(u) = 1, \dots, \epsilon_l(u) = 1$$

and the nonunit invariant polynomials of $C(u)$ are equal to those of $P(u)$.

$$\omega_1(u) = \bar{\epsilon}_1(u)(u-1)^{l_1}, \dots, \omega_f(u) = \bar{\epsilon}_f(u)(u-1)^{l_f}$$

$$\omega_{f+1}(u) = \bar{\epsilon}_{f+1}(u), \dots, \omega_{f+m-n}(u) = \bar{\epsilon}_{f+m-n}(u) \quad (14)$$

where

$$\bar{\epsilon}_i(u) = (u-1)^{l_i - \epsilon_i} \epsilon_i \left(\frac{-au}{u-1} \right) \quad (15)$$

Since (12) is irreducible $\epsilon_i(u)$ is prime to $\omega_j(u)$ $i = 1, 2, \dots, f + m - n$. Hence $p \leq f + m - n - q$. Since $l \leq n$ we have (8).

Now suppose without loss of generality that it is the first $f + m - n$ columns of $C(u)$ that are $R(u)$ linearly independent. Let $\bar{C}(u)$ be the submatrix of $C(u)$ formed by these columns. Then by assumption (7) $\bar{C}(u)$ is column proper with column degrees $\epsilon_1^* \geq \epsilon_2^* \geq \dots \geq \epsilon_{f+m-n}^*$. Then the product $\omega_j(u) = \omega_{f+m-n+1}(u)$ is the greatest common divisor of all minors of $\bar{C}(u)$ of order $f + m - n - j + 1$ which implies

$$\sum_{i=1}^+ \deg \omega_i(u) = \sum_{i=1}^+ \deg \bar{\epsilon}_i(u) + d \leq \sum_{i=1}^+ \epsilon_i^* \quad i = 1, \dots, f + m - n \quad (16)$$

where $d = 0$ for $i > p$ has been defined for convenience of summation.

Lemma 1 implies that $\bar{\epsilon}_i(u) = 1$ for $i = f + m - n + 1, \dots, l$. Adopting the convention that $\epsilon_i^* = 0$ for $i > f + m - n$ we can extend the upper summation limit in (16) to l . Finally since $\deg \bar{\epsilon}_i(u) = \deg \epsilon_i(s)$ $i = 1, 2, \dots, l$ the inequalities (9) are verified.

(Sufficiency) We consider a list of monic polynomials $\epsilon_1(s), \epsilon_2(s), \dots, \epsilon_l(s)$ in $R[s]$, a list of positive integers d_1, d_2, \dots, d_l and a subset $\epsilon_1^*, \epsilon_2^*, \dots, \epsilon_{l+m-n}^*$ of the controlability indexes $\epsilon_1, \epsilon_2, \dots, \epsilon_l$ that satisfy (7), (8) and (9). We are going to construct a matrix K over R such that the eigenstructure of (6) will be given by these two lists.

To this end we apply to $\epsilon_i(s)$ the inverse transformation of (10) to get the polynomials $\bar{\epsilon}_i(u)$ defined in (15). Clearly $\deg \bar{\epsilon}_i(u) = \deg \epsilon_i(s)$ $i = 1, 2, \dots, l$. It follows from (9) for $j = f + m - n + 1$ that $\bar{\epsilon}_i(u) = \epsilon_i(s) = 1$ for $i > f + m - n$.

Let $N(s)$, $D(s)$ be a normal external description of (1). Applying the same transformation to

$$\begin{bmatrix} N(s) \\ D(s) \end{bmatrix}$$

and $[sE - F - G]$, where E assumes the form (13), we obtain matrices $A(w)$, $B(w)$ that satisfy

$$\text{diag}[\underbrace{w-1, \dots, w-1}_f, 1, \dots, 1] \left[\frac{aw}{w-1} E - F - G \right] \cdot \begin{bmatrix} B(w) \\ A(w) \end{bmatrix} = 0. \quad (17)$$

As in (12),

$$\begin{bmatrix} B(w) \\ A(w) \end{bmatrix}$$

is a polynomial matrix over $R[w]$ that is irreducible and column proper with column degrees c_1, c_2, \dots, c_m .

Now we construct the matrix

$$\tilde{C}(w) = \text{diag}[\phi_1(w), \dots, \phi_{r+m-n}(w)]$$

where $\phi_i(w)$ are the polynomials defined in (14) and (15). In view of (7) and (9), we can apply to $\tilde{C}(w)$ Lemma 2 of the Appendix. There results a matrix $\hat{C}(w)$ having the same invariant polynomials $\phi_1(w), \dots, \phi_{r+m-n}(w)$, and that is column proper with column degrees $c_1^* \geq c_2^* \geq \dots \geq c_{r+m-n}^*$. We further define the $m \times m$ matrix

$$\hat{C}(w) = \begin{bmatrix} \hat{C}(w) & 0 \\ 0 & 0 \end{bmatrix}.$$

Let S be a permutation matrix such that the first $r+m-n$ columns of $B(w)S$ have degrees $c_1^*, c_2^*, \dots, c_{r+m-n}^*$. Consider the matrix

$$\begin{bmatrix} B(w)S \\ \hat{C}(w) \end{bmatrix}. \quad (18)$$

If (18) is irreducible, we put $C(w) = \hat{C}(w)S^{-1}$. If it is not, there must be a zero at $w = 1$ common to $B(w)S$ and $\hat{C}(w)$. This implies a zero column among the first p columns of (18). As (8) holds and the last $r+m-n-p$ columns of $\hat{C}(w)$ are linearly independent, there exists a nonsingular and constant matrix T such that

$$\begin{bmatrix} B(w)S \\ \hat{C}(w)T \end{bmatrix}$$

is irreducible. Then we put $C(w) = \hat{C}(w)TS^{-1}$. In either case, the matrix

$$\begin{bmatrix} B(w) \\ C(w) \end{bmatrix} \quad (19)$$

is irreducible and column proper with column degrees c_1, c_2, \dots, c_m . Applying the transformation (10) to (19), we obtain the matrix

$$\begin{bmatrix} N(s) \\ H(s) \end{bmatrix} = \begin{bmatrix} B \left(\frac{s}{s-a} \right) \\ C \left(\frac{s}{s-a} \right) \end{bmatrix} \text{diag}[(s-a)^{-1}, \dots, (s-a)^{-m}].$$

This matrix is irreducible, column proper, and its column degrees are equal to c_1, c_2, \dots, c_m .

Let us now consider the equation

$$XD(s) + YN(s) = H(s). \quad (20)$$

Since the matrices

$$\begin{bmatrix} N(s) \\ D(s) \end{bmatrix}, \quad \begin{bmatrix} N(s) \\ H(s) \end{bmatrix}$$

are both irreducible and column proper with column degrees c_1, c_2, \dots, c_m and $N(s)$, $D(s)$ is a normal external description,

the rows of these matrices span the same R -linear spaces. Then, by Lemma 3 of the Appendix, equation (20) has a constant solution pair X, Y such that X is nonsingular. Thus, $K = -X^{-1}Y$ qualifies as a feedback gain that assigns the desired eigenstructure to $sE - (F + GK)$. This immediately follows from Lemma 1.

V. CONSTRUCTION

We summarize the major steps of the sufficiency part of the proof of the Theorem, which provide a construction for K .

a) Given E, F, G with E having the form (13), calculate polynomial matrices $A(w), B(w)$ such that (17) holds where $B(w)$ and

$$\begin{bmatrix} B(w) \\ A(w) \end{bmatrix}$$

are irreducible and column proper, and

$$\begin{bmatrix} B(w) \\ A(w) \end{bmatrix}$$

is decreasingly column-degree ordered.

b) Read out c_1, c_2, \dots, c_m , the column degrees of

$$\begin{bmatrix} B(w) \\ A(w) \end{bmatrix}$$

and identify the subset of q proper controllability indexes.

c) Choose $\psi_1(s), \psi_2(s), \dots, \psi_r(s)$ and d_1, d_2, \dots, d_p and $c_1^*, c_2^*, \dots, c_{r+m-n}^*$ that satisfy (7) and check for the existence of K using (8) and (9).

d) Construct an $m \times m$ polynomial matrix $C'(w)$ having the invariant polynomials $\phi_i(w)$ defined in (14) and (15), and such that the composite matrix

$$\begin{bmatrix} B(w) \\ A(w) \end{bmatrix}$$

is irreducible and column proper with column degrees c_1, c_2, \dots, c_m .

e) Find a constant solution pair X, Y of the equation

$$XA(w) + YB(w) = C'(w)$$

such that X is nonsingular.

f) Put $K = -X^{-1}Y$.

Of course, there may be feedback gains other than K that solve the problem.

VI. CONCLUSIONS

The limits of proportional state feedback (2) in altering the eigenstructure of the linear controllable system (1) have been established in Theorem 1, under the assumption (7) that the total number of the dynamical modes desired is equal to a sum of $r+m-n$ controllability indexes. These limits can be summarized as follows.

- The eigenvalues can be placed at any position.
- The measure of regularity $r = \text{rank}(sE - F - GK)$ is bounded by (8).
- At most, $r+m-n$ cyclic chains can be associated with each finite eigenvalue.
- At most, $r+m-n-q$ cyclic chains can be associated with the infinite eigenvalue, because q is the number of infinite zero chains.
- The sizes of the cyclic chains are limited from below by (9).
- When E is nonsingular, all controllability indexes are proper, $q = m$, and no infinite eigenvalue can be assigned.

The controllability assumption can be relaxed. A generalization of the theorem to partially controllable systems is under study. We also conjecture that (7) is a necessary restriction on the eigenstructure desired whenever $r = n$.

APPENDIX

Lemma 1 [15] Let $P(s)$, $Q(s)$ and $B(s)$, $C(s)$ be polynomial matrices over $R[s]$ of respective size $n \times n$, $n \times m$ and $n \times m$, $m \times m$ such that

$$[P(s) \quad -Q(s)] \begin{bmatrix} B(s) \\ C(s) \end{bmatrix} = 0$$

here

$$[P(s) \quad -Q(s)] \text{ and } \begin{bmatrix} B(s) \\ C(s) \end{bmatrix}$$

are irreducible, and $\text{rank } Q(s) = m$. Then,

- the matrices $C(s)$ and $P(s)$ have the same rank deficiency
- the matrices $B(s)$ and $Q(s)$ have the same invariant polynomials
- the matrices $C(s)$ and $P(s)$ have the same nonunit invariant polynomials

Lemma 2 [15] Let $\bar{C}(s)$ be a column proper polynomial $l \times l$ matrix over $R[s]$ and let $\alpha_1(s) \alpha_2(s) \dots \alpha_k(s)$ be its invariant polynomials arranged so that $\alpha_{j+1}(s)$ divides $\alpha_j(s)$, $j = 1, 2, \dots, l-1$. Let $\epsilon_1 \geq \epsilon_2 \geq \dots \geq \epsilon_k$ be nonnegative integers such that

$$\sum_{i=1}^l \deg \alpha_i(s) = \sum_{i=1}^k \epsilon_i, \quad j = 1, 2, \dots, l$$

with equality holding when $j = 1$.

Then there exist unimodular matrices $U_1(s)$ and $U_2(s)$ such that the matrix

$$\bar{C}(s) = U_1(s)C(s)U_2(s)$$

is column proper with column degrees $\epsilon_1, \epsilon_2, \dots, \epsilon_k$.

Lemma 3 [7] Let $D(s)$, $N(s)$ and $H(s)$ be respectively $m \times m$, $n \times m$ and $m \times m$ polynomial matrices over $R[s]$. Then the equation

$$N(s)D(s) + Y(s)N(s) = H(s)$$

has a solution pair N, Y over R such that N is nonsingular if and only if the rows of the matrices

$$\begin{bmatrix} N(s) \\ D(s) \end{bmatrix} \quad \begin{bmatrix} N(s) \\ H(s) \end{bmatrix}$$

span the same R linear spaces.

Robust Regulation in the Presence of Norm-Bounded Uncertainty

J. Abedor, K. Nagpal, P. P. Khargonekar and K. Poolla

Abstract—We consider robust regulation (against steps and sinusoids) in the presence of unstructured uncertainty. The unstructured uncertainty is norm bounded by a constant that is given *a priori*. This problem is equivalent to a certain multiobjective problem where one objective is robust regulation and the other is the standard objective of \mathcal{H}_∞ suboptimal control. It is shown that a solution to this problem exists if and only if the standard \mathcal{H}_∞ problem admits a solution and certain matrix inequalities are satisfied. These solvability conditions are readily computable. Controller synthesis is also addressed.

1. INTRODUCTION

Before discussing the problem that is the focus of this note, we briefly review the standard problem of robust regulation. This problem will be defined with respect to Fig. 1. Here P is the plant and K is the controller to be designed. Both are finite dimensional linear time invariant systems, as are all systems throughout this note. In the figure, u is the exogenous input, y is the controlled output, v is the control input and q is the measurement. The signal q is assumed to be measured. Without loss of generality we assume, in fact, that q consists of the first l channels of y .

Suppose now that we are interested in regulating against sinusoids with frequencies $\omega_1, \omega_2, \dots, \omega_N$. Let \mathcal{F} denote the vector space of signals consisting of linear combinations of these sinusoids (\mathcal{F} will include the class of constant signals if one of these frequencies is zero). The robust regulation synthesis problem is the problem of designing an internally stabilizing controller such that the closed

Fig. 1. Setup for the robust regulation problem.

loop system asymptotically rejects \mathcal{F} from w to z , and does so locally robustly. The problem, in other words, is to design K so that

- 1) K internally stabilizes P .
- 2) $T_{zw}(j\omega_k) = 0$ for $k = 1, \dots, N$, and
- 3) property 2) holds for all plants in some neighborhood of P in the graph topology.

In part 2), T_{zw} is the closed-loop transfer function from w to z . The requirement that this transfer function evaluate to zero at frequencies $\omega_1, \dots, \omega_N$ is equivalent to the requirement that \mathcal{F} be asymptotically rejected from w to z . Part 3) is the local robustness requirement.

Now consider Fig. 2. In this figure the plant P_Δ is formed from the interconnection of the nominal plant P (augmented with the additional input w_1 and the additional output z_1) and the unstructured norm-bounded uncertainty block Δ . Again K is the controller to be designed, u is the control input, and y is the measurement. The exogenous input is w_2 , and z_2 is the controlled output, which again is assumed to be measured. Without loss of generality, we again assume that z_2 consists of the first l channels of y .

The following controller synthesis problem is addressed in this paper: given a real number $\gamma > 0$, design a controller K such that for all stable Δ with $\|\Delta\|_\infty \leq 1/\gamma$,

- 1) K internally stabilizes P_Δ .
- 2) $T_{z_2 w_2}(j\omega_k) = 0$ for $k = 1, \dots, N$, and
- 3) property 2) holds for all plants in some neighborhood of P_Δ in the graph topology.

This problem will be called the problem of robust regulation in the presence of norm-bounded uncertainty (RRNBU). It differs fundamentally from the standard problem of robust regulation in that we are requiring the controller to solve the robust regulation problem for an *a priori* given (possibly large) plant uncertainty set. To emphasize this point, we note that any controller that solves the robust regulation problem for the nominal plant P will, by virtue of local robustness, solve the RRNBU problem for small enough $1/\gamma$. However there are no guarantees on the size of $1/\gamma$. The amount of unstructured uncertainty that a particular robustly regulating controller can tolerate may be arbitrarily small. Given a value γ , the results of this note enable one to efficiently check whether the corresponding RRNBU problem is solvable, and in the event that it is, construct a controller that solves the problem. Results are given for both the state-feedback and output-feedback cases.

It is shown in Section III-A that the RRNBU problem is equivalent to a certain multiobjective problem that will be discussed in the context of Fig. 3. The multiobjective problem is to design a single controller that solves both the robust regulation problem (from w_2 to z_2 , with $w_1 \equiv 0$) and the \mathcal{H}_∞ suboptimal control problem (from w_1 to z_1 , with $w_2 \equiv 0$). Precisely: given a real number $\gamma > 0$, the problem is to design a controller K such that

- 1) K internally stabilizes P .
- 2) $T_{z_2 w_2}(j\omega_k) = 0$ for $k = 1, \dots, N$.
- 3) property 2) holds for all plants in some neighborhood of P in the graph topology, and
- 4) $\|T_{z_1 w_1}\|_\infty < \gamma$.

Objectives 1) through 3) constitute the standard problem of robust regulation as defined previously. Objective 4) is the usual \mathcal{H}_∞ norm

Fig. 2. Setup for the problem of robust regulation in the presence of norm-bounded uncertainty.

requirement. This multiobjective problem will be called the problem of robust regulation with an \mathcal{H}_∞ constraint (RR \mathcal{H}_∞ C).

The robust regulation objective is a special case of the robust regulator problem with internal stability which was investigated extensively in the 1970s using a variety of approaches. Asymptotic tracking and asymptotic disturbance rejection are special cases of this problem. This was one of the central problems to be solved using geometric control theory. See, for example, [12], [22], [23], and the references therein. Davison and his coworkers used a matrix approach to solve this problem in [6]–[8]. The robust regulator problem with internal stability has also been investigated in the frequency domain [3], [5], [11]. One of the main results of this research is the well-known “internal model principle.” The literature on this problem is extensive and the interested reader should consult these and related references for further details.

The second objective of the RR \mathcal{H}_∞ C multiobjective problem is the standard problem of \mathcal{H}_∞ control theory initiated by Zames [25]. This problem has also been extensively investigated using both state-space and frequency-domain techniques. The book by Francis [10] contains an account of the early frequency-domain/operator-theoretic approach to this problem as well as a large bibliography. For the state-space approach, see [9], [20], and the references therein.

Problems similar to the RR \mathcal{H}_∞ C problem have been considered by Vidyasagar [21], Sugie and Vidyasagar [19], Hara and Sugie [13], [18], and Wu and Mansour [24]. In all of these notes, a frequency-domain interpolation-theoretic approach is taken. One possible shortcoming of this approach is that the resulting controllers can be of unnecessarily high McMillan degree. In an earlier conference paper [2], we gave a solution to the RR \mathcal{H}_∞ C in the special case that only steps were to be regulated against.

In this note, we take a state-space approach to the RR \mathcal{H}_∞ C problem. One merit of our approach is that the solvability conditions are given directly in terms of plant data and the solutions to at most two algebraic Riccati equations. It is shown that the RRNBU or the RR \mathcal{H}_∞ C problem is solvable if and only if the suboptimal \mathcal{H}_∞ problem is solvable and N matrix inequalities hold, where N is the number of frequencies to be regulated against. The matrices are all of size l , where l is the dimension of z_2 , i.e., the number of (scalar) signals to be regulated.

As is well known, the robust regulation objective is equivalent to requiring that the controller contain an appropriate “internal model” (see, for example, [7], [12]). Thus an obvious approach to the RR \mathcal{H}_∞ C problem is to incorporate this internal model into the generalized plant P and then solve a standard \mathcal{H}_∞ control problem. However, a significant difficulty arises—and this is why the problem is interesting—the unstable modes of the internal model are unobservable at z_1 . Since these unstable modes are on the imaginary axis, this difficulty cannot be easily circumvented. One approach is to use Riccati inequality methods as in [14]–[16]. Our results are closely related to and can be derived from the recent work of Scherer [16]; however, the control theoretic problem contexts are

Fig. 3 Setup for the problem of robust regulation with an \mathcal{H}_∞ constraint

quite different. The importance of the asymptotic regulation problem in control theory is well established, and therefore it is important to derive an explicit solution to the RRNBUC problem.

The remainder of this note is organized as follows. Notation is set in the next section, results (along with proofs) are presented in Section III, and some background material on robust regulation is collected together in the appendix.

II. NOTATION

The set of all real numbers is \mathcal{R} , the set of all imaginary numbers is $j\mathcal{R}$, and the set of all complex numbers is \mathcal{C} . For a matrix M , M' is its transpose, M^* is its conjugate transpose, $\text{spec}(M)$ is its set of eigenvalues, and $\rho(M)$ is its spectral radius. The size of a matrix will be indicated by a subscript if it is not clear from the context. We abbreviate the finite dimensional linear time invariant system $\dot{x} = Ax + Bu$, $y = Cx + Du$ by

$$I_f \sim \left[\begin{array}{c|c} A & B \\ \hline C & D \end{array} \right]$$

where I_f is the transfer function mapping input u to output y . Finally, a controller is said to be admissible for a plant if the resulting closed-loop system is both well posed and internally stable.

III. MAIN RESULTS

In the first part of this section we show that the RRNBUC problem and the RRH ∞ C problem are equivalent. Then, making use of this equivalence, we state and prove the main results.

A. Equivalence of RRNBUC and RRH ∞ C Problems

Theorem 3.1 Let K be any finite dimensional linear time invariant controller. Then K solves the RRNBUC problem for P if and only if K solves the RRH ∞ C problem for P .

Proof (\Rightarrow) Let K solve the RRH ∞ C problem. Then K is admissible for P and renders $\|T_{11}\|_\infty < \infty$. Thus, by the small gain theorem, the closed-loop system of Fig. 2 is internally stable for all stable Δ with $\|\Delta\|_\infty < 1/\|T_{11}\|_\infty$. By Corollary A.3, then, K solves the robust regulation problem for all stable Δ with $\|\Delta\|_\infty \leq 1/\|T_{11}\|_\infty$. Hence, K solves the RRNBUC problem.

(\Leftarrow) Suppose K solves the RRNBUC problem for P . Then, in particular, the closed-loop system of Fig. 2 is internally stable for all stable Δ such that $\|\Delta\|_\infty \leq 1/\|T_{11}\|_\infty$, which implies, by the necessity part of the small gain theorem, that $\|T_{11}\|_\infty < \infty$. Moreover, because K solves the robust regulation problem when $\Delta = 0$, K solves the robust regulation problem for P . Thus, K solves the RRH ∞ C problem.

Solution: State Feedback Case

In this section, the RRH ∞ C problem, hence the RRNBUC problem, is solved in the case where the entire state is available for feedback. We make the following standard assumptions on P :

- SF1 $C_1 = I$ and $D_{21} = 0$ (state feedback)
- SF2 (A, B_2) is stabilizable
- SF3 (C_1, A, B_1) has no uncontrollable/unobservable modes on the imaginary axis
- SF4 $D_{12}'C_1 = 0$ and $D_{11}'D_{11} = I$

The next definition enables Theorem 3.3 to be stated concisely.

Definition 3.2 (internal model matrices) A and B are internal model matrices associated with the robust regulation problem determined by $\omega_1, \dots, \omega_N$ if these matrices satisfy

- 1) $\text{spec}(A) = \{\pm j\omega_1, \dots, \pm j\omega_N\}$
- 2) every eigenvalue of A has multiplicity l
- 3) A is diagonalizable, and
- 4) (A, B) is controllable

A discussion of the role that these matrices play in robust regulation can be found in Appendix A. The state feedback result follows.

Theorem 3.3 Let the plant P of Fig. 3 satisfy the standard assumptions SF1–SF4. Then the following are equivalent:

- i) There exists a controller admissible for P that solves the robust regulation problem from u to z_1 at the frequencies $\omega_1, \dots, \omega_N$ while also making $\|T_{11}\|_\infty < \infty$ (the RRH ∞ C problem)
- ii) There exists a controller admissible for P that renders $\|T_{11}\|_\infty < \infty$ and

$$T_k B B' T_k' \preceq T_k B_1 B_1' T_k' \quad (1)$$

for all $l = 1, \dots, N$. Here $I_l = [I_l 0](j\omega_l I - A)^{-1} A = A + (B_1 B_1' - B B')\lambda$ and λ is the positive semidefinite stabilizing solution to

$$\lambda \lambda + \lambda(A + \lambda(B_1 B_1' - B B'))\lambda + C_1 C_1' = 0 \quad (2)$$

Moreover, if either (hence both) of these conditions hold, then a controller K that solves the RRH ∞ C problem for P is given by

$$K \sim \left[\begin{array}{c|c} -\frac{1}{B' I W^{-1}} & -\frac{B[I_l 0]}{B' \lambda - \frac{B[I_l 0]}{B' I W^{-1}} I} \end{array} \right] \quad (3)$$

Here I is the unique solution to $I(A - A) = B[I_l 0]$, the internal model matrices A and B satisfy 1)–4) of Definition 3.2, and W is a positive definite matrix that satisfies the Lyapunov inequality

$$AW + W(A + \lambda(B_1 B_1' - B B')) + I B B' I' = 0 \quad (4)$$

Before proving this theorem, we address the problem of constructing the controller given by (3). To synthesize this controller, one must solve a Riccati equation for λ , a linear matrix equation for I , and a linear matrix inequality (LMI) for W (computing λ and I is straightforward. (Note that I always exists since 1 and A have no eigenvalues in common.) In the simple but important case where the only frequency to be regulated against is $\omega_1 = 0$, computing W is very easy. In this case, $A = 0$, so any positive definite matrix is an acceptable W . The general case is also tractable. LMIs are finite-dimensional convex feasibility problems and thus can be readily computed [4]. We emphasize that if i) or ii) of the theorem statement hold, then we are assured that a solution to this LMI exists.

Now we turn our attention to the proof of Theorem 3.3.

Proof (i \Rightarrow ii) Suppose there exists a controller K that solves the RRH ∞ C problem for P . We first show that, as a consequence, K solves the RRH ∞ C problem for the plant

$$P_{\text{aug}} \sim \left[\begin{array}{c|c} A + B B' \lambda & B_1 - B \\ \hline B_1' \lambda & 0 \\ I & 0 \end{array} \right]$$

Because K solves the \mathcal{H}_∞ problem for P , there exists a solution λ to the algebraic Riccati equation (2). This is part of the full information

Fig. 4. The closed-loop system consisting of plant P_{imp} and controller K . P_{imp} consists of stable system \bar{P} with state-feedback $B_2'X$.

result in [9, p. 836]. Therefore by the Redheffer lemma ([9, Lemma 9]), K also solves the \mathcal{H}_∞ problem for

$$\left[\begin{array}{c|cc} A + \gamma^{-2} B_1 B_1' X & B_1 & B_2 \\ \hline B_2' X & 0 & I \\ I & 0 & 0 \end{array} \right]$$

which is precisely the plant P_{imp} . Moreover, because K solves the robust regulation problem for P , K also solves the robust regulation problem for any plant for which it is an admissible controller (because it has the right internal model). This is just a restatement of Corollary A.3. In particular, K solves the robust regulation problem for P_{imp} . Thus, K solves for the RRH_∞ C problem for P_{imp} , as claimed.

Before continuing with the formal proof, we give an intuitive argument which will clarify the role of the coupling conditions (1). Let us write P_{imp} as the stable system \bar{P} (stable because X is the stabilizing Riccati solution) with state-feedback $\xi = B_2' X x + u$, and close the controller loop with K as shown in Fig. 4. The controller K solves the robust regulation problem for P_{imp} , so sinusoids of frequency ω_k are rejected from any input of P_{imp} to v_2 . In particular, sinusoids are rejected from r to v_2 . Now we apply a unit amplitude sinusoid of frequency ω_k to input r . Since v_2 is asymptotically zero we have, in the frequency domain

$$0 = \bar{P}_{v_2, r} v + \bar{P}_{v_2, \xi} \xi.$$

In general, in order for this equation to be satisfied, ξ will have to have some nonzero amplitude, say γ_k . Since $v_1 = \xi$, therefore, v_1 will also have amplitude γ_k . Thus, $\|T_{v_1, r}\|_\infty \geq \gamma_k$. This argument goes through for every frequency that is regulated against, so the robust regulation constraint defines N lower bounds on $\|T_{v_1, r}\|_\infty$. The matrix inequalities (1) are satisfied only if all N lower bounds are less than γ . We first establish some notation before making these arguments precise. Open-loop transfer functions of \bar{P} will be denoted by the symbol \bar{P} with the appropriate subscripts. Thus, the open-loop transfer function from r to v_2 will be denoted by $\bar{P}_{v_2, r}$. Closed-loop transfer functions, i.e., transfer functions of the feedback system of Fig. 4, will be denoted in the usual way; thus $T_{v_1, r}$ denotes the closed-loop transfer function from r to v_1 .

Now we investigate the feedback system of Fig. 4 in more detail. In the frequency domain $\xi = T_{\xi, r}(s)r$, but since $v_1 = \xi$ (see Fig. 4), we may also write $\xi = T_{v_1, r}(s)r$. We also have $v_2 = \bar{P}_{v_2, r}(s)r + \bar{P}_{v_2, \xi}(s)\xi$, hence, substituting for ξ , $v_2 = \bar{P}_{v_2, r}(s)r + \bar{P}_{v_2, \xi}(s)T_{v_1, r}(s)r$. Thus

$$T_{v_2, r}(s) = \bar{P}_{v_2, r}(s) + \bar{P}_{v_2, \xi}(s)T_{v_1, r}(s).$$

Now let ω_k be a frequency that is regulated against. Because K solves the robust regulation problem for P_{imp} , we know that $T_{v_2, r}(j\omega_k) = 0$, hence

$$\bar{P}_{v_2, r}(j\omega_k) + \bar{P}_{v_2, \xi}(j\omega_k)T_{v_1, r}(j\omega_k) = 0. \quad (5)$$

We note that $\bar{P}_{v_2, r}(j\omega_k) = T_k B_1$ and $\bar{P}_{v_2, \xi}(j\omega_k) = T_k B_2$, where T_k is defined in ii) of the theorem statement. Thus (5) can be rewritten

as $T_k B_1 + T_k B_2 T_{v_1, r}(j\omega_k) = 0$, which implies

$$T_k B_2 T_{v_1, r}(j\omega_k) T_{v_1, r}(j\omega_k)^* B_2' T_k^* = T_k B_1 B_1' T_k^*. \quad (6)$$

From Theorem A.1 we know that P_{imp} cannot have transmission zeros from u to v_2 at the frequency $j\omega_k$. Thus, because transmission zeros are invariant under state-feedback, \bar{P} cannot have transmission zeros from ξ to v_2 , i.e., the matrix

$$\begin{bmatrix} j\omega_k I - \bar{A} & B_2 \\ [I \ 0] & 0 \end{bmatrix}$$

must have independent rows. This, in turn, implies that $T_k B_2$ has independent rows. In addition, because $\|T_{v_1, r}\|_\infty < \gamma$, we also know that $\gamma^2 I - T_{v_1, r}(j\omega_k) T_{v_1, r}(j\omega_k)^* > 0$. These two facts imply that $\gamma^2 T_k B_2 B_2' T_k^* > T_k B_2 T_{v_1, r}(j\omega_k) T_{v_1, r}(j\omega_k)^* B_2' T_k^*$. Now bring in (6) to conclude $\gamma^2 T_k B_2 B_2' T_k^* > T_k B_1 B_1' T_k^*$.

(ii \Rightarrow i). The first step is to show that

$$v^* (\gamma^{-2} L B_1 B_1' L' - L B_2 B_2' L') v < 0 \quad (7)$$

for any left eigenvector v of \bar{A} . With this in mind let v be a left eigenvector of \bar{A} and suppose that the corresponding eigenvalue is $j\omega_k$, so

$$v^* \bar{A} = j\omega_k v^*. \quad (8)$$

We recall from ii) of the theorem statement that L is defined by $L\bar{A} - \bar{A}L = B[I \ 0]$. Multiplying this equation through on the left by v^* , using (8), and then rearranging, we obtain $-v^* L = v^* B[I \ 0](j\omega_k I - \bar{A})^{-1}$. Using the definition of T_k this can be rewritten as

$$-v^* L = v^* B T_k. \quad (9)$$

Now from ii) of the theorem, we have $\gamma^{-2} T_k B_1 B_1' T_k^* - T_k B_2 B_2' T_k^* < 0$. Because $v^* B \neq 0$ (since, by Theorem A.2, the internal model (\bar{A}, B) is controllable), it follows that

$$\gamma^{-2} v^* B T_k B_1 B_1' T_k^* B' v - v^* B T_k B_2 B_2' T_k^* B' v < 0.$$

Hence, by (9), $\gamma^{-2} v^* L B_1 B_1' L' v - v^* L B_2 B_2' L' v < 0$, thus proving the claim.

Next, we bring a result of Scherer ([17, p. 128, Theorem 4]) to conclude that, by virtue of inequality (7), there exists a $W > 0$ such that

$$AW + W\bar{A}' + \gamma^{-2} L B_1 B_1' L' - L B_2 B_2' L' < 0.$$

Thus the controller K given in the theorem statement is well defined. Next, we show that this controller solves the \mathcal{H}_∞ problem for P . If the controller loop of G_{imp} is closed with K we obtain

$$T_{v_1, r} \sim \left[\begin{array}{c|c} \bar{A} - B_2 B_2' L' W^{-1} L & B_2 B_2' L' W^{-1} \\ \hline \bar{B}[I \ 0] & A \end{array} \middle| \begin{array}{c} B_1 \\ 0 \end{array} \right].$$

A change of coordinates via $\begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}$ results in

$$T_{v_1, r} \sim \left[\begin{array}{c|c} \bar{A} & -B_2 B_2' L' W^{-1} \\ \hline 0 & \bar{A} - L B_2 B_2' L' W^{-1} \end{array} \middle| \begin{array}{c} B_1 \\ L B_1 \end{array} \right]$$

which can be simplified by eliminating stable unobservable modes to yield

$$T_{v_1, r} \sim \left[\begin{array}{c|c} \bar{A} - L B_2 B_2' L' W^{-1} & L B_1 \\ \hline -B_2' L' W^{-1} & 0 \end{array} \right] =: \left[\begin{array}{c|c} \hat{A} & \hat{B} \\ \hline \hat{C} & 0 \end{array} \right].$$

We note that

$$\begin{aligned} & \Gamma' W^{-1} + W^{-1} A + \gamma^{-2} W^{-1} B B' W^{-1} + C' C \\ &= W^{-1} (A W + W A' + \gamma^{-2} L B_1 B_1' L' - I B_2 B_2' L') W^{-1} \\ &< 0 \end{aligned}$$

where the inequality is a consequence of (4). It follows from the bounded real lemma (the algebraic Riccati inequality analysis result—see for example [26, Lemma 2.2]) that K solves the \mathcal{H}_∞ problem for G_{imp} . Thus, again bringing in Redheffer ([9, Lemma 9]), K also solves the \mathcal{H}_∞ problem for P . In addition, since K has the internal model structure of Theorem A.2, K also solves the robust regulation problem for P ; hence the $\text{RRH}_\infty\text{C}$ problem for P .

C. Solution: Output Feedback Case

In this section the $\text{RRH}_\infty\text{C}$ problem (hence the RRNBU problem) is solved in the output feedback case. We make the following standard assumptions on P :

- OF1: (A, B_2) is stabilizable and (C, A) is detectable.
- OF2: (C_1, A, B_1) has no uncontrollable/unobservable modes on the imaginary axis.
- OF3: $D_1' C_1 = 0$ and $D_1' D_1 = I$.
- OF4: $B_1 D_1' = 0$ and $D_1 D_1' = I$.

Theorem 3.4 Let the plant P of Fig. 3 satisfy the standard assumptions OF1–OF4. Then the following are equivalent:

- i) There exists a controller admissible for P that solves the robust regulation problem from u to y at the frequencies $\omega_1, \dots, \omega_N$ while also making $\|T_{11}\|_\infty < \infty$ (the $\text{RRH}_\infty\text{C}$ problem).
- ii) There exists a controller admissible for P that renders $\|T_{11}\|_\infty < \infty$ and

$$I_k B' B' I_k' \succ (I_k \bar{B}_1 + [I_k 0])(I_k \bar{B}_1 + [I_k 0])' \quad (10)$$

for all $k = 1, \dots, N$. Here

$$\begin{aligned} I_k &= [I_k 0] \bar{C} (I_k \omega_k I - \bar{A})^{-1} \\ \bar{A} &= A + \gamma^{-2} C' C_1 + \gamma^{-2} C' C_1' Z - B' B' Z \\ \bar{B}_1 &= \gamma C' \\ Z &= \lambda (I - \gamma^{-2} \lambda \lambda)^{-1} \end{aligned}$$

λ is the positive semidefinite stabilizing solution to the algebraic Riccati equation

$$A' \lambda + \lambda A + \lambda (C_1 B_1' - B B') \lambda + C_1 C_1' = 0$$

and γ is the positive semidefinite stabilizing solution to the Riccati equation

$$A' \gamma + \gamma A' + \gamma (C_1 C_1' - C_2' C_2) \gamma + B_1 B_1' = 0$$

Moreover, if either (hence both) of these conditions hold, then a controller that solves the $\text{RRH}_\infty\text{C}$ problem for P is given by (11) found at the bottom of the page. Here I is the unique solution to $I \bar{A} - A I = B [I 0] \bar{C}$, $C_2 = C_2' (I + \gamma Z)$, the internal model matrices A and B satisfy 1)–4) of Definition 3.2, and W is a positive definite matrix satisfying the Lyapunov inequality

$$\begin{aligned} & W + W A' + \gamma^{-2} (I B_1 - B [I 0]) (I B_1 - B [I 0])' \\ & \quad - I B_2 B_2' I' < 0 \quad (12) \end{aligned}$$

Fig. 5 The closed loop system consisting of plant P and controller K . P_{11} consists of stable system P with state feedback $B'Z$.

Proof ($i \Rightarrow ii$) This proof parallels that of the state feedback case. Suppose there exists a controller K that solves the $\text{RRH}_\infty\text{C}$ problem for P . The first step is to show that K also solves the $\text{RRH}_\infty\text{C}$ problem for

$$P_{11} \sim \left[\begin{array}{c|c} \bar{A} + B' B' Z & \bar{B}_1 - B \\ \hline B' Z & 0 \quad I \\ \hline C & I \quad 0 \end{array} \right]$$

where \bar{A} , \bar{B}_1 , and \bar{C} are defined in the theorem statement. To prove this, we make use of two system transformations as in [20].

Because there exists a controller K that solves the \mathcal{H}_∞ problem for P (and P satisfies assumptions OF1–OF4), the Riccati solutions λ and γ of the theorem statement exist. This follows from [9, Theorem 3]. In particular, γ exists. Therefore, by the dual of the Redheffer Lemma ([9, Lemma 9]), K also solves the \mathcal{H}_∞ problem for the plant

$$\left[\begin{array}{c|c} \bar{A} + \gamma C' C_1 & \bar{B}_1 - B \\ \hline C_1 & 0 \quad D_1 \\ \hline C & I \quad 0 \end{array} \right] \quad (13)$$

Similarly, because there exists a controller K that solves the \mathcal{H}_∞ problem for (13), we know that there exists a unique stabilizing solution $Z = 0$ to the λ Riccati equation for (13). In fact, it can be easily verified that $Z = \lambda (I - \gamma \lambda)^{-1}$. Thus, again bringing in Redheffer, K also solves the \mathcal{H}_∞ problem for

$$\left[\begin{array}{c|c} \bar{A} + \gamma C' C_1 + B_1 B_1' Z & \bar{B}_1 - B \\ \hline B' Z & 0 \quad I \\ \hline C_2 + \bar{B}_1' Z & I \quad 0 \end{array} \right]$$

which is precisely the plant P_{11} .

Next, we write P_{11} as the stable system P with state feedback $\xi = B' Z x + u$ and close the controller loop with K as shown in Fig. 5. The remainder of the proof then consists of an analysis of Fig. 5 just as the feedback system of Fig. 4 was analyzed in the state feedback case. The details are omitted.

($ii \Rightarrow i$) We show that K given by (11) solves the \mathcal{H}_∞ problem for P by showing that it solves the \mathcal{H}_∞ problem for P_{11} and then appealing to the Redheffer lemma ([9, Lemma 9]) and its dual Λ realization for the closed loop system consisting of P_{11} and K (stacking plant states on top of controller states) is shown in the

$$K \sim \left[\begin{array}{c|c} \bar{A} & 0 \\ \hline B_2 B_2' I' W^{-1} & \bar{A} + \gamma (C_1 C_1' - C_2' C_2) - B' B' Z - B_2 B_2' I' W^{-1} I \\ \hline B' L' W^{-1} & -B_2' Z - B' L' W^{-1} I \\ \hline & 0 \end{array} \right] \quad (11)$$

$$T_{11} \sim \left[\begin{array}{ccc|c} \bar{A} + B_2 B_2' Z & B_2 B_2' L' W^{-1} & -B_2 B_2' Z - B_2 B_2' L' W^{-1} L & \bar{B}_1 \\ \bar{B}[I_l 0] \bar{C}_2' & \bar{A} & 0 & \bar{B}[I_l 0] \\ \hline \bar{B}_1 \bar{C}_2 & B_2 B_2' L' W^{-1} & \bar{A} - \bar{B}_1 \bar{C}_2 - B_2 B_2' L' W^{-1} L & \bar{B}_1 \\ B_2' Z & B_2' L' W^{-1} & -B_2' Z - B_2' L' W^{-1} L & 0 \end{array} \right].$$

equation found at the top of the page. After changing coordinates via

$$\begin{bmatrix} I & 0 & 0 \\ L & -I & 0 \\ 1 & 0 & -I \end{bmatrix}$$

and eliminating stable unobservable and uncontrollable modes, we obtain

$$T_{11} \sim \left[\begin{array}{c|c} \bar{A} - L B_2 B_2' L' W^{-1} & L \bar{B}_1 - B[I_l 0] \\ \hline -B_2' L' W^{-1} & 0 \end{array} \right].$$

Now we can appeal to the bounded real lemma (as in the state-feedback case) to conclude that K solves the H_∞ problem for P_{imp} , and thus for P as well. But K also has the internal model structure of Theorem A.2, so K solves the $RRH_\infty C$ problem for P .

APPENDIX A THE ROBUST REGULATION PROBLEM

This appendix includes well-known results on the robust regulation problem that are used in the proofs of Section III. A precise definition of the robust regulation problem is given in the introduction, and all theorems here apply to the plant of Fig. 1. The first theorem addresses the question of when there exists a controller that solves this problem.

Theorem A.1 [7], [12], [11] There exists a controller that solves the robust regulation problem determined by $\omega_1, \dots, \omega_N$ for P if and only if

- i) (A, B_2) is stabilizable and (C_2, A) is detectable, and
- ii) the matrix $\begin{bmatrix} sI - A & B_2 \\ C_2 & 0 \end{bmatrix}$ has independent rows for every $k = 1, \dots, N$.

A controller K solves the robust regulation problem if and only if it contains the right "internal model." This "internal model principle" [1], [3], [5], [7], [8], [11], [12], [22], [23] is the central result in robust regulation. A particularly simple statement of this result is given in the following.

Theorem A.2 [1]: A controller K solves the robust regulation problem determined by $\omega_1, \dots, \omega_N$ for P if and only if

- i) K is admissible for P , and
- ii) K admits the realization

$$K \sim \left[\begin{array}{cc|c} A & 0 & \bar{B}[I_l 0] \\ * & * & A \\ \hline * & * & * \end{array} \right] \quad (14)$$

(the "*" entries are any matrices of appropriate dimensions) where

- a) $\text{spec}(A) = \{\pm j\omega_1, \dots, \pm j\omega_N\}$,
- b) every eigenvalue of \bar{A} has multiplicity l ,
- c) \bar{A} is diagonalizable, and
- d) (\bar{A}, \bar{B}) is controllable.

Matrices A and \bar{B} satisfying a)–d) of Theorem A.2 can be realized in many different ways. We give one realization here. Another may be found in, for example, [8].

With every frequency ω_k to be regulated against, associate system matrices \bar{A}_k and \bar{B}_k as follows. If $\omega_k = 0$, choose integrator dynamics

$$\bar{A}_k := 0 \in \mathbb{R}^{l \times l} \quad \text{and} \quad \bar{B}_k := I \in \mathbb{R}^{l \times l}.$$

If $\omega_k \neq 0$, choose harmonic oscillator dynamics

$$A_k := \begin{bmatrix} 0 & \omega_k I \\ -\omega_k I & 0 \end{bmatrix} \in \mathbb{R}^{2l \times 2l} \quad \text{and} \quad \bar{B}_k := \begin{bmatrix} 0 \\ I \end{bmatrix} \in \mathbb{R}^{2l \times l}.$$

Now set

$$A := \begin{bmatrix} A_1 & & \\ & \ddots & \\ & & A_N \end{bmatrix} \quad \text{and} \quad B := \begin{bmatrix} B_1 \\ \vdots \\ B_N \end{bmatrix}.$$

It is straightforward to verify that A and B as constructed do, in fact, satisfy requirements a)–d) of Theorem A.2.

The last result on robust regulation is a straightforward consequence of Theorem A.2.

Corollary A.3 Suppose K solves the robust regulation problem for P . Then K solves the robust regulation problem for any other finite-dimensional linear time-invariant plant for which it is an admissible controller.

Frequency-Domain Criteria of Robust Stability for Slowly Time-Varying Systems

A. Megretski

Abstract—The problem of stability of feedback systems with structured slowly time-varying uncertain gains is considered. For the case when the pair "uncertain gain/its derivative" belongs to a given convex set, a sufficient frequency domain condition of stability is obtained. This condition is an MIMO generalization of the SISO results derived in the 60s in the context of the positivity theory.

1. INTRODUCTION

Consider the system with uncertainty in the feedback loop shown in Fig. 1 where P is the linear time invariant (LTI) nominal plant and Δ is the linear block representing the uncertainty $\xi(t) = \delta(t)y(t)$. The (unknown) function $\delta(\cdot)$ is such that for any t the pair $(\delta(t), \dot{\delta}(t))$ belongs to a given set D of pairs of matrices. Note that in the case when $\delta_1 = 0$ for any $(\delta_0, \dot{\delta}_1) \in D$ the setup describes an LTI system with a real parametric uncertainty.

Manuscript received December 21, 1992; revised June 18, 1993 and April 1994. The original version of the manuscript was prepared when the author was visiting the Department of Electrical Engineering at the University of Newcastle, Australia. This work was supported in part by the Institute for Mathematics and Its Applications with funds provided by the National Science Foundation.

Fig. 1

The setup from Fig. 1 can be represented in the equivalent form

$$\dot{x}(t) = A(t)x(t) \quad A(t) = A_0 + B_1 \delta(t) C_1 \quad \begin{pmatrix} x(t) \\ y(t) \end{pmatrix} = \begin{pmatrix} I \\ C_0 \end{pmatrix} x(t) \quad (1.1)$$

where $x(t)$ is the state vector of P , $y = C_0 x$ and A, B, C are given matrices. A well studied case of the problem is when

$$A_0 = 0 \quad B_0 = C = I$$

$$D = \{(\delta_0, \dot{\delta}_1) \mid \|\delta_0\| \leq M, R(\dot{\delta}_1) \leq -\alpha \|\dot{\delta}_1\| - \epsilon\} \quad (1.2)$$

i.e. the pointwise bounds on the norms of $\dot{\delta}(t)$ and $\delta(t)$ and on the Lyapunov index of $\dot{\delta}(t)$ are given ($\|F\|$ and $R(F)$ denote the largest singular value and the largest real part of eigenvalue of F respectively, I denotes a unit matrix). It was shown in [1] that system (1.1)–(1.2) is stable provided that $\epsilon < \epsilon_0(M, \alpha)$ is sufficiently small. Explicit bounds $\epsilon_0(M, \alpha)$ were obtained for example in [2] and [3] where a more general formulation is also considered with M, α and ϵ being the average values of $\|\dot{\delta}(t)\|$, $R(\dot{\delta}(t))$ and $\|\delta(t)\|$ respectively. See also [4] for the infinite dimensional case and see [5] for the application of the technique in the gain scheduling and adaptive control. The general results mentioned above establish the so called frozen time principle in the analysis of slowly time varying (STV) systems. The issues of concern, however, are the conservativity of the upper bound $\epsilon < \epsilon_0(M, \alpha)$ and the complexity of the analysis required to check the condition $R(\dot{\delta}(t)) \leq -\alpha$. First, most practical systems of interest do have structure which means that $\dot{\delta}(\cdot)$ is not expected to be an arbitrary matrix function satisfying the bounding conditions (1.2). For example, when the order of the plant P on Fig. 1 is greater than one, the coefficients of $\dot{\delta}$ are not independent. Since the stability condition $\epsilon < \epsilon_0(M, \alpha)$ does not utilize such information, the bound may be very conservative. Although no systematic study of the conservativity is delivered in the note, a reasonable example of a second order system is given for which the criterion from Theorem 1 below (which does utilize the structure) gives about 30 000 times larger bound on the admissible rate of variation. Second, when a generic set of expected values of matrices $\dot{\delta}(t)$ is given, the problem of finding the upper bound α in (1.2) is equivalent to a robust stability problem in the presence of a multivariable real parametric uncertainty which is known to be NP hard.

An alternative approach to studying STV systems was developed within the positivity theory (see for example [6] and [7] and references therein). In many (but not in all) examples, this approach yields much (thousands times) less conservative upper bounds than the unstructured one. However, the classical papers like [6] and [7] treat the case of a single time varying parameter only. In this note, relatively simple sufficient frequency domain conditions of robust stability in the STV case are proved. With some reservations, the result can be viewed as a generalization of the criteria [6]–[7] to the case of any number of time varying coefficients. The analysis required by the new criteria is similar to that used in the real μ case (see for example [8]) where the uncomputable real μ is replaced by a convenient upper bound. A similar approach to the analysis of STV systems was developed independently in [9].

II. MAIN RESULT

We consider system equations given by (1.1) where A_0 is a Hurwitz $n \times n$ matrix and D is a given convex compact set of pairs of $m \times l$ matrices containing the pair of zero matrices. For a complex matrix F , let F^* denote the Hermitian conjugate. We shall write $F \geq 0$ if the real part of $f^* F f$ is not negative for any complex vector f .

Definition 1: The uncertain STV system (1.1) is called stable (exponentially) if there exist $c_1, c_2 > 0$ such that $|x(t_1)| \leq c_1 e^{c_2(t_1-t_0)} |x(t_0)|$ for any $x(\cdot)$, $\delta(\cdot)$ satisfying (1.1) and for any $t_1 > t_0$.

Definition 2: System (1.1) is called Ψ -stable if

- $\delta_1 = 0$ for any $(\delta_0, \delta_1) \in D$ [i.e., $A = \text{const}$ in (1.1)];
- there exist $c > 0$ and an $l \times l$ transfer matrix Ψ (bounded in the right-half plane) such that

$$[I - \delta_0 G(j\omega)] \Psi(j\omega) - cI \geq 0 \quad \forall (\delta_0, \delta_1) \in D, \omega \in \mathbb{R}$$

where $G(s) = C_0(sI - A_0)^{-1}B_0$.

It is well known and easy to show (and follows from the proof of Theorem 1 below) that Ψ -stability implies the ordinary exponential stability. The advantage of using the Ψ -stability is in the relative simplicity of its verification. A possible disadvantage is that a stability criterion based on the Ψ -stability may be conservative. However, in many applications, the Ψ -stability is "close" to the standard robust stability. For example, if $m = 1$, i.e., B_0 is a vector, then Ψ -stability is equivalent to robust stability (see [10] and [11]).

Let us formulate the main result of this note. For $r \in (0, -\mathbf{R}(A_0))$, the modified system (1.1) is defined by

$$A_1 = A_0 + rI, \quad B_1 = B_0, \quad C_1 = C_0,$$

$$D_1 = \left\{ \left(\delta_0 - \frac{\delta_1}{2r}, 0 \right) : (\delta_0, \delta_1) \in D \right\}$$

where A_1, B_1, C_1, D_1 are the modified A_0, B_0, C_0, D .

Theorem 1: System (1.1) is stable if the modified system (1.1) is Ψ -stable, i.e., if there exists $c > 0, r \in (0, -\mathbf{R}(A_0))$, and an $m \times m$ rational function Ψ (bounded in the right-half plane $\text{Re}(s) > 0$) such that

$$\left[I - \left(\delta_0 - \frac{\delta_1}{2r} \right) G(j\omega - r) \right] \Psi(j\omega - r) - cI \geq 0 \quad (2.1)$$

for any $\omega \in \mathbb{R}, (\delta_0, \delta_1) \in D$.

Remark 1: For a fixed $r > 0$, condition (2.1) is convex in $\Psi(\cdot)$. The following procedure can be used to apply Theorem 1 in robustness analysis.

a) choose a finite set $\{c_0, c_1, \dots, c_q\}$ of scalar rational functions (bounded in the right-half plane);

b) for a fixed $r > 0$, use standard convex optimization to check whether there exists $\Psi(s) = \sum_{j=0}^q \Psi_j \Phi_j(s)$ (where Ψ_j are constant real matrices) satisfying (2.1) (for some $c > 0$, for any $\omega \in \mathbb{R}, (\delta_0, \delta_1) \in D$);

c) use random search over r to find whether the function Ψ in b) exists for some $r \in (0, -\mathbf{R}(A_0))$. It can be shown that, when D is a polytope and r is fixed, the search for Ψ_j can be reduced to solving a system of Linear Matrix Inequalities (LMI's), see [12].

Remark 2: Consider the problem of robust stabilization of the uncertain STV system on Fig. 1. This is the case when the transfer matrix G of P is not fixed but has to be chosen from an affine set given by the Youla parameterization $G = G_0 + G_1 H G_2$, where G_0, G_1, G_2 are given stable transfer matrices, and H ranges over the set of stable transfer matrices of appropriate dimension. When $G_2 = I$ (i.e., in the state feedback stabilization problem), the set of H , for which the robust stability of the STV system can be proved by using Theorem 1 with a fixed r , allows a convex parameterization, which reduces the problem to solving a

system of LMI's. This parameterization is similar to the projective parameterization introduced in [10]:

$$H(s) = \Phi(s) \Psi(s+r)^{-1}$$

where (Ψ, Φ) is the "parameter"—arbitrary pair of stable transfer matrices of appropriate size such that

$$\Psi(j\omega) - \left(\delta_0 - \frac{\delta_1}{2r} \right) [G_0(j\omega - r) \Psi(j\omega) + G_1(j\omega - r) \Phi(j\omega - r)] \geq cI$$

for some $c > 0$ for any $\omega \in \mathbb{R}, (\delta_0, \delta_1) \in D$.

III. THE "RANK ONE" CASE

In this section, we discuss application of the main result in the case when $m = 1$, i.e., ξ is scalar. Note that this is not the case of one single uncertain coefficient: basically, this is the case when we investigate stability of the linear differential equation

$$u^{(k)} + f_{k-1}(t)u^{(k-1)} + \dots + f_0(t)u = 0 \quad (3.1)$$

where u is scalar. The following result is a simple corollary to Theorem 1, based on the fact [10], [11] that the Ψ -stability is equivalent to the ordinary exponential stability in the rank one case ($m = 1$).

Theorem 2: Let K be a convex compact subset of \mathbb{R}^{2k} such that $(\bar{f}_0, \bar{f}_1, \dots, \bar{f}_{k-1}, 0, 0, \dots, 0) \in K$ for some Hurwitz polynomial $f(s) = f_0 + f_1 s + \dots + f_{k-1} s^{k-1} + s^k$. The differential equation (3.1) with the time-varying coefficients f_i such that

$$(f_0(t), f_1(t), \dots, f_{k-1}(t), \dot{f}_0(t), \dot{f}_1(t), \dots, \dot{f}_{k-1}(t)) \in K$$

for any t , is stable if for some $r > 0$ any polynomial

$$p_r(s) = (s-r)^k + \left(\bar{f}_{k-1} - \frac{\bar{g}_{k-1}}{2r} \right) (s-r)^{k-1} + \dots + \left(f_0 - \frac{\bar{g}_0}{2r} \right) \quad (3.2)$$

with $(\bar{f}_0, \bar{f}_1, \dots, \bar{f}_{k-1}, g_0, g_1, \dots, g_{k-1}) \in K$, is a Hurwitz polynomial.

Consider, as an example, the second-order differential equation

$$\ddot{w}(t) + f_1(t)\dot{w}(t) + f_2(t)w(t) = 0 \quad (3.3)$$

where $w(t)$ is scalar, and $f_j(t)$ are uncertain coefficients. Assume that $f_j(t)$ are within 100% of their (known) minimal values $f_1 = 1$ (s^{-1}) and $f_2 = F \geq 2$, i.e.,

$$1 \leq f_1(t) \leq 2, \quad F \leq f_2(t) \leq 2F. \quad (3.4)$$

Our aim is to find admissible relative rate of variation a for $f_j(t)$, i.e., to find $a > 0$ (as large as possible) such that the conditions

$$|\dot{f}_1(t)| \leq a, \quad |\dot{f}_2(t)| \leq Fa \quad (3.5)$$

and (3.4) guarantee exponential stability of (3.3).

First, let us apply Theorem 2 of this note in the case of the system setup (3.3)–(3.5). The sufficient condition of stability is existence of $r > 0$ such that all the polynomials

$$p(s) = (s-r)^2 + \left(\bar{f}_1 - \frac{\bar{g}_1}{2r} \right) (s-r) + \left(\bar{f}_2 - \frac{\bar{g}_2}{2r} \right),$$

$$\bar{f}_1 \in [1, 2], \quad |\bar{g}_1| \leq a, \quad \bar{f}_2 \in [F, 2F], \quad |\bar{g}_2| \leq Fa$$

are Hurwitz. It is easy to see (remember that $F \geq 2$) that the condition is satisfied for $r = 1/4, a < 1/4$. Therefore, $a < 1/4$ is a criterion of stability given by Theorem 2.

Now let us apply the result [2] (Theorem 3.2, (ii), with corrections),

$$\epsilon(M, \alpha) = \frac{1}{2} \frac{1}{(N-1)^2} \left(1 - \frac{1}{2N-1} \right)^{1/N-2} \frac{\alpha^{1/N-2}}{(2MF)^{1/N-1}} \quad (3.6)$$

in analysis of the system (3.3)–(3.5). To do this, we should represent (3.3) in a state-space form (1.1). One can use the canonical form, or any equivalent state-space realization,

$$\dot{A}(t) = \begin{bmatrix} 0 & 1 \\ -f_2(t) & -f_1(t) \end{bmatrix} \quad \text{or}$$

$$\dot{A}(t) = S \begin{bmatrix} 0 & 1 \\ -f_2(t) & -f_1(t) \end{bmatrix} S^{-1}$$

Indeed, we have

$$\operatorname{Re}(\lambda(t)) \geq -0.5 \operatorname{tr}(\dot{A}(t)) = -0.5$$

$$\|\dot{A}(t)\| \geq \sqrt{|\det \dot{A}(t)|} = \sqrt{2F} \quad \|\dot{A}(t)\| \geq \sup |f_1(t)| = a$$

Hence, the criterion would not give a bound better than $a < 1/2\sqrt{2}F$. Even for the smallest value of F under consideration $F = 2$, this is about 30000 times worse than the criterion $a < 1/4$. Also, the last bound yields $a \rightarrow 0$ as $F \rightarrow \infty$ while the bound given by Theorem 2 does not depend on $F \in [2, \infty)$. Therefore, for the example under consideration the criterion [2] does not give good practical numbers, and also does not allow us to observe the important theoretical phenomenon: the admissible bound for the relative rate of variation does not tend to zero as the phase of the nominal system poles tends to $\pm\pi/2$.

IV. CONCLUDING REMARKS

The sufficient criterion of stability presented in this paper is far from being necessary. It appears that the criterion would provide a good balance between complexity and conservativity of analysis for dynamical systems with 'low to medium' speed time-varying coefficients (i.e., not too fast). It can be shown that the criterion is based on using a certain set of Integral Quadratic Constraints (see [13]) describing STV gains. Therefore, it can be used in the case of a mixed uncertainty combining real parametric uncertainty, fast time-varying gains, conic nonlinearities, unmodeled IT dynamics, and so on. These extensions will be discussed in a forthcoming paper.

V. APPENDIX

Proof of Theorem 1. In this proof, L_2 denotes the standard Hilbert space of square summable functions $h: \mathbf{R} \rightarrow \mathbf{R}^l$ with the norm $\|\cdot\|$ and the scalar product (\cdot, \cdot) . If δ is a bounded measurable matrix-valued function on \mathbf{R} , M_δ denotes the operator of multiplication by δ , i.e., $(M_\delta h)(t) = \delta(t)h(t)$, acting from one L_2 -space to (generally) another. Similarly, if $F = F(s)$ is a rational matrix-valued function bounded on the imaginary axis, the L_F denotes the Fourier operator of multiplication in the frequency domain: $h_1(j\omega) = F(j\omega)h(j\omega) \forall \omega \in \mathbf{R}$ for $h_1 = T_F h$ where T_F denotes the Fourier transform. Remember that $T_F L_2 = L_2$ and that if F is bounded in the right-half plane $\operatorname{Re}(s) > 0$ then the operator T_F is causal, i.e., $(T_F h)(t) = 0$ if $h(t_1) = 0$ for any $t_1 < t$.

It is sufficient to show that the operator $I - M_\delta L_2$ is invertible for any $\delta(\cdot)$, and that the norm of $(I - M_\delta L_2)^{-1}$ is bounded. Since the set of $\delta(\cdot)$ is convex and contains the zero function, one only needs to show that there exists $q > 0$ such that

$$\|\xi - M_\delta T_F \xi\| \geq q \|\xi\| \quad (4.1)$$

for any δ and for any $\xi \in L_2$. Note that since $(0, 0) \in \mathcal{D}$, condition (2.1) implies that $\Psi(j\omega) - qI \geq 0$ for any $\omega \in \mathbf{R}$. Therefore, since Ψ is bounded in the right-half plane, $\Psi(s) - qI \geq 0$ for any s with $\operatorname{Re}(s) \geq 0$. Hence, the rational function $\Psi(s)^{-1}$ where $\Psi(s) = \Psi(s+j)$ is well defined and bounded in the right-half plane. Therefore, the operator T_Φ is invertible and it is sufficient to prove

existence of $q_1 > 0$ such that

$$\|I_\Phi \xi - M_\delta L_2 \Phi \xi\| \geq q_1 \|\xi\| \quad (4.2)$$

for all $\delta(\cdot)$ and for all $\xi \in L_2$. We will prove this by showing that $\|(I - T_\Phi \xi - M_\delta L_2 \Phi \xi)\| \geq \epsilon \|\xi\|^2$.

Suppose (with no loss of generality) that ξ has compact support. Let $u = I_\Phi \xi$, $y = T_\Phi \xi$, $v(t) = \epsilon^{-1} \xi(t) - u(t)$, $y(t) = \epsilon^{-1} y(t)$. It is easy to check that u , y are square summable, and $u = \Psi v$, $y = \Gamma v$ where $\Gamma(s) = \Gamma(s-j)$. Therefore, by (2.1), using the Parseval formula, we have $(v, u) = (\delta_0 - \delta_1/(2j))y_1 \geq \epsilon \|\xi\|^2$ for any $(\delta_0, \delta_1) \in \mathcal{D}$. Since the operators T_Φ and $T_\Phi \Phi$ are causal and the last inequality holds for an arbitrary $\xi \in L_2$, we have $\operatorname{tr}\{(2jD(t) - D(t))W(t)\} > 0$ for any t where

$$D(t) = [I - \delta(t) - \epsilon I] \quad W(t) = \begin{bmatrix} u(t) \\ y(t) \\ v(t) \end{bmatrix}$$

$$W(t) = \int_{-\infty}^t (\tau) v(\tau)^* \epsilon^{-1} \tau d\tau$$

Note that the matrix W is bounded and $W(\tau) = 0$ for τ approaching $-\infty$. Hence

$$\begin{aligned} & \|(I - T_\Phi \xi - M_\delta L_2 \Phi \xi) - \epsilon \xi\| \\ &= \operatorname{tr} \int D^{-1} u^* dt - u \int \epsilon^{-1} D W dt \\ &= \int \epsilon^{-1} u^* \{(2jD - D)W\} dt \geq 0 \end{aligned}$$

(where the integrals are over \mathbf{R}) \square

Routing and Scheduling in Heterogeneous Systems: A Sample Path Approach

Panayotis D. Sparagkis

Abstract—Consider the problem of routing customers to a set of K parallel servers that have different rates. Each server has a buffer with infinite capacity. The arrival process is general and the service times are assumed to be i.i.d. exponential random variables. Using sample path arguments, we show that, given any Bernoulli policy π , there exists another policy ρ which outperforms π by partially using a randomized version of a round-robin policy. Moreover, ρ is easily specified and implemented. We present extensions of our results to systems with finite capacities and service times that have an increasing hazard rate. Finally, a similar result is shown to hold in the context of scheduling customers from a set of K parallel queues.

1. INTRODUCTION

Consider a queueing system with K parallel queues, each of which has a buffer with infinite or finite capacity and a dedicated server. There is a single arrival stream and a controller that routes customers to one of the K queues as soon as they arrive. The situation arises in at least two contexts: communication networks and multiprocessor computer systems. In the context of computer networks, for example, there are usually multiple paths to remote destinations and routing decisions have to be made locally, i.e., at the source node, based on information regarding the delay characteristics of the available paths.

The determination of a routing policy that is optimal with respect to a certain performance criterion (such as throughput or delay) has been the subject of extensive research in the past. In the simple case, i.e., when service times are i.i.d. exponential random variables and the controller has queue length information available at arrival instants, the shortest queue (SQ) policy has been shown to maximize throughput in systems with infinite capacities (see [3], [19], and [21]). This is often referred to as the symmetric routing problem. In addition, it has been shown that the SQ policy stochastically minimizes the number of customers that are lost by any time t when the buffers have finite queueing space, e.g., [5], [9], [16]. A counterexample for nonexponential service times is provided in [20]. Very recently, the optimality of the SQ policy was shown to hold over all service time distributions that are increasing in likelihood ratio [17]. When the rates at the K servers are not equal, however, the problem becomes significantly more difficult (see [1], [2]). A routing policy which for an infinite number of stations performs almost optimally over the class of deterministic policies is described in [11].

In an interesting variation of the symmetric routing problem, the controller does not have any queue length information. Indeed, this is a more plausible assumption in many applications. It has been shown that, when the servers are homogeneous and the customers have either exponential [3] or deterministic [12], [13] service times, the round-robin (RR) policy that alternates among the queues maximizes the system's throughput. Recently, it was proven in [6] that, in fact, the optimality of the RR policy covers all service-time distributions that have an increasing hazard rate. Extending the basic symmetric routing problem, it was assumed in [13] that there exists multiple arrival streams, each of which has a controller that selects one of the K queues each time a customer has to be routed, based only on its own

previous routing decisions. When the service times are deterministic and all the servers operate at the same rate, it was shown in [13] that a set of randomized RR policies (see Section II for a definition) becomes an equilibrium set of policies. That is, if all controllers use a randomized version of RR then, from the perspective of minimizing the expected steady-state delay of customers on its own stream, no individual controller has incentive to deviate from this scheme.

When the servers operate at different rates, a simple routing policy is to use Bernoulli splitting, i.e., route a customer to queue i with probability p_i , $\sum_{i=1}^K p_i = 1$, regardless of past decisions. The idea is to allocate larger portions of the incoming traffic to faster servers, effectively aiming to materialize the most benefits of load distributing. It is the main result of this note that if the service times are exponential then, given any Bernoulli policy π , there exists another routing policy, which partly uses a randomized version of RR, and which is superior to π in the sense of separable increasing convex ordering (the definition given in the following) of the queue length process. This will be proved in Section IV. Note that π need not be the optimal Bernoulli policy. As it will be seen, given the routing probabilities for π , policy ρ can be easily specified and implemented. Thus, this result has immediate applications since, in practice, probabilistic splitting is a common policy for static routing. When the system is Markovian, a numerical example shows that ρ can significantly reduce the stationary mean system delay at moderate-to-high traffic.

A similar result is shown to hold in the context of scheduling customers from K queues, each of which receives customers from a dedicated arrival stream (see Section V). Here, it is assumed that there is a single server which may switch to one of the queues according to a scheduling policy that is determined by a controller. The server can be thought as a communication channel shared by a number of stations. In this case, our result covers probabilistic collision-free access policies that are implemented in a distributed fashion. Another application arises in the context of scheduling transmissions in packet radio networks, where time slots are assigned to various classes of customers satisfying certain interference constraints (see, for example, [4] and [15]). When scheduling is done probabilistically, the policy is often referred to as random polling.

II. PRELIMINARIES

Let \mathbf{q}, \mathbf{r} , be two vectors in \mathbb{R}^K . We introduce the notation q_k to denote the k th largest element in vector \mathbf{q} and define the following ordering (see [8]).

Definition 1: Vector \mathbf{q} is said to weakly majorize vector \mathbf{r} (written $\mathbf{r} \prec_w \mathbf{q}$) if

$$\sum_{i=1}^k r_i \leq \sum_{i=1}^k q_i, \quad k = 1, \dots, K.$$

In particular, if $\sum_{i=1}^K r_i = \sum_{i=1}^K q_i$, then \mathbf{q} is said to majorize \mathbf{r} . The ordering in Definition 1 is usually referred to as weak submajorization (as opposed to the weak supermajorization ordering; see [8] for a comprehensive treatment). Throughout the rest of the note, we will use the broad term majorization to refer to the ordering " \prec_w ." Majorization has been a useful analysis tool in the context of routing or scheduling of customers (see, for example, [7] and [9]). The ordering makes precise the idea that the vectors of queue lengths in one system are "less" or "more balanced" than those in another system, thus, setting a convenient framework for making sample path comparisons among different load distributing policies.

Following the notation in [8] let C_1^1 denote the class of functions $f: \mathbb{R}^K \rightarrow \mathbb{R}$ of the form $f(\mathbf{q}) = \sum_{i=1}^K g(q_i)$, where $g: \mathbb{R} \rightarrow \mathbb{R}$

Fig. 1 An example of a system with multiple arrival streams

is increasing and convex C_1 is a subset of the class of Schur convex functions defined on \mathbb{R}^K (see [8]) thus having the property $r \prec q \Rightarrow f(r) \leq f(q) \forall f \in C_1$. A natural way to associate C_1 with a stochastic majorization ordering between random vectors is the following (see [8] for a complete discussion of stochastic majorization)

Definition 2 If N and M are random vectors we have

$$M \leq_{C_1} N \text{ if } F[\phi(M)] \leq F[\phi(N)] \quad \forall \phi \in C_1$$

The aforementioned ordering is sometimes referred to as separable increasing convex ordering ([6]). Finally we write $\{N(t) : t \geq 0\} \leq_{C_1} \{M(t) : t \geq 0\}$ if

$$(N(t_1), \dots, N(t_n)) \leq_{C_1} (M(t_1), \dots, M(t_n))$$

for all n, t_1, \dots, t_n

III THE RANDOMIZED ROUND ROBIN POLICY

In this section we consider a system of K parallel queues that admit customers from M external arrival streams. Each queue has infinite capacity and a dedicated server. Customers from each stream arrive at a controller that routes them to one of the K queues (see Fig. 1). The controller has available the past routing decisions on its own stream but no queue length information. We assume that the service times at each queue form a sequence of i.i.d. exponential random variables with a constant rate μ . On the other hand the sequence of arrival times on any particular stream is assumed to be independent of all service times but otherwise arbitrary. For example it can be a deterministic sequence. The arrival processes are mutually independent although not necessarily identically distributed.

We are interested in the class of symmetric routing policies Σ defined as follows. A policy belongs to Σ if for each arrival stream the probability that the i th customer is routed to queue j is $1/K$ for all $j = 1, \dots, K, i = 1, 2, \dots$. An example is a policy that uses Bernoulli splitting with equal routing probabilities at each controller. Another example is a policy that uses a randomized round robin (R3) policy (introduced in [13]) at each controller. Recall that given the first K customers to arrive a round robin (RR) policy routes exactly one customer to each of the K queues according to some routing pattern and repeats this pattern thereafter. R3 can be thought of as a stochastic version of RR: the controller uses a round robin policy that selects the routing pattern for the first K customers randomly in such a way that the probability of the i th customer being routed to queue j is $1/K, i, j = 1, \dots, K$. An example is a policy that selects a routing pattern among the K cyclic shifts of the set $\{1, \dots, K\}$ with probability $1/K$. Given a policy π in Σ let $N_i^\pi(t)$ denote the number of customers in queue i at time t and $N^\pi(t) = (N_1^\pi(t), \dots, N_K^\pi(t))$. Finally let $D^\pi(t)$ denote the total number of departures by time t under π .

Using dynamic programming it was shown in [13] that in a system that consists of K queues with deterministic servers and

M independent but identically distributed arrival streams, a set of R3 policies employed by the M controllers is optimal among all policies in the following sense: if each of $M-1$ controllers uses a R3 policy then the M th controller should do the same. The result shows that for the system considered in this section a set of R3 policies minimizes the queue length process in the sense of separable increasing convex ordering, among all policies in Σ . The proof follows the steps taken in [13].

More specifically as it will become clear in the following we will prove the optimality of a set of R3 policies: it suffices to show that RR is optimal among all policies that use no queue length information when $M = 1$ and in addition there exist K independent arrival streams one to each queue, that are identically distributed. Let Σ_1 be the class of feasible routing policies for this system. The result can be shown by constructing a modified probability space in which all arrivals from the K dedicated streams occur simultaneously at the K queues and all departures from the K queues also occur simultaneously at the jump points of a Poisson process with parameter μ . Given a policy $\pi \in \Sigma_1$ let $\{N^\pi(t) : t \geq 0\}$ denote the queue length process in this modified space. Clearly $N^\pi(t) = N^\pi(t)$ for all $t \geq 0$ and $i = 1, \dots, K$ but $\{N^\pi(t) : t \geq 0\} \neq \{N^\pi(t) : t \geq 0\}$. That is the joint statistics of the queue lengths are modified.

A slight extension of an argument given in [3] (see also [18] for more details) shows that $N^{R3}(t) \leq N^\pi(t)$ for all $\tau \in \Sigma_1, t \geq 0$. Then by an elementary property of majorization

$$(N^{R3}(t_1), \dots, N^{R3}(t_n)) \leq_{C_1} (N^\pi(t_1), \dots, N^\pi(t_n)) \quad \forall n, t_1, \dots, t_n$$

Since the marginal distributions of the queue lengths are not modified by the construction it follows that $\sum_{i=1}^K \sum_{j=1}^M F[q(N_i^\pi(t))]$ is increasing and convex. Thus we get the following proposition.

Proposition 1 In a system with K dedicated arrival streams and one common external stream RR minimizes the queue lengths in the following sense

$$\{N^{R3}(t) : t \geq 0\} \leq_{C_1} \{N^\pi(t) : t \geq 0\}$$

for all π in Σ_1 provided that $N^{R3}(0) = N_j^\pi(0)$ for all $j = 1, \dots, K$.

Going back to our original problem it now becomes easy to see that a set of R3 policies employed by the M controllers outperforms all policies in Σ . Let ρ be a policy in Σ such that on at least one stream say stream 1 a policy different from R3 is used. The key is in noting that due to the way Σ is defined the aggregate arrival process from streams 2 to M is such that each queue sees an identically distributed subsequence of arrivals. In other words conditioned on arrivals that are not from the first stream the arrival process at queue i is equal in law to that at queue j for all i and j . Therefore it follows from Proposition 1 that a policy ρ which copies ρ on all streams except from the stream 1 where it applies R3 instead does outperform ρ in the sense of separable increasing convex ordering of the queue length process. Repeating the argument for all streams on which ρ does not use R3 we get the following result.

Proposition 2 In a system with M common external arrival streams a set of R3 policies minimizes the queue lengths in the following sense

$$\{N^{R3}(t) : t \geq 0\} \leq_{C_1} \{N^\pi(t) : t \geq 0\}$$

for all π in Σ provided that $N^{R3}(0) = N_j^\pi(0)$ for all $j = 1, \dots, K$.

Fig. 2. A comparison of three policies.

Remark 1: As a consequence of the aforementioned result, it follows that a set of R3 policies maximizes the expected value of $D^*(t)$, for all $t \geq 0$, among all policies in Σ . Note, however, that this set of policies need not be optimal over all feasible routing policies (in particular, nonsymmetric policies). For example, $K = M$ and the arrival processes are identically distributed renewal processes with deterministic interarrival times, then the optimal policy is the one that assigns a single queue to each stream, so that all customers from that stream are routed to one particular queue. It follows that this scheme reduces to an RR policy applied to the aggregate arrival process (streams 1 to M), which by Proposition 1 ensures optimality.

A numerical example is given in Fig. 2. There are four Poisson streams, each with rate λ , and four queues, each with an exponential server of rate $\mu = 1$. The graph compares the steady-state mean system delay of a set of Bernoulli policies against that of a set of R3 policies as well as a set of semi-R3 policies. The latter is defined to be one in which each of streams 1 and 2 apply an R3 algorithm to queues 1 and 2, and each of streams 3 and 4 apply an R3 algorithm to queues 3 and 4. We assume that all Bernoulli policies use a vector of equal routing probabilities, which then makes the system equivalent to a set of four independent $M/M/1$ queues. The performance of the R3 and semi-R3 policies was determined via a simulation experiment. Each point in the graph represents an average of 100 replications of the experiment, each run for 10 000 customers.

As seen in the graph, the set of R3 policies reduces the mean system delay considerably, especially at heavy load where it pays off significantly to avoid routing consecutively to the same queue. It is worth noting that the set of semi-R3 policies does indeed perform better than the set of R3 policies at light traffic (although the difference in the mean delay is small, but observable within the confidence interval of our simulation, and is not clearly seen in the graph). This was first noted in [13] in the context of queues with deterministic servers. The intuition lies on a trade-off between the degree of sharing of individual servers by customers from different arrival streams and the variability in the arrival process that is seen by a particular server.

IV. ROUTING IN HETEROGENEOUS SYSTEMS

In this section, we consider a system consisting of K heterogeneous queues each of which has infinite capacity and a dedicated server. The service times at queue i form a sequence of i.i.d. exponential random variables with rate μ_i . There is one arrival stream (see Fig. 3) and a controller that has no queue length information and must select a queue for each customer that arrives only based on information regarding its past routing decisions. We assume that the arrival process is independent from all the service processes but is otherwise arbitrary. Let Σ_h denote the class of feasible routing policies.

Fig. 3. A system with heterogeneous servers.

We use the term probabilistic policy to refer to any routing policy in Σ_h that uses Bernoulli splitting, i.e., routes an arriving customer to queue i with probability p_i , $\sum_{i=1}^K p_i = 1$, regardless of past decisions. Our objective is to show that, given any probabilistic routing policy π , there exists another policy ρ which partly employs an R3 algorithm, and which performs better than π in the sense of separable increasing convex ordering of the queue lengths. In particular, policy ρ uses a Bernoulli algorithm to split the arrival process into a finite number of subprocesses, effectively creating a finite number of substreams of customers. Then, for each substream, ρ either routes all customers to a particular queue or applies an R3 algorithm, possibly only to a subset of the K queues. The exact way in which the splitting of the arrival process is done depends on the routing probabilities for π and is described in the following. We prove our result for $K = 2$ and later discuss how the result can be generalized to arbitrary K .

Theorem 1: For any probabilistic policy π in Σ_h , employed in a system with two queues, there exists a policy ρ in Σ_h that partly employs an R3 algorithm such that the following is true:

$$\{N^\rho(t); t \geq 0\} \leq_{I_1} \{N^\pi(t); t \geq 0\}$$

provided that $N_i^\rho(0) =_{st} N_i^\pi(0)$ for all $i, j = 1, \dots, K$.

Proof We condition on initial queue lengths, arrival times, and service times. We assume that service completions at queue i can only occur at the jump points of a Poisson process with rate μ_i . Consider a probabilistic policy π that routes an arriving customer to queue 1 or 2 with probabilities p_1, p_2 , respectively, $p_1 + p_2 = 1$. Without loss of generality, we can assume that $p_1 \geq p_2$. The proof is by construction. Specifically, we construct a policy ρ as follows. When a customer arrives, ρ draws a random number u uniformly from the interval $[0, 1]$. If $u \in [0, p_1 - p_2]$, the customer is routed to queue 1. Otherwise, the customer is routed to either queue 1 or queue 2 according to an R3 algorithm applied to queues 1 and 2. That is, for the subsequence of arrivals associated with random numbers that fall in the interval $(p_1 - p_2, 1]$ policy ρ uses an R3 routing policy.

For each of the two policies, i.e., π and ρ , we create two copies of the system, as follows. First, we divide the interval $I = [0, 1]$ into three subintervals, namely, $I_1 = [0, p_1 - p_2]$, $I_2 = (p_1 - p_2, p_1]$, and $I_3 = (p_1, 1]$. In the first copy of the system, π draws a random number u from $[0, 1]$ and routes to queue 1 if $u \in I_1 \cup I_2$, otherwise it routes to queue 2. Policy ρ , on the other hand, draws a random number u from $[0, 1]$ and routes to queue 1 if $u \in I_1$, otherwise uses an R3 algorithm that starts from queue 1 if the first random number u that falls in $I_2 \cup I_3$ is such that $u \in I_2$; otherwise, it starts the algorithm from queue 2. In the second copy of the system, π routes to queue 1 if $u \in I_1 \cup I_3$, otherwise it routes to queue 2. Policy ρ , routes to queue 1 if $u \in I_1$, otherwise uses an R3 algorithm that starts from queue 1 if the first random number u that falls in $I_2 \cup I_3$ is such that $u \in I_3$; otherwise, it starts the algorithm from queue 2 (see Fig. 4).

 Fig. 4 The construction $R3(i)$ denotes $R3$ starts from queue i

To distinguish between the two copies we use the notation $(n_1^1(t), n_2^1(t))$ and $(m_1(t), m_2(t))$ to denote the vectors of the queue lengths for the first and the second copy respectively. $\pi = \rho \circ \pi$. Noting that $|I_1 \cup I_2| = |I_1 \cup I_1| = p_1$ and $|I_2| = |I_1| - p_2$ it is seen that the marginal queue lengths in each of the two copies are stochastically equal to those of the original system for either π or ρ . Coupling the random numbers that ρ and π use for making routing decisions, the key of the proof is in showing that the following relations are true on a sample path for all $t > 0$:

$$(n_1^1(t), m_1^1(t)) \leq (n_1^\pi(t), m_1^\pi(t)) \quad (1)$$

$$(n_2^1(t), m_2^1(t)) \leq (n_2^\pi(t), m_2^\pi(t)) \quad (2)$$

We only discuss (1); relation (2) follows similarly. Consider the two cross systems namely $(n_1^1(t), m_1^1(t))$ and $(n_1^\pi(t), m_1^\pi(t))$. By assumption, service completions occur simultaneously in these two systems (at the jump points of a Poisson process with rate μ_1) and so do arrivals associated with random numbers drawn from I_1 . As to arrivals associated with random numbers from $I_2 \cup I_1$, note that under ρ these alternate between the queues with lengths $n_1^1(t)$ and $m_1^1(t)$. Thus the cross system under ρ (see the left hand side of (1)) can be thought as one consisting of two queues with homogeneous exponential servers, two dedicated arrival streams (arrivals associated with us in I_1) and one common external stream (arrivals associated with us in $I_2 \cup I_1$) with a controller that uses an RR policy. The same is true for the cross system under π except that the controller on the external stream does not use an RR policy. Thus (1) follows by the arguments preceding Proposition 1.

Let $\mathbf{n}^\pi(t) = (n_1^\pi(t), n_2^\pi(t), m_1^\pi(t), m_2^\pi(t)) = \rho \circ \pi$. From (1) (2) and an elementary property of majorization it follows that

$$(\mathbf{n}^1(t_1), \mathbf{n}^1(t_2)) \leq (\mathbf{n}^\pi(t_1), \mathbf{n}^\pi(t_2)) \quad \forall t_1, t_2$$

Thus

$$\begin{aligned} \sum_{i=1}^l [g(n_1^1(t_i)) + g(n_2^1(t_i))] + \sum_{i=1}^l [g(m_1^1(t_i)) + g(m_2^1(t_i))] \\ \geq \sum_{i=1}^l [g(n_1^\pi(t_i)) + g(n_2^\pi(t_i))] \\ + \sum_{i=1}^l [g(m_1^\pi(t_i)) + g(m_2^\pi(t_i))] \quad (3) \end{aligned}$$

for all g increasing and convex. Taking expectations and recalling that the marginal queue lengths for each of the two copies are stochastically equal to those of the original system for both ρ and π the result follows. ■

As it is seen from the proof, ρ can be easily implemented. Let us now describe how ρ is specified for arbitrary K . For simplicity assume the routing probabilities for π are in decreasing order, i.e. $p_1 \leq p_2 \leq \dots \leq p_K$. Then ρ acts as follows: 1) uses an R3 algorithm applied to queues 1 to K for a Kp_1 portion of the incoming traffic; 2) uses another independent R3 algorithm applied

 Fig. 5 Comparing π (Bernoulli) and ρ

to queues 2 to K for a $(K-1)(p_1 - p_1)$ portion of the incoming traffic. $(K-1)$ uses an R3 algorithm applied to queues $K-1$ and K for a $2(p_{K-1} - p_K)$ portion of the incoming traffic and finally (K) routes all customers from the remaining $(p_K - p_{K-1})$ portion of the traffic to queue K . Note that these portions of the incoming traffic are specified by a probabilistic routing algorithm.

In the interest of space we will sketch the proof for $K=3$. This essentially describes the inductive argument that extends the proof to arbitrary K . First define a policy ρ_1 as follows. Policy ρ_1 uses an R3 algorithm applied to queues 1, 2, 3 for a $3p_1$ portion of the traffic; routes a $2(p_1 - p_1)$ portion of the traffic to queue 2 and a $p_1 - p_2$ portion of the traffic to queue 3. To prove that ρ_1 is better than π one needs to construct three copies of the system such that the order of arrivals to queues 1, 2, 3 under R3 is 1, 2 and 3 for copy 1, 2, 3 and 1 for copy 2 and finally 3, 1 and 2 for copy 3. Then similarly to Theorem 1 (see (1) and (2)) it can be shown that

$$(n_1^1(t), n_2^1(t), n_3^1(t)) \leq (n_1^\pi(t), n_2^\pi(t), n_3^\pi(t)) \quad i=1, 2, 3 \quad (4)$$

where n_i denotes the queue length process at queue i in copy j under policy ρ_1 .

Now let ρ be a policy that uses an R3 algorithm applied to queues 1, 2, 3 for a $3p_1$ portion of the traffic, uses another R3 algorithm applied to queues 2, 3 for a $2(p_1 - p_1)$ portion of the traffic and routes a $p_1 - p_2$ portion of the traffic to queue 3. An application of Theorem 1 to queues 2 and 3 proves that ρ outperforms ρ_1 . Thus ρ is the optimal policy in Σ_1 .

A numerical example is given in Fig. 5. There are two queues with service times that are exponential, the rates are $\mu_1 = 0.6$, $\mu_2 = 0.1$. Customers arrive from a Poisson stream of rate λ . The optimal routing probabilities for a Bernoulli policy (in terms of minimizing the steady state mean system delay) are known (e.g. [18]) to be given by

$$p_1 = \min \left\{ \frac{\mu_1 \sqrt{\mu_2} - \mu_2 \sqrt{\mu_1} + \lambda \sqrt{\mu_1}}{\lambda(\sqrt{\mu_1} + \sqrt{\mu_2})}, 1 \right\} \quad p_2 = 1 - p_1 \quad \mu_1 \geq \mu_2 \quad (5)$$

The graph compares the mean delay under a probabilistic routing policy π that uses the aforementioned routing probabilities with a policy ρ that routes a $(p_1 - p_2)$ portion of the incoming traffic to queue 1 and uses an R3 algorithm for the remaining portion of the traffic. The graph also presents a lower bound on the performance of policies that use no queue length information, expressed as the mean delay of a preemptive M/M/2 queue, that is the slow server, i.e., the one with rate μ_2 , can be preempted so that the fast server is always kept busy as long as there are customers in the system. This bound will, of course, never be achieved.

As it is seen in the graph, policy ρ reduces the mean system delay considerably at heavy load, compared to π . At light load all

Fig. 6. A scheduling system with K queues.

three policies behave approximately the same, as the fast server is almost exclusively used. In particular, the Bernoulli policy and ρ have exactly the same performance since under the former, customers are always routed to the fast server: for $\lambda < 0.1$, it follows from (5) that $p_1 = 1$. Thus, by the way ρ is constructed, it follows that it also always routes to the fast server. On the other hand, at heavy load, the performance of ρ approaches that of the $M/M/2$ system. In contrast, the Bernoulli policy increases the mean system delay away from its lower bound.

V. THE SCHEDULING PROBLEM

In this section, we consider a system consisting of K queues each of which has infinite capacity. Queue i receives customers from a Poisson stream with rate λ_i . There is a single server that may switch to one of the queues according to a scheduling policy that is determined by a controller (see Fig. 6). We assume that the controller has no queue length information and schedules the server based only on the history of its past decisions. Once the controller selects a queue to which the server is scheduled, we assume that a single customer from that queue is served (if one exists) before the server switches to another queue. If immediately upon the time the server joins a queue, that queue is empty, it is assumed that the server remains idle for a time period equal to the service time of a single customer; then it joins another queue. This is a reasonable assumption, for example, when time is slotted and all service times are deterministic equal to the duration of a time slot. In the following, we assume that the distribution of the service times is general and that the arrival processes are mutually independent as well as independent of the service processes.

The interest in studying these systems primarily arises in the context of multiple access communication systems. One may think of K stations sharing a common channel and wishing to transmit fixed-length packets at the beginning of time slots. One of the types of policies that can be used for accessing the channel are collision-free policies, under which it is not possible for two or more stations to attempt transmission of a packet at the beginning of the same time slot. Such policies can be deterministic, e.g., time division multiplexing, or probabilistic. The latter can be implemented in a distributed fashion, i.e., without any need for centralized coordination, provided that all stations use the same random number sequence.

Let $\Sigma_{s,h}$ be the class of scheduling policies for the system that we have just described. The result in this section is similar to that proved in Section IV. That is, given any probabilistic scheduling policy π in $\Sigma_{s,h}$, there exists another policy ρ that partly employs an R3 algorithm, and that outperforms π in the sense of separable increasing convex ordering of queue lengths. Then, ρ can be easily constructed on basis of these probabilities and be guaranteed to reduce the total workload at all times. The proof and the construction are similar to those in Section IV and are omitted.

Fig. 7. Routing customers to queues. Arrivals from the external stream (thick lines) are as if the RR algorithm applied only to them.

Theorem 2: For any probabilistic policy π in $\Sigma_{s,h}$, there exists a policy ρ that partly employs an R3 algorithm such that the following is true:

$$\{N^{\rho}(t); t \geq 0\} \leq_t \{N^{\pi}(t); t \geq 0\}$$

provided that $N_i^{\rho}(0) =_{st} N_j^{\pi}(0)$ for all $i, j = 1, \dots, K$.

Remark 2: It is not difficult to see that the arrival processes need not, in fact, be Poisson. Note that in the routing problem, we were not able to relax the assumption of the service times being exponentially distributed, since we required that both real and fictitious service completions be synchronized at the jump points of the service-counting process. This simplifies the proof considerably. In the scheduling system, of course, arrivals are always real, thus, there is no need to use the memoryless property of the exponential distribution.

VI. EXTENSIONS

This section contains a discussion of further issues that arise in the context of routing. Similar remarks can be made, of course, for the scheduling problem. First, it is interesting to study systems with finite capacities. A slight extension of Theorem 1 in [12] shows that in a system with M external arrival streams and K homogeneous exponential servers, a set of R3 policies minimizes the expected number of departures by any time t and, at the same time, it minimizes the expected number of losses by t . As a consequence, Theorem 1 can be extended to systems with finite buffers. As one expects, due to losses that may occur, the E_t^1 ordering on the queue lengths no longer holds when capacities are finite.

Theorem 1 does in fact hold for IHR service-time distributions. The key is in extending Theorem 1 in [6] (that proves the optimality of the RR policy when the service times form a sequence of i.i.d. r.v.s with IHR distribution) to systems that may admit arrivals from K dedicated arrival streams. The extension is rather straightforward. Since the arrival process in [6] is assumed to be arbitrary, one can simply assume that arrivals from the dedicated streams that can be assumed to occur simultaneously at the K queues are part of the external arrival process and are routed according to the RR policy. This does not modify the algorithm for the original common external arrival process (see, for example, Fig. 7, where $K = 3$).

ACKNOWLEDGMENT

The author is grateful to Prof. C. Cassandras and Prof. D. Towsley for their support, encouragement, and invaluable advice. The author is also thankful for many discussions with them that stimulated this research and improved the final version of this note.

Methods and Theory for Off-Line Machine Learning

S. Yakowitz and J. M. Wu

Abstract—Many problems in machine learning can be abstracted to the sequential design task of finding the minimum of an unknown, often and possibly discontinuous function on the basis of noisy measurement. In the present work, it is presumed that there is no penalty for bad choices during the experimental stage, and at some time, not known to the decision maker, or under his control, the experimentation will be terminated, and the decision maker will need to specify the point considered best, on the basis of the experimentation. In this note, we seek the best trade-off between i) acquiring new test points, and ii) retesting at points previously selected so as to improve the estimates of relative performance. The algorithm is shown to achieve a performance standard described herein. This decision setting would seem natural for function minimization in a simulation context or for tuning up a production process prior to putting it into service.

1. INTRODUCTION

There are myriads of situations in which one is confronted with a sequence of stochastically similar decision problems. In such situations, as in real life, one often has the opportunity to select better decisions as a data base of actions and outcomes accumulates. When this sifting and exploration of decision space is done by a computer algorithm, we term the process machine learning. Such an activity can be abstractly viewed as the process of finding the minimum of an unknown function on the basis of noisy measurements. In the present note, the focus is on this abstraction.

A characteristic of off-line learning is that there is no need to be concerned with performance during the exploration stage. (By contrast, on-line learning seeks to minimize observed loss as the process evolves.) The criterion of 'goodness' of off-line algorithms is that the decision or design provided at the end of the session performs as well as possible. It is tacitly assumed that this decision point will be selected for implementation without further testing. For example, in blackjack, during simulations, no money is to be gained or lost. In a long sequence of exploratory games, one could occasionally test to see how good the best tens count strategy found thus far is, and end the experimental session and head off to Nevada when performance seems promising. The blackjack study [1], however, employed on-line learning, but in view of results to follow, it appears that the learning plan could have been sharpened further.

The goal of the present theoretical study is to pose and examine off-line learning algorithms. We are aware of a lively literature (e.g., Devroye [2], [3], Jarvis [4], Guin [5], and Matyas [6]) which includes convergence results, but to our knowledge, rates have not been established for off-line methods. The conclusion substantiated herein is that significantly faster convergence rates can be achieved off-line under various hypotheses than by on-line algorithms.

We proceed now with the particulars. A formal statement of the problem we intend to address is as follows:

Definition 1.1—Let $f(\cdot)$ denote a bounded real valued measurable function on an infinite Borel action set $\mathcal{A} \subset R^1$. The off-line learning problem is the task of sequentially

IEEE Log Number 9407033.

1) choosing design points x_n , on the basis of a history of noisy observations

$$y_j = y(x_j) = f(x_j) + \epsilon(x_j), \quad j < n, \quad (1)$$

and

2) designating a particular design point x_n^* on the basis of these observations, so that for some specified positive number ϵ , as $n \uparrow \infty$

$$P[f(x_n^*) - f_{\min} > \epsilon] \rightarrow 0. \quad (2)$$

Convergence rate assurances are desirable.

In (2) f_{\min} is the minimum (or Lebesgue-essential infimum) of $f(x)$. Also $\epsilon(x_j)$ in (1) is a 0-mean random variable and the sequence $\{\epsilon(x_j)\}$ is hypothesized to satisfy certain assumptions to be stated in Section II.

One can intuitively justify an off-line learning criterion by imagining that one can perform experiments until some unknown time when it will be demanded that the experimentation cease and the best operating point, i.e., x_n^* , found so far be declared and used.

II. AN OFF-LINE LEARNING ALGORITHM

A. The Off-Line Method

The simple plan of the algorithm is occasionally to add a new randomly chosen design point to our list of test points. At other times, one refines the estimate of the expected performance of design points already on the list.

We first offer a generic off-line learning algorithm, and the subsequent discussions will be aimed at stating properties of this algorithm under various postulates. In what follows, the symbol \mathcal{C} will represent various positive constants, the values of which are not important for the associated discussions. The algorithm has as parameters a probability density function $p(\cdot)$ on the action set \mathcal{X} and a nondecreasing integer sequence $\{NP(n)\}_n$. The density does not affect the rate of convergence (provided it satisfies postulates to be stated). If the user has some intuition about the location of promising points in decision space \mathcal{X} , this could be reflected by relatively large density values. The $NP(n)$ sequence specifies times at which new decision points should be acquired and added to our experimentation list. The selection of this sequence should depend on properties one is willing to assume about the noise. In Section II-C, the important cases of finite moment and finite moment generating function are covered.

Algorithm Parameters: i) $p(x)$ is a probability density function having as support all of a (measurable) decision space $\mathcal{X} \subset \mathcal{R}^d$. (If \mathcal{X} is discrete, take $p(x)$ to be a probability mass function.)

ii) $\{NP(n)\}$ is a nondecreasing unbounded sequence of integers such that

$$NP(1) = 1, \quad NP(n)/n \downarrow 0, \quad \text{and} \quad \forall P(n) - NP(n-1) \in \{0, 1\}$$

If $\sup_x E|\epsilon(x)|^p < \infty$, let $NP(n) \propto \ln(n)$.

If $\sup_x E|\exp(\theta\epsilon(x))| < \infty$, let $NP(n) \propto \sqrt{n}$.

Set $n = 1$ and proceed to the iterative step.

The Iterative Step:

New Sample Times (Steps 1 and 2): If $n = 1$ or $NP(n-1) < NP(n)$, randomly select and test a new point from \mathcal{X} .

1) Choose a point, designated by $t(NP(n))$, from \mathcal{X} at random according to the pdf $p(x)$. Set $x_n = t(NP(n))$ and observe $y_n = y(x_n)$.

2) Start a running average $m_{NP(n)}$ for observations at $t(NP(n))$ by declaring

$$m_{NP(n)} = y_n$$

and start a counter at $t(NP(n))$ by setting $NS(NP(n)) = 1$.

Remark: The user-specified sequence " $NP(n)$ " (See item ii)) tells the number of New [sample] Points that have been gathered by time n . The random quantity " $NS(j)$," which is determined by the realization of the learning process, gives the number of samples that have been taken at a given sample point $t(j)$, $j \leq NP(n)$.

Go to 6.

Resample Times (Steps 3, 4, and 5): Else if $NP(n-1) = NP(n)$, resample at the point which has been tested the fewest number of times.

3) Let I be any index i , $1 \leq i \leq NP(n)$, such that

$$NS(i) \leq NS(j), \quad 1 \leq j \leq NP(n). \quad (3)$$

Set $x_n = t(I)$, and observe y_n .

4) Update the sample mean and sample counter. Set

$$m_I = [m_I \cdot NS(I) + y_n] / (NS(I) + 1). \quad (4)$$

and

$$NS(I) = NS(I) + 1. \quad (5)$$

5) At all times n such that $\forall P(n) > 1$, announce as the best point (BP) the test point $t(I^*)$, with $I^* = i$ where i is any index less than $NP(n)$ such that

$$m_i \leq m_j, \quad 1 \leq j < NP(n). \quad (6)$$

(Note that $t(NP(n))$ is not a candidate for the BP because it has recently been selected, $NS(NP(n)) \ll NS(j)$, $j < NP(n)$. Thus, the precision of the running mean $m_{NP(n)}$ as an estimate of $f(x_{NP(n)})$ is worse than that of the precision of the other running means.)

6) Set $n = n + 1$. Repeat the iterative step. (There is no official stopping condition, although one anticipates that at some arbitrary time, not known to the designer, the experimentation will be halted.)

[End of Algorithm]

The properties of the algorithm will require various hypotheses, some of which will always be assumed in force. These are now presented.

B. Convergence Analysis

Action Space Assumption: The set \mathcal{X} is either discrete (but infinite) or has positive Lebesgue measure.

Noise Hypothesis 1: For any $t \in \mathcal{X}$, define $I_t = \{i(x_j) : x_j = t\}$. Then this random subsequence, if not empty, is independent and identically distributed (i.i.d.). Any collection $I_{t(1)}, I_{t(2)}, \dots$ of such sequences are mutually stochastically independent.

Noise Hypothesis 2: Let us suppose that for any error tolerance d and any number N of observations of $Y(x)$, at any fixed x , there is a known function $P(d, N)$ which satisfies the following conditions:

i) uniformly in $x \in \mathcal{X}$

$$P[|m_{\cdot}(N) - f(x)| > d] \leq P(d, N). \quad (7)$$

Here, we have let $m_{\cdot}(N)$ represent the mean of a sample of $Y(x)$ of size N at design point x .

ii) If N is regarded as a variable on the positive numbers, then for any d , $P(d, N)$ is continuously differentiable and strictly convex.

The off-line algorithm assures that the number of observations, $NS(i)$, made at each test point $t(i)$, is about the same for each i , $1 \leq i < NP$. A property of this strategy which is fundamental to our analysis is the following proposition.

Proposition 2.1 Assume property ii) of the Noise Hypothesis 2. Then among all static algorithms for allocating M observations among a given number $\backslash P$ of test points the allocation $\Lambda \propto M/\backslash P$ to each test point $t(i)$ is the one which minimizes

$$\sum_{i=1}^{\backslash P} P(d \backslash \Lambda_i) \quad (8)$$

Proof By the Lagrange multiplier procedure, the minimizer of (8), subject to $\sum_{i=1}^{\backslash P} \Lambda_i = M$ must satisfy for each i , $1 \leq i \leq \backslash P$ and for some number λ

$$\partial/\partial \Lambda_i \left\{ \sum_{i=1}^{\backslash P} P(d \backslash \Lambda_i) + \lambda \left(\sum_{i=1}^{\backslash P} \Lambda_i - M \right) \right\} = 0 \quad (9)$$

from which we have the following necessary condition

$$\partial/\partial \Lambda_i P(d \backslash \Lambda_i) = -\lambda \quad 1 \leq i \leq \backslash P \quad (10)$$

But this evidently implies that the derivatives of $P(d \backslash \Lambda_i)$ must all be equal. By the strict convexity hypothesis the derivatives are strictly monotonically increasing so the value at which they equal any given value $-\lambda$ must be unique. That in turn implies uniqueness of the optimizing value Λ_i . That is all the Λ_i s are the same. QED

In this study the objective of learning is to try to assure that at the designated best design point the objective function value is within some given tolerance ϵ of optimality. That is in reference to Algorithm Step 5 we seek a testing plan which guarantees that

$$P[\text{Mistake}(n)] = P[f(t(I^*)) > f_{\text{opt}} + \epsilon] \downarrow 0 \quad (11)$$

at some assured rate. Let

$$f_{\text{opt}}(n) = \min_{t \in T(n)} f(t(i))$$

We construct a sequence giving an assured rate by noting that for functions $Q_1(\backslash P(n)/n)$ and $Q_2(\backslash P(n)/n)$ defined below

$$\begin{aligned} P(\text{Mistake}(n)) &\leq P[f_{\text{opt}}(n) > f_{\text{opt}} + \epsilon/2] \\ &\quad + P\left[\max_i |m_i - f(t(i))| > \epsilon/2\right] \\ &\leq Q_1(\backslash P(n)/n) + Q_2(\backslash P(n)/n) \end{aligned} \quad (12)$$

It will be apparent that for fixed n as $\backslash P$ increases Q_1 decreases while Q_2 gets larger. So the logical thing to do is to balance these probabilities. Specifically select $\backslash P^*(n)$ to assure that for some constants $C_1 > C_2 > 0$ and all n

$$C_1 Q_1(\backslash P^*(n)/n) \leq Q_2(\backslash P^*(n)/n) \leq C_2 Q_1(\backslash P^*(n)/n) \quad (13)$$

Toward achieving this design define $F(d) = P[f(T) < d]$ where T is distributed according to the algorithm search density $p(\cdot)$. Then $Q_1(\backslash P(n)/n) = (1 - F(\epsilon/2))^{1/\backslash P(n)}$. Under the independence assumption of Noise Hypothesis 1

$$\begin{aligned} P\left[\max_i |m_i - f(t(i))| > \epsilon/2\right] \\ \leq Q_2(\backslash P(n)/n) \\ = \backslash P^*(n) P(\epsilon/2 \backslash n/\backslash P^*(n)) \\ (1 + q(\backslash P^*(n) P(\epsilon/2 \backslash n/\backslash P^*(n)))) \end{aligned}$$

where $q(\backslash P^*(n) P(\epsilon/2 \backslash n/\backslash P^*(n))) = o(\backslash P^*(n) P(\epsilon/2 \backslash n/\backslash P^*(n)))$. Thus by simply equating Q_1 and Q_2 we obtain the implicit relation

$$\backslash P^*(n) \sim \ln(\backslash P^*(n)) P(\epsilon/2 \backslash n/\backslash P^*(n)) / \ln(1 - F(\epsilon/2)) \quad (14)$$

Since $\ln(\backslash P^*(n))/\backslash P^*(n) \rightarrow 0$ it suffices for $t(i)$ to satisfy the relation

$$\backslash P^*(n) = \text{Integer Part} [P(\epsilon/2 \backslash n/\backslash P^*(n)) / \ln(1 - F(\epsilon/2))]$$

We summarize the developments on an achievable rate in Proposition 2.2

Proposition 2.2 Under the preceding noise and decision hypotheses if $\backslash P^*(n)$ satisfies (15) then given any tolerance ϵ for some $0 < \rho < 1$

$$P[f(t(I^*)) > f_{\text{opt}} + \epsilon] = O(\rho^{n^{1/2}}) \quad (16)$$

Usually the value $F(\epsilon/2)$ is not known to the designer but (16) remains satisfied for any positive value $\rho < 1$ of this constant. The effect of omitting the divisor in (15) is perhaps to require a value ρ closer to 1.

C Applications and Implications

The cases of obvious interest are when the noises are known to have uniformly bounded moments of some order $q > 1$ or alternatively are known to have a moment generating function. Thus in the notation of (1), respectively

$$\sup |F(t(i))| \leq C \quad (17)$$

or

$$\sup E[\exp(\theta t(i))] \leq C \quad (18)$$

for all θ in some interval I . Between the two conditions of finitely many moments (17) and infinitely many moments (18) essentially all of the well known random variable families will be accounted for in the following statement

Proposition 2.3 Under the conditions of the Proposition 2.2 for the moment condition (17) the condition (13) is satisfied if

$$\backslash P(n) \sim C \log(n) \quad (19)$$

and for (18) if

$$\backslash P(n) \sim C \sqrt{n} \quad (20)$$

In the moment bound case we have

$$P[\text{Mistake}(n)] = O(n^{-(1/2)} \log(n)) \quad (21)$$

and in the finite moment generating function setting

$$P[\text{Mistake}(n)] = O(\rho^{n^{1/2}}) \quad (22)$$

for some (ϵ dependent) number ρ in the open unit interval

Proof For (19) a moment/probability bound e.g. [7] under the moment condition (17) is that

$$P(d \backslash n) \leq C/n^{1/2}$$

Equation (21) results from substitution of this bound into (15). Then by the equation preceding (14) and the balance relation (13) we have

$$P[\text{Mistake}(n)] \leq C \log(n)/n^{1/2} \quad (23)$$

which gives (21)

Similarly from Cramer's theorem e.g. [8 p. 9] we have the assurance that the existence of the moment generating function implies the exponential inequality for (7)

$$P(d \backslash n) = C \exp(-Qn) \quad (24)$$

where $Q = Q(d)$ is the dominating point of the large deviation rate function. See [8] for details on its calculation. In the Gaussian case

$Q(d) = d^2/2\sigma^2$ where σ^2 is an upper bound for the variances of $\epsilon(x)$, $x \in \mathcal{X}$.

Set $\rho < 1$ to be some number slightly larger than $\exp(-Q(d))$, say $\rho = J \exp(-Q(d))$ and note that for any $j > 1$, $j^n > \sqrt{n}$ for n sufficiently large. In view of (24), this gives (20), and (22) by the arguments for the moment case. QED

Under the circumstance that either the noise has a symmetric distribution, or that the distribution function of the noise is given, one can estimate $f(t(i)) + C$, for some constant C not depending on $t(i)$, by med_i , the sample median at $t(i)$. In the known-noise case, if the median is not defined, use the sample minimum of any defined quantile. For quantiles, probability bounds of type (20) are satisfied [9]. That is, for fixed $d > 0$, and some positive constant C'

$$P[|\text{med}_i - f(t(i)) + C| > d] = O(\exp(-C' NS(i))), 1 \leq i \leq NP.$$

The analysis for the moment generating function case then implies that for $t(I^*)$ the minimizer of the sample medians, and for $NP(n) \propto \sqrt{n}$, the probability of mistake is $O(\rho^{\sqrt{n}})$, some $0 < \rho < 1$. These observations might be useful if the noise has undefined expectation, as in the case of the Cauchy family.

We now argue that the rate cannot be uniformly improved by any other sampling plan.

Proposition 2.4: Over the class of noise processes satisfying (18), the fastest achievable rate of convergence of probability of mistakes to 0, with increasing decision time n , is $O(\rho^{\sqrt{n}})$, for some (problem dependent) number ρ in the open-unit interval.

Proof: It suffices to exhibit a single learning problem for which no improvement over $O(\rho^{\sqrt{n}})$ is possible. The waiting time until a sample point T satisfies $f(T) < f_{\min} + \epsilon/2$ is geometrically distributed. The only conceivable way to improve upon the conjectured rate is to gather new design points at a rate faster than \sqrt{n} . This, of course, entails requiring that $NS(i)/\sqrt{n} = o(1)$ at all design points $t(i)$: $i < NP(n)$.

Now suppose that unknown to the decision maker, $f(x)$ only has two points, say 0 and 1, in its range, and that $0 < p_1 := P(f(T) = 1) < 1$. Further, it is presumed that the noise $\epsilon(t) = 0$ if $f(t) = 0$ and standard normal otherwise, and that the tolerance $\epsilon = 1/2$, so that a mistake occurs whenever $f(t(I^*)) = 1$. It is now easy to confirm that for "bad" indexing the sample points $t(j)$: $f(t(j)) = 1$, and m_j being the sample mean or median at t_j , that for some number $C' > 0$

$$P\left[\min_{j \in \text{bad}} m_j < 0\right] \geq \exp(-C' \cdot NSM(n)) \quad (25)$$

where $NSM(n) = \min NS(i)$, $i < NP(n)$. Now from (25) it is clear that the probability that $f(t(I^*)) = 1$ cannot diminish faster than $\rho^{NSM(n)}$ with $\rho = \exp(-C')$. Thus, any sampling plan for which $NSM(n) = o(\sqrt{n})$ will have larger asymptotic probability of mistakes than $NP^*(n)$ in (15).

D. Comparison to On-Line Learning Rates

The on-line criterion is that for x_n the point tested at epoch n , a mistake occurs if

$$f(x_n) - f_{\min} > \epsilon.$$

Yakowitz and Lowe [10] have analyzed the expected number of mistakes in the first n decision times. The expected number of mistakes can be written as

$$J(n) = \sum_{i=1}^n P[f(x_i) > f_{\min} + \epsilon]. \quad (26)$$

This criterion can be viewed as the measure of cumulative performance in the control process, up to time n . Since it measures the cost

of each control x , actually applied, as opposed to what is estimated to be the best control found so far, i.e., $t(I^*)$, there is the potential that the expected performance improvement is slower than for off-line learning.

Toward comparison with Proposition 2.3, one can approximate the probability $P_{ON}(n)$ of error in the on-line case by the first difference,

$$P_{ON}(n) = \nabla J(n) = J(n+1) - J(n) \sim P[\text{on-line Mistake}(n)].$$

From Theorem 3 of the aforementioned work, for the moment bound case (17) and the exponential case (18), it turns out that the corresponding rates of convergence to 0 are, respectively,

$$P_{ON}(n) = O(\log(n)/n^{1-1/q}) \quad (27)$$

and

$$P_{ON}(n) = O(\log(n)/n). \quad (28)$$

It is known [11] that even in the case of finite decision space \mathcal{X} , and known parametric noise having moment generating functions, the best achievable rate for on-line strategies is $P[\text{Mistake}(n)] = O(1/n)$.

III. CONCLUSIONS

The present note contributes to the important decision-theoretic issue of how to undertake experimental design during an exploration phase so that the terminal decision is as wise as possible. This is an important piece of the larger picture of machine learning, a rigorous "black-box" approach to asymptotically optimal decision making.

From applications, e.g., [12]–[14], there is a convincing case that our machine learning techniques are feasible and useful for problems for which alternatives (such as genetic algorithms and neural nets) do not yet seem viable. Much of the theory is in place, and in particular, there are results about what is achievable [10], [11], [15], [16] and algorithms for attainment of the achievable. Some nontrivial toy problems have been mastered and initial investigations on serious problems (AIDS policy [13] and assembly line control [17]) have been published. We foresee a rich future for this statistical methodology. Ongoing investigations include algorithms for identification, control, and prediction for nonlinear systems to complement methodology of linear systems.

The present note, which is our first foray into off-line strategies, has contributed to the understanding of convergence behavior. We have noted that Gurin, Devroye, and others had already investigated off-line algorithms and established conditions for convergence. But to our knowledge, we are the first to "tune" these strategies to consider rates and trade-off between allocation of times to acquiring and testing new samples *vs* refining estimates of samples already collected. Clearly, algorithms in this note are to be preferred to the on-line methods when there is an experimental or simulation phase of system tuning during which actual performance is of no concern. The methods offered in Section II are optimal, in a minimax rate sense, with respect to asymptotic convergence, but they are practical, and easy to code. The memory requirements are small: at time n , one needs only to have stored the test points, the sample means, and the sample counts, i.e., the triplets $\{t(i), m_i, NS(i)\}$: $1 \leq i \leq NP(i)$. Even for a huge number of algorithm iterations, and a fairly large decision-space dimension, this is a modest demand because $NP(n)$ grows at most as \sqrt{n} . In many cases, the time to the final mistake can be seen [18] to have a short tail. In brief, the claim is that these learning algorithms are simple, efficient, and plainly feasible.

ACKNOWLEDGMENT

This note was strongly influenced by conversations, publications, and encouragement of L. Devroye, and fills out an invited (by Devroye) presentation [19] at the 1992 Winter Simulation Conference

Discrete-Time Observers with Random Noises in Dynamic Block

by A. Lyashenko and L. B. Ryashko

Abstract—The minimum variance state estimation of linear stochastic discrete-time systems by an observer of reduced-order is investigated. There is an additional random noise with known intensity in the dynamic block of the observer. The local optimal reduced-order state estimator is found which takes into account the presence of such noise. The equations of an optimal stationary observer are derived for linear stochastic time invariant system.

1. INTRODUCTION

We consider the following discrete time linear system

$$x_{t+1} = Ax_t + \xi_t \quad (1)$$

$$y_t = Cx_t + \eta_t \quad (2)$$

where $x_t \in R^n$, $y_t \in R^m$ are the state and the measurement vectors, respectively. A and C are matrices of appropriate dimensions ($\text{rank}(C) = m$), the vectors ξ_t and η_t are zero mean discrete time noise signals that satisfy

$$E\xi_t \xi_t^T = W > 0, \quad E\eta_t \eta_t^T = V > 0 \quad (3)$$

We assume also that x_0 is Gaussian with mean and covariance given by

$$Ex_0 = \bar{x}_0, \quad E(x_0 - \bar{x}_0)(x_0 - \bar{x}_0)^T = \Delta_0 \quad (4)$$

Furthermore x_0 , ξ_t and η_t are mutually independent.

An optimal (minimum variance) estimate \hat{x}_t of x_t and its covariance Δ_t are usually formed by the discrete Kalman-Bucy filter (KBF). In practice, the presence of disregarded errors connected with inaccuracy in the model used or with roundoff errors in the computer during digital computations can easily lead to entirely unacceptable estimates and moreover to divergence of KBF [1]–[3]. In [10] such errors were modeled by random disturbances in the filter. An optimal estimator was constructed which takes into account the influence of this additional noise. In some cases, it enables us to improve essentially the quality of the estimates obtained.

The present note that deals with similar investigation of reduced order observer (ROO) with additional noise in the dynamic block goes along with vast research into robust estimation [4]–[5]. It turns out that the estimates of ROO may be much better than the full order filter's ones.

This note is structured as follows. In Section II we design observers for three different situations: ROO 1—there is no additional noise; ROO 2—the presence of noise in the dynamic block is ignored; ROO 3—the influence of such noise is taken into account by seeking out the parameters of an optimal observer. The error equations are given for all of these estimators. In Section III we consider the design of an optimal stationary observer with additional noise for time invariant systems. The equations for its parameters are presented. Section IV contains an example that demonstrates the stability of ROO in the presence of noise in the dynamic block.

II. REDUCED-ORDER OBSERVERS WITH ADDITIONAL NOISES AND THEIR ERRORS

Define a reduced-order observer for system (1) as a pair of dynamic block

$$\dot{z}_{i+1} = F_i z_i + D_i y_i + \nu_{i+1} \quad (5)$$

and connection

$$\dot{\hat{x}}_i = P_i \dot{z}_i + R_i y_i. \quad (6)$$

Here $z_i \in R^l$, $\hat{x}_i \in R^n$ are the estimation vectors for $T_i x_i$ and x_i , respectively; T_i , F_i , D_i , P_i , R_i are matrices of appropriate dimensions; $\nu_i \in R^n$ is a zero mean discrete-time random signal with covariance $E\nu_i \nu_i^T = Q_i$, that is independent of other system noises.

Case $\nu_i = 0$ has been completely investigated in [6]. We assume as usual that parameters of ROO satisfy the Huddle structure

$$F_i = T_{i+1} A_i P_i, \quad D_i = T_{i+1} A_i R_i \quad (7)$$

and the limitation on precision

$$P_i T_i + R_i C_i = I_n. \quad (8)$$

With respect to (7), (8), the error matrix $\Delta_i = E(x_i - \hat{x}_i)(x_i - \hat{x}_i)^T$ of estimate \hat{x}_i is given by the recursive relation

$$\Delta_{i+1} = P_{i+1} T_{i+1} \Pi_i(\Delta_i) T_{i+1}^T P_{i+1}^T + R_{i+1} V_{i+1} R_{i+1}^T + P_{i+1} Q_{i+1} P_{i+1}^T \quad (9)$$

where

$$\Pi_i(\Delta) = A_i \Delta A_i^T + W_{i+1}.$$

Let the first m_1 components of measurement vector (2) be disturbed by comparatively small noises. These measurements would be used for reducing the order of an observer to $r = n - m_1$. We assume also, without loss of generality, that system (1), (2) has the observation canonic form

$$\begin{bmatrix} x_{i+1}^1 \\ x_{i+1}^2 \end{bmatrix} = \begin{bmatrix} A_i^{11} & A_i^{12} \\ A_i^{21} & A_i^{22} \end{bmatrix} \begin{bmatrix} x_i^1 \\ x_i^2 \end{bmatrix} + \begin{bmatrix} \xi_{i+1}^1 \\ \xi_{i+1}^2 \end{bmatrix},$$

$$y_i^1 = x_i^1 + \eta_i^1, \quad y_i^2 = \dot{C} x_i^2 + \eta_i^2. \quad (10)$$

Here, x_i^1 , y_i^1 , ξ_i^1 , η_i^1 are m_1 -dimensional vectors; x_i^2 , ξ_i^2 are $(n - m_1)$ -dimensional vectors and y_i^2 , η_i^2 are $(m - m_1)$ vectors. The matrices A_i , C_i , and V_i are partitioned according to

$$A_i = \begin{bmatrix} A_i^{11} & A_i^{12} \\ A_i^{21} & A_i^{22} \end{bmatrix}, \quad C_i = C' = \begin{bmatrix} I_{m_1} & 0 \\ 0 & \dot{C}' \end{bmatrix}, \quad V_i = \begin{bmatrix} V_i^{11} & V_i^{12} \\ V_i^{21} & V_i^{22} \end{bmatrix}$$

respectively, where A_i^{11} , V_i^{11} are $m_1 \times m_1$; A_i^{12} is $m_1 \times (n - m_1)$; A_i^{21} is $(n - m_1) \times m_1$; A_i^{22} is $(n - m_1) \times (n - m_1)$; $\dot{C}' = [I_{m-m_1} : 0]$ is $(m - m_1) \times (n - m_1)$; $V_i^{12} = V_i^{21T}$ is $m_1 \times (m - m_1)$; V_i^{22} is $(m - m_1) \times (m - m_1)$.

Since η_i^1 is small, we adopt $x_i^1 = y_i^1$ that entails (see (6)–(8)) the following:

$$P_i = \begin{bmatrix} 0 \\ I_{n-m_1} \end{bmatrix}, \quad R_i = \begin{bmatrix} I_{m_1} & 0 \\ R_i^1 & R_i^2 \end{bmatrix}, \quad (11)$$

$$T_i = [-R_i^1 : I_{n-m_1} - R_i^2 \dot{C}'],$$

where R_i^1 is $(n - m_1) \times m_1$ and R_i^2 is $(n - m_1) \times (m - m_1)$. So, if we know Δ_i , then the error matrix Δ_{i+1} is entirely defined by $\hat{R}_{i+1} = [R_{i+1}^1 : R_{i+1}^2]$ and satisfies the equation

$$\Delta_{i+1} = \Phi_{i+1}(\Delta_i, \hat{R}_{i+1}) + S_{i+1}$$

where

$$\Phi_{i+1}(\Delta, \hat{R}) = (I_n - RC)\Pi_i(\Delta)(I_n - RC)^T + R V_{i+1} R^T,$$

$$R = \begin{bmatrix} I_{m_1} & 0 \\ R^1 & R^2 \end{bmatrix}, \quad S_{i+1} = \begin{bmatrix} 0 & 0 \\ 0 & Q_{i+1} \end{bmatrix}. \quad (12)$$

An optimal estimator is derived from the following problem:

$$J = \text{tr} \Phi_{i+1}(\Delta_i, \hat{R}_{i+1}) \rightarrow \min_{\hat{R}_{i+1}}.$$

Let there be no noise in the dynamic block of ROO ($\nu_i = 0$). Then the parameters of an optimal observer are defined as follows:

$$\hat{R}_{i+1}^{(1)} = \Psi_{i+1}(\Delta_i^{(1)}). \quad (13)$$

$$\Delta_{i+1}^{(1)} = \Phi_{i+1}(\Delta_i^{(1)}), \quad \Delta_0^{(1)} = \Delta_0 \quad (14)$$

where

$$\Psi_{i+1}(\Delta) = [\Pi_i^{21}(\Delta) : \Pi_i^{22}(\Delta) \dot{C}^T] (C \Pi_i(\Delta) C^T + V_{i+1})^+. \quad (15)$$

$$\Phi_i = \begin{bmatrix} \Phi_i^{11} & \Phi_i^{12} \\ \Phi_i^{21} & \Phi_i^{22} \end{bmatrix},$$

$$\Phi_i^{11} = V_i^{11}, \quad \Phi_i^{12} = [V_i^{11} : V_i^{12}] \Psi_i^T(\Delta), \quad (16)$$

$$\Phi_i^{21} = \Phi_i^{12T},$$

$$\Phi_i^{22} = \Pi_{i-1}^{22}(\Delta) - [\Pi_{i-1}^{21}(\Delta) : \Pi_{i-1}^{22}(\Delta) \dot{C}^T] \Psi_i^T(\Delta).$$

Similar equations were derived in [6]. The observer which satisfies (13)–(16), will be denoted ROO-1. The estimate $\hat{x}_i^{(1)}$, of ROO-1 has the error $\Delta_i^{(1)}$.

Now, we consider the estimator (5), (6) with disturbances $\nu_i \neq 0$. Let the matrix \hat{R}_{i+1} be given as before by (13)–(16): $\hat{R}_{i+1}^{(2)} = \hat{R}_{i+1}^{(1)}$. Such construction will be called ROO-2 and its estimate will be designated as $\hat{x}_i^{(2)}$. The matrix of real error $\Delta_i^{(2)}$ is connected with the expected error $\Delta_i^{(1)}$ according to

$$\Delta_i^{(2)} = \Delta_i^{(1)} + G_i. \quad (17)$$

The additive matrix G_i , caused by noise ν_i , has the following structure:

$$G_i = \begin{bmatrix} 0 & 0 \\ 0 & \dot{G}_i \end{bmatrix}$$

where $(n - m_1) \times (n - m_1)$ matrix \dot{G}_i is calculated from the recurrent equation

$$\dot{G}_{i+1} = B_{i+1} \dot{G}_i B_{i+1}^T + Q_{i+1}, \quad \dot{G}_0 = 0, \quad (18)$$

$$B_{i+1} = (I_n - R_{i+1}^{(1)} C') A_i.$$

Obviously, ROO-2 is not optimal because we ignore the information about the additional noise when we choose the coefficient \hat{R}_{i+1} .

ROO 3 that optimally uses such information for the selection R_{+1} satisfies

$$R_{+1}^{(i)} = \Psi_{+1}(\Delta_{+1}^{(i)}) \quad (19)$$

$$\Delta_{+1}^{(i)} = \Phi_{+1}(\Delta_{+1}^{(i-1)}) + S_{+1} \quad \Delta_0^{(i)} = \Delta_0 \quad (20)$$

The next lemma proves the optimum of ROO 1 and ROO 3

Lemma Let R be an arbitrary $n \times m$ matrix that satisfies (11). Then

$$\Delta_{+1}(R) = \Delta_{+1}^{(i)} + (R - R_{+1}^{(i)})[C\Pi(\Delta)(I - RC)^T + V_{+1}] \\ (R - R_{+1}^{(i)})^T + I_{+1}(R - R_{+1}^{(i)}) \quad (21)$$

where

$$I_{+1} = \begin{bmatrix} 0 & I_{+1}^T \\ I_{+1} & 0 \end{bmatrix}$$

$$I_{+1}^T = [V_{+1}^T \quad V_{+1}^T](R - R_{+1}^{(i)})^T \quad I_{+1} = I_{+1}^T$$

The proof follows directly from the relations (12)–(15)–(16)–(19) and (20). This lemma is correct for ROO 1 when $\nu = 0$.

Note ROO 1–3 are only local optimal observers. Actually the values of R_{+1} are chosen step by step independently to minimize $J = \text{tr} \Delta_{+1}$ with given Δ . It may be easily shown that the joint selection of matrices R_1, R_2, \dots, R_{+1} enables us to obtain a smaller value of $\text{tr} V_{+1}$. We remark that both procedures yield the same result for an observer of full order (in this case $m_1 = 0, I = 0$).

III. STATIONARY REDUCED ORDER OBSERVERS

We consider the following time invariant system

$$\dot{x}_{+1} = Ax_{+1} + \xi_{+1} \quad (22)$$

$$y = Cx_{+1} + \eta$$

where

$$C = \begin{bmatrix} I & 0 \\ 0 & C \end{bmatrix} \quad C = [I \quad 0]$$

$$E\xi\xi^T = W > 0 \quad E\eta\eta^T = V \geq 0$$

and the stationary observer

$$\dot{z} = I\dot{z} + Dy + z_{+1} \quad (23)$$

$$z = P\dot{z} + Ry$$

where

$$P = \begin{bmatrix} 0 \\ I \end{bmatrix} \quad R = \begin{bmatrix} I & 0 \\ R^T & R \end{bmatrix} \quad R = [R^T \quad R]$$

$$\Gamma = TAP - D - TARB - T = [-R^T \quad I \quad 0 \quad -RC]$$

The constant matrix R is chosen from the set $\mathbb{R} = \{R/(I - RC)A - \text{stable}\}$. For any $R \in \mathbb{R}$ the sequence of matrices $\Delta(R)$ from (12) has the limit $\Delta(R) = \lim_{i \rightarrow \infty} \Delta_{+1}^{(i)}(R)$ which satisfies the Lyapunov matrix equation

$$\Delta = (I - RC)\Pi(\Delta)(I - RC)^T + R[V \quad R^T] + S \\ \Pi(\Delta) = A\Delta A^T + W \quad (24)$$

In such circumstances the problem of the design of an optimal stationary ROO may be formulated as follows

$$\text{tr} \Delta \rightarrow \min_{R \in \mathbb{R}} \quad (25)$$

where Δ satisfies (24). Lagrange function for this problem

$$H = H(\Delta, \Lambda, R) = \text{tr} \Delta \\ + \text{tr}[(\Delta - (I - RC)\Pi(\Delta)(I - RC)^T + V)]$$

where

$$\Delta = \begin{bmatrix} \Delta^{11} & \Delta^T \\ \Delta^T & \Delta \end{bmatrix} \quad \Lambda = \begin{bmatrix} \Lambda^{11} & \Lambda^T \\ \Lambda^T & \Lambda \end{bmatrix}$$

are the error matrix of stationary observer and the matrix of Lagrange multipliers, respectively

$$\Pi(\Delta) = \begin{bmatrix} \Pi^{11} & \Pi^T \\ \Pi^T & \Pi \end{bmatrix}$$

Here $\Delta^{11}, \Lambda^{11}, \Pi^{11}$ are $m_1 \times m_1$, $\Delta^T = \Delta^{1T} = \Lambda^{1T} = \Lambda^{1T}$, $\Pi^T = \Pi^{1T}$ are $m_1 \times (n - m_1)$, $\Delta = \Lambda = \Pi$ are $(n - m_1) \times (n - m_1)$. The necessary conditions of extremum are presented by the nonlinear system

$$\Delta^{11} - \Lambda^{11} = 0$$

$$\Delta^T - \Lambda^{1T}R^{1T} - \Lambda^T R^T = 0 \quad (26)$$

$$\Delta = R^T(\Pi^T + V^{11})R^{1T} - R\Lambda^{1T}R^T - R\Lambda - R \\ - R\Lambda - R^T + (I - RC) - R(C)\Pi - R \\ + R^T\Pi^T(I - RC)^T - R(C)^T - Q = 0$$

$$I + \Lambda^{11} - [R^T A^{11} - (I - RC)A^{1T}]^T \\ \Lambda = [R^T A^{11} - (I - RC)A^{1T}] = 0$$

$$\Lambda^{1T} - [R^T A^{11} - (I - RC)A^{1T}]^T \\ \Lambda = [R^T A^{11} - (I - RC)A^{1T}] = 0 \quad (27)$$

$$I - \Lambda^{11} + \Lambda = [R^T A^{11} - (I - RC)A^{1T}]^T \\ \Lambda = [R^T A^{11} - (I - RC)A^{1T}] = 0$$

$$\Lambda = [R^T(\Pi^{11} + V^{11}) + R(C\Pi^T + V^T) - \Pi] \\ + \Lambda^{11}\Lambda^{11} = 0 \quad (28)$$

$$\Lambda = [R^T(\Pi^T C^T + V^T) + R(C\Pi C^T + V) - \Pi C^T] \\ + \Lambda^{11}\Lambda^{11} = 0$$

The equations (26)–(28) give us the stationary observers that are analogous to ROO 1–3 from Section II. The error of stationary ROO 2 is defined from (24) by substitution $R^{(i)} = R^{(1)}$. Section IV contains the comparison of stationary observers 1–2–3.

Note For system (22) as in [9] we may find the limiting ($i \rightarrow \infty$) values of the observers from Section II. These limiting estimators will differ from the corresponding stationary ones of Section III. We remark that such difference does not take place when $\eta^1 = 0$ (first m_1 measurements without noises) and in case of full order [10].

IV. EXAMPLE

We consider the following differential system:

$$\dot{x} = \hat{A}x(t) + b\dot{\xi}(t) \quad (29)$$

where

$$\hat{A} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad b = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad x(t) = \begin{bmatrix} x^1(t) \\ x^2(t) \end{bmatrix}$$

$$E\dot{\xi}(t) = 0, \quad E\dot{\xi}(t)\dot{\xi}(\tau) = \delta(t - \tau)$$

with discrete measurements in steady time moments $t_{i+1} = t_i + h$

$$y_i = [1 \ 0]x_i. \quad (30)$$

The state vector $x_i = x(t_i)$ of continuous-time system (29) satisfies the following discrete system:

$$x_{i+1} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix} x_i + \xi_{i+1} \quad (31)$$

where

$$\xi_{i+1} = \int_{t_i}^{t_{i+1}} \exp[\hat{A}(t_{i+1} - \tau)] b d\dot{\xi}(\tau)$$

$$E\xi_i = 0, \quad E\xi_i \xi_i^T = \begin{bmatrix} h^3/3 & h^2/2 \\ h^2/2 & h \end{bmatrix}.$$

We compare the estimation precision of Kalman filter [10]

$$\hat{x}_{i+1} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix} \hat{x}_i + \begin{bmatrix} 1 \\ k \end{bmatrix} (y_{i+1} - [1 \ h] \hat{x}_i) + \begin{bmatrix} \nu_{i+1}^1 \\ \nu_{i+1}^2 \end{bmatrix} \quad (32)$$

and the reduced-order observer (23), (24)

$$z_{i+1} = (1 - hr)z_i - y_i hr^2 + \nu_{i+1}, \quad (33)$$

$$\hat{x}_{i+1} = \begin{bmatrix} y_{i+1} \\ z_{i+1} + r y_{i+1} \end{bmatrix}$$

which contain the mutually independent noises ν_i^1 , ν_i^2 , and ν_i with characteristics $E\nu_i^1 = E\nu_i^2 = E\nu_i = 0$, $E(\nu_i^1)^2 = E(\nu_i^2)^2 = E(\nu_i)^2 = q$. We shall take the magnitude $\delta = \lim_{h \rightarrow 0} E(x_i^2 - \hat{x}_i^2)^2$ as a precision test and denote the error of KBF as δ_f , and the error of ROO as δ_o .

1): Let $\nu_i^1 = \nu_i^2 = \nu_i = 0$ (there is no additional noise). Then the optimal parameters of KBF-1 and ROO-1 are equivalent

$$k = r = \frac{3 + \sqrt{3}}{h(2 + \sqrt{3})}, \quad \delta_f^{(1)} = \delta_o^{(1)} = \frac{h}{2\sqrt{3}}. \quad (34)$$

2): Let the filter and the observer be disturbed by noise but the parameters r and k be chosen as in (34) (the presence of noise is ignored). Then

$$\delta_o^{(2)} = \delta_o^{(1)} + \frac{q}{4\sqrt{3} - 6}, \quad \delta_f^{(2)} = \delta_f^{(1)} + \frac{q\sqrt{3}}{h^2}. \quad (35)$$

Fig. 1. The errors of ROO-1, 3 and KBF-1, 3 (ROO-1 = KBF-1).

3): The parameters of KBF and ROO are selected with account of additional noise. So, we obtain

$$r = \frac{\delta_o^{(3)} + h/2}{h(\delta_o^{(3)} + h/3)}, \quad \delta_o^{(3)} = \frac{1}{2} \left(q + \sqrt{q^2 + \frac{h}{3}(4q + h)} \right),$$

$$k = \frac{\delta_f^{(1)} + h/2}{h(\delta_f^{(1)} + h/3) + q},$$

$$\delta_f^{(1)} = \frac{1}{2} \left(q + \sqrt{q^2 + \frac{h}{3}(4q + h) + \frac{4q}{h} \left(\frac{q}{h} + 1 \right)} \right). \quad (36)$$

The error behavior of the optimal stationary filter and observer with noises depending on the discretization step h of system (29) is shown in Fig. 1.

If there is no additional noise then the estimation errors of KBF and ROO are the same and are improved by decrease of step h : $\delta_f^{(1)} = \delta_o^{(1)} = O(h)$. The presence of noise makes the estimation error of KBF essentially larger when h is small: $\delta_f^{(2)} = O(1/h^2)$. The optimization of KBF only lowers the order of vanishing: $\delta_f^{(1)} = O(1/h)$. The errors of ROO-2, 3 keep in the natural monotony on h .

We can correct KBF-2, 3 by the suitable selection of step h [7]. However, the Fig. 1 demonstrates that this method is less effective than the use of corresponding ROO. It may be also shown that the employment of a reduced-order observer is more preferable here than the known regularization [8] of the Kalman filter.

V. CONCLUSION

In this note, we consider the state estimation of linear discrete-time stochastic system by a reduced-order observer with noise in the dynamic block. It turns out that the estimation quality of ROO may be much better than the quality of full-order filter. We derived the local optimal observer which takes into account the influence of additional noise. The optimal stationary observer was designed for time-invariant systems. An example of Section IV demonstrates the stability of ROO in the presence of noise in the dynamic block.

Nevanlinna-Pick Interpolation Problem for Two Frequency Scale Systems

Hossein M. Oloomi

Abstract—The Nevanlinna-Pick interpolation problem for a parametric set of data is considered. Sufficient conditions are obtained that guarantee a two frequency scale solution. Decomposition of the problem into two Nevanlinna-Pick interpolation problems with smaller data size is presented. An algorithm is developed which computes the solution as the result of combining the solutions for these two smaller problems.

I. INTRODUCTION

Many interesting problems of circuits and systems, as well as a number of control problems, can be formulated as the Nevanlinna-Pick (NP) interpolation problem [1]. Indeed, many early attempts to solve the H_∞ problem used this interpolation technique as its mathematical foundation. Examples include [2] and [3]. The NP interpolation problem was also used to solve the robust stabilization problem in [4] and [5]. A good account of the theory is given in [6]–[8]. We use the version presented in [4].

The NP problem considered in this note is different from the standard NP problem in a number of ways. The main difference is in the data set. The data considered here is more general because it is parametric. This should be contrasted with the standard case where data is a fixed set of numbers. However, only first order singularity and analytic perturbation are allowed. This particular structure was considered since it enables us to seek a two frequency scale solution. Nonetheless, generalization to higher order singularities is possible provided one allows multifrequency scale solutions.

Two frequency scale (TFS) transfer functions were first introduced in [9]. The most notable feature of a TFS transfer function is that it can be studied in terms of two lower order transfer functions referred to as the slow transfer function and the fast transfer function. It is evident that when complexity and high dimensionality is of major concern, TFS property is a highly useful attribute. This is precisely the motivation behind the present note.

Once it is guaranteed that the NP problem yields a TFS solution, it certainly makes sense to approximate the solution by constructing

another nearby solution which is easier to obtain than the solution which is obtained as the result of solving two smaller NP problems and is close to the actual solution in some norm. This idea will be pursued later in this note.

We refer the interested reader to [9] for the definition of TFS transfer functions. We will denote the set of all TFS transfer functions by T . When $u(s, \epsilon) \in T$, we will denote its slow and fast transfer functions by $u^s(s)$ and $u^f(p)$ respectively, where $s = j\omega$. We will also need the definition of strictly bounded real functions which we will give here for completeness.

Definition 1 A function $u(s)$ analytic in $\text{Re}[s] > 0$ is said to be a strictly bounded real (SBR) function if $|u(j\omega)| < 1$ for all ω .

The following lemma will be needed in the sequel.

Lemma 1 Let $u(s, \epsilon) \in T$ have no unstable lost poles and have SBR slow and fast transfer functions $u^s(s)$ and $u^f(p)$ respectively. Then for sufficiently small ϵ , $u(s, \epsilon)$ is an SBR transfer function.

Q.E.D.

In [10], it has been proven that if $u(s, \epsilon) \in T$ has no unstable lost poles and if $\|u^s(s)\|_\infty \leq 1$ and $\|u^f(p)\|_\infty \leq 1$ then for sufficiently small ϵ , $\|u(s, \epsilon)\|_\infty \leq 1 + O(\epsilon)$. We specialize this result to the present situation. We have $\|u^s(s)\|_\infty = \theta^s < 1$ and $\|u^f(p)\|_\infty = \theta^f < 1$. Let $\theta_{\text{eff}} = \max\{\theta^s, \theta^f\}$. Then there exists a constant K such that for sufficiently small ϵ , $\|u(s, \epsilon)\|_\infty \leq \theta_{\text{eff}} + K\epsilon$. When $K \leq 0$, then $\|u(s, \epsilon)\|_\infty \leq \theta_{\text{eff}} + K\epsilon < \theta_{\text{eff}} < 1$. On the other hand, when $K > 0$, set $\epsilon^* = \frac{1 - \theta_{\text{eff}}}{K} > 0$. Then for all $0 \leq \epsilon < \epsilon^*$, $\|u(s, \epsilon)\|_\infty \leq \theta_{\text{eff}} + K\epsilon < \theta_{\text{eff}} + K\left(\frac{1 - \theta_{\text{eff}}}{K}\right) = 1$. Hence $\|u(s, \epsilon)\|_\infty < 1$, i.e., for sufficiently small ϵ , $u(s, \epsilon)$ is an SBR function.

Q.E.D.

II. THE INTERPOLATION PROBLEM

Suppose we are given two sequences of l complex numbers

$$\begin{aligned} \alpha_1(\epsilon) &= \alpha_{l_1}(\epsilon) = \frac{\alpha_{l_1+1}(\epsilon)}{\epsilon} = \dots = \alpha_l(\epsilon) \\ \beta_1(\epsilon) &= \beta_{l_1}(\epsilon) = \beta_{l_1+1}(\epsilon) = \dots = \beta_l(\epsilon) \end{aligned}$$

where each $\alpha_i(\epsilon)$ and $\beta_i(\epsilon)$ is a function of ϵ and analytic at $\epsilon = 0$. In addition, suppose there exists an $\epsilon^* > 0$ such that for all $0 \leq \epsilon < \epsilon^*$, $\text{Re}[\alpha_i(\epsilon)] > 0$ and $|\beta_i(\epsilon)| < 1$ for $i = 1, \dots, l$. The NP problem for this set of data is one of finding an SBR function $u(s, \epsilon)$ which interpolates the data, i.e.,

$$u(\alpha_i(\epsilon), \epsilon) = \beta_i(\epsilon) \quad i = 1, \dots, l$$

It is well known that the solution exists (see [4]) iff the Pick matrix

$$P(\epsilon) = \begin{bmatrix} P_{11}(\epsilon) & \epsilon P_{1l}(\epsilon) \\ \epsilon \overline{P_{1l}(\epsilon)} & \epsilon P_{ll}(\epsilon) \end{bmatrix} > 0$$

where

$$\begin{aligned} P_{11}(\epsilon) &= \left\{ \frac{1 - \beta_j(\epsilon) \overline{\beta_i(\epsilon)}}{\alpha_i(\epsilon) + \overline{\alpha_j(\epsilon)}} \right\} & i = 1 & \dots & l_1 \\ & & j = 1 & \dots & l_1 \\ P_{ll}(\epsilon) &= \left\{ \frac{1 - \beta_j(\epsilon) \overline{\beta_i(\epsilon)}}{\epsilon \alpha_i(\epsilon) + \overline{\epsilon \alpha_j(\epsilon)}} \right\} & i = l_1 + 1 & \dots & l \\ & & j = l_1 + 1 & \dots & l \\ P_{22}(\epsilon) &= \left\{ \frac{1 - \beta_j(\epsilon) \overline{\beta_i(\epsilon)}}{\alpha_i(\epsilon) + \overline{\alpha_j(\epsilon)}} \right\} & i = l_1 + 1 & \dots & l \\ & & j = l_1 + 1 & \dots & l \end{aligned}$$

Moreover, the solution $u(s, \epsilon) := u_1(s, \epsilon)$ can be generated recursively from the algorithm (see [7])

$$u_j(s, \epsilon) := \frac{(\epsilon s - \alpha_j(\epsilon))u_{j+1}(s, \epsilon) + \rho_j(\epsilon)(\epsilon s + \bar{\alpha}_j(\epsilon))}{(\epsilon s + \bar{\alpha}_j(\epsilon)) + \bar{\rho}_j(\epsilon)(\epsilon s - \alpha_j(\epsilon))u_{j+1}(s, \epsilon)},$$

$$j = l, \dots, l_1 + 1, \quad (1)$$

$$u_j(s, \epsilon) := \frac{(s - \alpha_j(\epsilon))u_{j+1}(s, \epsilon) + \rho_j(\epsilon)(s + \bar{\alpha}_j(\epsilon))}{(s + \bar{\alpha}_j(\epsilon)) + \bar{\rho}_j(\epsilon)(s - \alpha_j(\epsilon))u_{j+1}(s, \epsilon)},$$

$$j = l_1, \dots, 1 \quad (2)$$

where $u_{l+1}(s, \epsilon)$ is any SBR function, and the Fenyves array $\beta_{i,j}(\epsilon)$ is generated via

$$\beta_{i,1}(\epsilon) := \beta_i(\epsilon), \quad i = 1, \dots, l,$$

$$\beta_{i,j+1}(\epsilon) := \frac{(\alpha_i(\epsilon) + \bar{\alpha}_j(\epsilon))(\beta_{i,j}(\epsilon) - \beta_{j,j}(\epsilon))}{(\alpha_i(\epsilon) - \alpha_j(\epsilon))(1 - \bar{\beta}_{j,j}(\epsilon)\beta_{i,j}(\epsilon))},$$

$$1 \leq j \leq i-1 \leq l-1,$$

$$\rho_j(\epsilon) := \beta_{j,j}(\epsilon), \quad j = 1, \dots, l.$$

It is well-known that $P(\epsilon) > 0$ iff $|\beta_{i,j}(\epsilon)| < 1$, $\forall i, j$ [7]. In particular, $P(\epsilon) > 0$ implies $|\rho_j(\epsilon)| < 1$, $\forall j$. We call this the full-order NP problem. Associated with this problem, we consider two subproblems.

1) The Fast NP Problem: Consider two sequences of $(l-1)$ complex numbers

$$\alpha_{l_1+1}^f, \dots, \alpha_l^f$$

$$\beta_{l_1+1}^f, \dots, \beta_l^f$$

with the property that $\operatorname{Re}[\alpha_i^f] > 0$ and $|\beta_i^f| < 1$ for $i = l_1+1, \dots, l$. We seek to find an SBR function $u^f(p)$ such that

$$u^f(\alpha_i^f) = \beta_i^f, \quad i = l_1+1, \dots, l.$$

The solution exists iff

$$P^f := \left\{ \frac{1 - \beta_i^f \bar{\beta}_j^f}{\alpha_i^f + \bar{\alpha}_j^f} \right\} > 0, \quad i = l_1+1, \dots, l,$$

$$j = l_1+1, \dots, l$$

and is given by

$$u_j^f(p) := \frac{(p - \alpha_j^f)u_{j+1}^f(p) + \rho_j^f(p + \bar{\alpha}_j^f)}{(p + \bar{\alpha}_j^f) + \bar{\rho}_j^f(p - \alpha_j^f)u_{j+1}^f(p)},$$

$$j = l, \dots, l_1 + 1, \quad (3)$$

$$u^f(p) := u_{l_1+1}^f(p) \quad (4)$$

where $u_{l_1+1}^f(p)$ is any SBR function and

$$\beta_{i,1}^f := \beta_i^f, \quad i = l_1+1, \dots, l,$$

$$\beta_{i,j+1}^f := \frac{(\alpha_i^f + \bar{\alpha}_j^f)(\beta_{i,j}^f - \beta_{j,j}^f)}{(\alpha_i^f - \alpha_j^f)(1 - \bar{\beta}_{j,j}^f \beta_{i,j}^f)},$$

$$l_1+1 \leq j \leq i-1 \leq l-1,$$

$$\rho_j^f := \beta_{j,j}^f.$$

$P^f > 0$ iff $|\beta_{i,j}^f| < 1$. Hence, $P^f > 0$ implies $|\rho_j^f| < 1$.

2) The Slow NP Problem: Consider two sequences of l_1 complex numbers

$$\alpha_1^s, \dots, \alpha_{l_1}^s$$

$$\beta_1^s, \dots, \beta_{l_1}^s$$

with the property that $\operatorname{Re}[\alpha_i^s] > 0$ and $|\beta_i^s| < 1$ for $i = 1, \dots, l_1$. We seek to find an SBR function $u^s(s)$ such that

$$u^s(\alpha_i^s) = \beta_i^s, \quad i = 1, \dots, l_1.$$

The solution exists iff

$$P^s := \left\{ \frac{1 - \beta_i^s \bar{\beta}_j^s}{\alpha_i^s + \bar{\alpha}_j^s} \right\} > 0, \quad i = 1, \dots, l_1, \quad j = 1, \dots, l_1$$

and is given by

$$u_j^s(s) := \frac{(s - \alpha_j^s)u_{j+1}^s(s) + \rho_j^s(s + \bar{\alpha}_j^s)}{(s + \bar{\alpha}_j^s) + \bar{\rho}_j^s(s - \alpha_j^s)u_{j+1}^s(s)}, \quad j = l_1, \dots, 1, \quad (5)$$

$$u^s(s) := u_{l_1+1}^s(s) \quad (6)$$

where $u_{l_1+1}^s(s)$ is any SBR function and

$$\beta_{i,1}^s := \beta_i^s, \quad i = 1, \dots, l_1,$$

$$\beta_{i,j+1}^s := \frac{(\alpha_i^s + \bar{\alpha}_j^s)(\beta_{i,j}^s - \beta_{j,j}^s)}{(\alpha_i^s - \alpha_j^s)(1 - \bar{\beta}_{j,j}^s \beta_{i,j}^s)}, \quad 1 \leq j \leq i-1 \leq l_1-1,$$

$$\rho_j^s := \beta_{j,j}^s.$$

$P^s > 0$ iff $|\beta_{i,j}^s| < 1$. Hence, $P^s > 0$ implies $|\rho_j^s| < 1$.

We relate the slow and fast NP problems to the full-order NP problem by setting

$$(\alpha_j^s, \beta_j^s) := (\alpha_j(0), \beta_j(0)), \quad j = 1, \dots, l_1,$$

$$(\alpha_j^f, \beta_j^f) := (\alpha_j(0), \beta_j(0)), \quad j = l_1+1, \dots, l.$$

It then follows that $\beta_{i,j}^s = \beta_{i,j}(0)$, $\rho_j^s = \rho_j(0)$ for $i, j = 1, \dots, l_1$, and $\beta_{i,j}^f = \beta_{i,j}(0)$, $\rho_j^f = \rho_j(0)$ for $i, j = l_1+1, \dots, l$.

Our objectives are as follows:

- to show that the solvability condition for the full-order problem is implied by the solvability conditions for the slow and the fast subproblems;
- to construct an SBR-TFS transfer function $u^{s,f}(s, \epsilon)$ from the solutions of the slow and fast subproblems which approximates the solution $u(s, \epsilon)$ of the full-order problem arbitrarily closely, i.e., an SBR transfer function $u^{s,f}(s, \epsilon) \in T_\epsilon$ such that

$$\|u(s, \epsilon) - u^{s,f}(s, \epsilon)\|_\infty = O(\epsilon).$$

Since the size of data are smaller for the slow and the fast problems when compared to the full-order problem, it is evident that one gains a computational advantage by solving for $u^{s,f}(s, \epsilon)$ instead of $u(s, \epsilon)$.

III. ON THE SOLVABILITY CONDITION

In this section, we will show that the NP problem is solvable for the full-order problem if it is solvable for the slow and fast subproblems.

Theorem 1: Let $P^s > 0$ and $P^f > 0$. Then there exists an $\epsilon^* > 0$ such that for all $\epsilon \in (0, \epsilon^*)$, $P(\epsilon) > 0$.

Proof Since $P_{11}(0) = P^* > 0$, for sufficiently small ϵ $P_{11}(\epsilon) > 0$. Hence, for sufficiently small ϵ , $P_{11}^{-1}(\epsilon)$ exists. Thus, using a well-known result on the similarity transformation [11] we conclude that $P(\epsilon)$ is similar to the lower block triangular matrix

$$\begin{bmatrix} P_{11}(\epsilon) & 0 \\ \star & \epsilon[P_{22}(\epsilon) - \epsilon P_{12}(\epsilon)P_{11}^{-1}(\epsilon)\bar{P}_{12}(\epsilon)] \end{bmatrix}$$

where \star stands for the block whose value is unimportant in the following development. Therefore $P(\epsilon) > 0$ iff $L(\epsilon) = P_{22}(\epsilon) - \epsilon P_{12}(\epsilon)P_{11}^{-1}(\epsilon)\bar{P}_{12}(\epsilon) > 0$. But since $L(0) = P_{22}(0) = P^* > 0$ we see that for sufficiently small ϵ $L(\epsilon) > 0$. Hence there exists an $\epsilon^* > 0$ such that for all $\epsilon \in (0, \epsilon^*)$, conditions $P^* > 0$ and $P^* > 0$ imply $P(\epsilon) > 0$. \square F. D.

IV. THE TFS SOLUTION

The main step towards the construction of $u^l(s, \epsilon)$ is to find conditions which ensure a TFS solution to the full order algorithm (1)–(2). To this end we introduce the following family of transfer functions

$$u_j^s(s) = \frac{-\alpha_j^l u_{j+1}^s(s) + \rho_j^l \alpha_j^l}{\bar{\alpha}_j^l - \bar{\rho}_j^l \alpha_j^l u_{j+1}^s(s)} \quad j = l, \dots, l_1 + 1 \quad (7)$$

$$u_j^l(s) = \frac{u_{j+1}^l(p) + \rho_j}{1 + \rho_j^s u_{j+1}^l(p)} \quad j = l_1, \dots, 1 \quad (8)$$

and prove a lemma about them.

Lemma 2 Let $u_{j+1}^s(s)$ and $u_{j+1}^l(p)$ be two SBR transfer functions. Then $u_j^s(s)$ defined by (7) and $u_j^l(p)$ defined by (8) are SBR transfer functions for $j = l, \dots, l_1 + 1$ and $j = l_1, \dots, 1$ respectively.

Proof We prove by induction that $u^l(p)$ is an SBR transfer function. The proof for $u_j(s)$ is quite similar and is omitted. We are given that $u_{l_1+1}^l(p)$ is an SBR transfer function. So suppose $u_{j+1}^l(p)$ is also an SBR transfer function and consider $u_j^l(p)$ obtained from (8). Certainly $u_j^l(p)$ is a proper rational function. It is also analytic in the closed right half plane since otherwise $1 + \rho_j u_{j+1}^l(\zeta) = 0$ for some ζ with $\text{Re}[\zeta] > 0$. But then $|u_{j+1}^l(\zeta)| = 1/|\rho_j^s| > 1$ which leads to a contradiction in view of the maximum principle. To complete the proof we have by a simple calculation

$$1 - |u_j^l(i\omega)|^2 = \frac{(1 - |\rho_j^s|)(1 - |u_{j+1}^l(i\omega)|^2)}{|1 + \rho_j u_{j+1}^l(i\omega)|^2}$$

Since $|\rho_j| < 1$ and $|u_{j+1}^l(i\omega)| < 1$ it follows that $u_j^l(p)$ is an SBR function. \square F. D.

We now use Lemma 2 to show that the algorithm (1)–(2) will indeed produce a TFS solution provided it is initialized with a correct TFS transfer function.

Theorem 2 Let $u_{l_1+1}^l(p)$ and $u_{l_1+1}^s(s)$ be two SBR transfer functions used to initiate the algorithms (3)–(4) and (5)–(6) respectively where $u_{l_1+1}^s(s)$ is generated from (7) using an SBR transfer function $u_{l_1+1}^l(p)$ as the initial data. Let $u_{l_1+1}(s, \epsilon) \in \mathcal{I}$ have no unstable lost poles and let $u_{l_1+1}^s(s)$ and $u_{l_1+1}^l(p)$ be its slow and fast transfer functions, respectively. Then the transfer function $u(s, \epsilon)$ generated via the full order algorithm (1)–(2) is an SBR-TFS transfer function.

Proof By Lemma 1 $u_{l_1+1}(s, \epsilon)$ is an SBR transfer function. Therefore from the general theory $u(s, \epsilon)$ produced by algorithm (1)–(2) is also an SBR transfer function. It remains to show that $u(s, \epsilon)$ is a TFS transfer function. For that, we consider two cases.

Case I $l_1 + 1 \leq j \leq l$. We prove by induction. By assumption $u_{l_1+1}(s, \epsilon) \in \mathcal{I}$. So suppose $u_{j+1}(s, \epsilon) \in \mathcal{I}$ and invoke [9 Theorem 2.2] to write

$$u_{j+1}(s, \epsilon) = \frac{n_{j+1}(s, \epsilon) + s^{k_{j+1}} n_{2,j+1}(s, \epsilon)}{d_{j+1}(s, \epsilon) + s^{k_{j+1}} d_{2,j+1}(s, \epsilon)} \quad (9)$$

where

- 1) $n_{j+1}(s, \epsilon)$, $n_{2,j+1}(s, \epsilon)$, $d_{j+1}(s, \epsilon)$ and $d_{2,j+1}(s, \epsilon)$ are polynomials with coefficients analytic at $\epsilon = 0$.
- 2) $\deg[d_{j+1}(s, \epsilon)] = \deg[d_{j+1}(s, 0)] - l$.
- 3) $\deg[d_{2,j+1}(p, \epsilon)] = \deg[d_{2,j+1}(p, 0)]$.
- 4) $\deg[n_{j+1}(s, \epsilon)] \leq k_{j+1}$.
- 5) $\deg[n_{2,j+1}(p, \epsilon)] \leq \deg[d_{2,j+1}(p, \epsilon)]$.
- 6) The constant terms of $n_{j+1}(p, \epsilon)$ and $d_{2,j+1}(p, \epsilon)$ are both zero.

Now the first and the last conditions allow us to expand the polynomials in (9) as

$$n_{j+1}(s, \epsilon) = \sum_{k=0}^{k_{j+1}} \Lambda_{j+1}^k(\epsilon) s^k$$

$$n_{2,j+1}(s, \epsilon) = \sum_{k=1}^{k_{j+1}} \Lambda_{j+1}^k(\epsilon) s^k$$

$$d_{j+1}(s, \epsilon) = \sum_{k=0}^{k_{j+1}} D_{j+1}^k(\epsilon) s^k$$

$$d_{2,j+1}(s, \epsilon) = \sum_{k=1}^{k_{j+1}} D_{j+1}^k(\epsilon) s^k$$

So using these expansions we substitute (9) in (1) and express $u_j(s, \epsilon)$ as

$$u_j(s, \epsilon) = \frac{n_{j+1}(s, \epsilon) + s^{k_{j+1}} n_{2,j+1}(s, \epsilon)}{d_{j+1}(s, \epsilon) + s^{k_{j+1}} d_{2,j+1}(s, \epsilon)} \quad (10)$$

where $k_j = k_{j+1}$ and

$$\begin{aligned} n_{j+1}(s, \epsilon) &= (\epsilon s - \alpha_j(\epsilon)) n_{j+1}(s, \epsilon) \\ &\quad + \rho_j(\epsilon)(\epsilon s + \bar{\alpha}_j(\epsilon)) d_{j+1}(s, \epsilon) \\ &\quad - \epsilon s (\Lambda_{j+1}^{k_{j+1}}(\epsilon) + \rho_j(\epsilon) D_{j+1}^{k_{j+1}}(\epsilon)) s^{k_{j+1}-1} \end{aligned} \quad (11)$$

$$\begin{aligned} n_{j+1}(\epsilon s, \epsilon) &= (\epsilon s - \alpha_j(\epsilon)) n_{j+1}(\epsilon s, \epsilon) + \rho_j(\epsilon)(\epsilon s + \bar{\alpha}_j(\epsilon)) \\ &\quad d_{j+1}(\epsilon s, \epsilon) + \epsilon s (\Lambda_{j+1}^{k_{j+1}}(\epsilon) + \rho_j(\epsilon) D_{j+1}^{k_{j+1}}(\epsilon)) \end{aligned} \quad (12)$$

$$\begin{aligned} d_{j+1}(s, \epsilon) &= (\epsilon s + \bar{\alpha}_j(\epsilon)) d_{j+1}(s, \epsilon) + \bar{\rho}_j(\epsilon)(\epsilon s - \alpha_j(\epsilon)) \\ &\quad n_{j+1}(s, \epsilon) - \epsilon s (D_{j+1}^{k_{j+1}}(\epsilon) + \bar{\rho}_j(\epsilon) \Lambda_{j+1}^{k_{j+1}}(\epsilon)) s^{k_{j+1}-1} \end{aligned} \quad (13)$$

$$\begin{aligned} d_{2,j+1}(\epsilon s, \epsilon) &= (\epsilon s + \bar{\alpha}_j(\epsilon)) d_{2,j+1}(\epsilon s, \epsilon) + \bar{\rho}_j(\epsilon)(\epsilon s - \alpha_j(\epsilon)) \\ &\quad n_{2,j+1}(\epsilon s, \epsilon) + \epsilon s (D_{j+1}^{k_{j+1}}(\epsilon) + \bar{\rho}_j(\epsilon) \Lambda_{j+1}^{k_{j+1}}(\epsilon)) \end{aligned} \quad (14)$$

We claim that

- 1) $n_{j+1}(s, \epsilon)$, $n_{2,j+1}(s, \epsilon)$, $d_{j+1}(s, \epsilon)$ and $d_{2,j+1}(s, \epsilon)$ are polynomials with coefficients analytic at $\epsilon = 0$. This follows since all polynomials in (9) have coefficients analytic at $\epsilon = 0$.
- 2) $\deg[d_{j+1}(s, \epsilon)] = \deg[d_{j+1}(s, 0)] = k_j$. To prove this claim we note that if

$$\bar{\alpha}_j^l D_{j+1}^{k_{j+1}}(0) - \bar{\rho}_j^l \alpha_j^l \Lambda_{j+1}^{k_{j+1}}(0) \neq 0 \quad (15)$$

then degree of $d_{j+1}(s, \epsilon)$ in (13) does not drop to a lower value when ϵ is set to zero. That is, for sufficiently small ϵ , the claim is true. On the other hand, setting $\epsilon = 0$ in (1) and comparing the result with (7) we see by induction that $u_j(s, 0) = u_j(s)$

for $j = l, \dots, l_1 + 1$. Thus, upon computing $u_{j+1}^*(s)$ from (9) and substituting the result in (7), we deduce that

$$u_j^*(\infty) = \frac{-\alpha_j^l N_{1,j+1}^{k'+1}(0) + \rho_j^l \bar{\alpha}_j^l D_{1,j+1}^{k'+1}(0)}{\bar{\alpha}_j^l D_{1,j+1}^{k'+1}(0) - \bar{\rho}_j^l \alpha_j^l N_{1,j+1}^{k'+1}(0)}.$$

But then the properness of $u_j^*(s)$ implies that $u_j^*(\infty) \neq \infty$. Hence, (15) holds.

- 3) $\deg[d_{2,j}(p, \epsilon)] = \deg[d_{2,j}(p, 0)]$. The method of proof for this part is similar to the previous part. That is, we see from (14) that if

$$D_{2,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{2,j+1}^{k'+1}(0) \neq 0 \quad (16)$$

then for sufficiently small ϵ , the claim is true. On the other hand, computing $u_j(p/\epsilon, \epsilon)|_{\epsilon=0}$ from (1) and comparing it with $u_j^l(p)$ in (3), it follows by induction that the two transfer functions are equal for each $j = l, \dots, l_1 + 1$. Thus, upon computing $u_{j+1}^l(p)$ from (9) and substituting the result in (3), we deduce that

$$u_j^l(\infty) = \frac{N_{2,j+1}^{k'+1}(0) + \rho_j^l D_{2,j+1}^{k'+1}(0)}{D_{2,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{2,j+1}^{k'+1}(0)}.$$

But the properness of $u_j^l(p)$ implies that $u_j^l(\infty) \neq 0$. Hence, (16) holds.

- 4) $\deg[u_{1,j}(s, \epsilon)] \leq k_j$. This follows easily by examining (11).
 5) $\deg[u_{2,j}(p, \epsilon)] \leq \deg[d_{2,j}(p, \epsilon)]$. This follows easily by examining (12).
 6) The constant terms of $u_{2,j}(p, \epsilon)$ and $d_{2,j}(p, \epsilon)$ are both zero. This follows by examining (12) and (14), noting that the constant terms of the polynomials $u_{2,j+1}(p, \epsilon)$ and $d_{2,j+1}(p, \epsilon)$ are zeros.

Therefore, by [9, Theorem 2.2], $u_j(s, \epsilon) \in T$, for $j = l_1 + 1, \dots, l$.

Case 2— $1 \leq j \leq l_1$. We prove by induction. By the previous step, we know that $u_{l_1+1}(s, \epsilon) \in T$. So, let us suppose $u_{j+1}(s, \epsilon) \in T$, and invoke [9, Theorem 2.2] to express $u_{j+1}(s, \epsilon)$ as in (9) with the six properties as was stated in Case 1. Next, we substitute (9) in (2) and express $u_j(s, \epsilon)$ as in (10) where $k_j = k_{j+1} + 1$, and

$$\begin{aligned} u_{1,j}(s, \epsilon) &= (s - \alpha_j(\epsilon))n_{1,j+1}(s, \epsilon) \\ &\quad + \rho_j(\epsilon)(s + \bar{\alpha}_j(\epsilon))d_{1,j+1}(s, \epsilon) \\ &\quad + \epsilon(-\alpha_j(\epsilon)N_{2,j+1}^1(\epsilon) + \rho_j(\epsilon)\bar{\alpha}_j(\epsilon)D_{2,j+1}^1(\epsilon)) \\ &\quad \cdot s^{k_{j+1}+1}. \end{aligned} \quad (17)$$

$$\begin{aligned} u_{2,j}(\epsilon s, \epsilon) &= u_{2,j+1}(\epsilon s, \epsilon) + \rho_j(\epsilon)d_{2,j+1}(\epsilon s, \epsilon) \\ &\quad - \alpha_j(\epsilon) \left(\frac{u_{2,j+1}(\epsilon s, \epsilon)}{s} - \epsilon N_{2,j+1}^1(\epsilon) \right) \\ &\quad + \rho_j(\epsilon)\bar{\alpha}_j(\epsilon) \left(\frac{d_{2,j+1}(\epsilon s, \epsilon)}{s} - \epsilon D_{2,j+1}^1(\epsilon) \right). \end{aligned} \quad (18)$$

$$\begin{aligned} d_{1,j}(s, \epsilon) &= (s + \bar{\alpha}_j(\epsilon))d_{1,j+1}(s, \epsilon) \\ &\quad + \bar{\rho}_j(\epsilon)(s - \alpha_j(\epsilon))n_{1,j+1}(s, \epsilon) \\ &\quad + \epsilon(\bar{\alpha}_j(\epsilon)D_{2,j+1}^1(\epsilon) - \bar{\rho}_j(\epsilon)\alpha_j(\epsilon)N_{2,j+1}^1(\epsilon)) \\ &\quad \cdot s^{k_{j+1}+1}. \end{aligned} \quad (19)$$

$$\begin{aligned} d_{2,j}(\epsilon s, \epsilon) &= d_{2,j+1}(\epsilon s, \epsilon) + \bar{\rho}_j(\epsilon)u_{2,j+1}(\epsilon s, \epsilon) \\ &\quad + \bar{\alpha}_j(\epsilon) \left(\frac{d_{2,j+1}(\epsilon s, \epsilon)}{s} - \epsilon D_{2,j+1}^1(\epsilon) \right) \\ &\quad - \bar{\rho}_j(\epsilon)\alpha_j(\epsilon) \left(\frac{u_{2,j+1}(\epsilon s, \epsilon)}{s} - \epsilon N_{2,j+1}^1(\epsilon) \right). \end{aligned} \quad (20)$$

We claim the following:

- 1) $u_{1,j}(s, \epsilon)$, $u_{2,j}(\epsilon s, \epsilon)$, $d_{1,j}(s, \epsilon)$, and $d_{2,j}(\epsilon s, \epsilon)$ are polynomials with coefficients analytic at $\epsilon = 0$. This follows since all polynomials in (9) have coefficients analytic at $\epsilon = 0$.
- 2) $\deg[d_{1,j}(s, \epsilon)] = \deg[d_{1,j}(s, 0)] = k_j$. This is proved by noting from (19) that if

$$D_{1,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{1,j+1}^{k'+1}(0) \neq 0 \quad (21)$$

then for sufficiently small ϵ , the claim is true. On the other hand, setting $\epsilon = 0$ in (2) and comparing the result with (5), we see by induction that $u_j(s, 0) = u_j^*(s)$ for $j = l_1, \dots, 1$. Thus, upon computing $u_{j+1}^*(s)$ from (9) and substituting the result in (5), we deduce that

$$u_j^*(\infty) = \frac{N_{1,j+1}^{k'+1}(0) + \rho_j^l D_{1,j+1}^{k'+1}(0)}{D_{1,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{1,j+1}^{k'+1}(0)}.$$

But then the properness of $u_j^*(s)$ implies that $u_j^*(\infty) \neq \infty$. Hence, (21) holds.

- 3) $\deg[d_{2,j}(p, \epsilon)] = \deg[d_{2,j}(p, 0)]$. To prove this, note from (20) that if

$$D_{2,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{2,j+1}^{k'+1}(0) \neq 0 \quad (22)$$

then for sufficiently small ϵ , the claim is true. On the other hand, computing $u_j(p/\epsilon, \epsilon)|_{\epsilon=0}$ from (2) and comparing it with $u_j^l(p)$ in (3), we see by induction that the two transfer functions are equal for each $j = l_1, \dots, 1$. Thus, upon computing $u_{j+1}^l(p)$ from (9) and substituting the result in (8), we deduce that

$$u_j^l(\infty) = \frac{N_{2,j+1}^{k'+1}(0) + \rho_j^l D_{2,j+1}^{k'+1}(0)}{D_{2,j+1}^{k'+1}(0) + \bar{\rho}_j^l N_{2,j+1}^{k'+1}(0)}.$$

But then properness of $u_j^l(s)$ implies that $u_j^l(\infty) \neq \infty$. Hence, (22) holds.

- 4) $\deg[u_{1,j}(s, \epsilon)] \leq k_j$. This follows easily by examining (11).
- 5) $\deg[u_{2,j}(p, \epsilon)] \leq \deg[d_{2,j}(p, \epsilon)]$. This follows easily by examining (12).
- 6) The constant terms of $u_{2,j}(p, \epsilon)$ and $d_{2,j}(p, \epsilon)$ are both zero. This follows by examining (12) and (14) and noting that the constant polynomials $u_{2,j+1}(p, \epsilon)$ and $d_{2,j+1}(p, \epsilon)$ are zero.

Therefore, by [9, Theorem 2.2], $u_j(s, \epsilon) \in T$, for $j = 1, \dots, l_1$. Combining the two cases, we conclude that $u_j(s, \epsilon) \in T$, for all j . This completes the proof.

Q.E.D.

We now present an algorithm for the construction of the TFS-SBR transfer function $u^{s^k}(s, \epsilon)$.

Algorithm.

- 1) Check to see if $P^l > 0$ and $P^h > 0$. If these conditions are satisfied, proceed to the next step. Otherwise, terminate the algorithm.
- 2) Choose an SBR transfer function $u_{l_1+1}^l(p)$ and compute $u_{l_1+1}^F(p)$ from (3).
- 3) Choose an SBR transfer function $u_{l_1+1}^*(s)$ and compute $u_{l_1+1}^*(s)$ from (7).
- 4) Use the SBR transfer function $u_{l_1+1}^F(p)$ obtained in Step 2 to compute $u_1^F(p)$ from (8).
- 5) Use the SBR transfer function $u_{l_1+1}^*(s)$ obtained in Step 3 to compute $u_1^*(s)$ from (5).
- 6) Set $u^l(p) := u_1^l(p)$ and $u^h(s) := u_1^*(s)$.
- 7) Set $u^{s^k}(s, \epsilon) := u^h(s) + u^l(\epsilon s) - u^h(\infty)$.

We have the following theorem.

Theorem 3 Let $u(s, \epsilon)$ be the solution to the full-order NP problem (1)–(2) with the initial data given by Theorem 2 and let $u^{s,f}(s, \epsilon)$ be the transfer function constructed in the aforementioned algorithm. Then for sufficiently small ϵ

- 1) $u^{s,f}(s, \epsilon)$ is a TFS–SBR transfer function, and
- 2) $\|u(s, \epsilon) - u^{s,f}(s, \epsilon)\|_{\infty} = O(\epsilon)$

Proof By Theorem 2, $u(s, \epsilon)$ is a TFS–SBR transfer function. Also $u^{s,f}(s, \epsilon) \in T$ because it has the same slow and fast transfer functions as $u(s, \epsilon)$. Since both of these slow and fast transfer functions are SBR functions by Lemma 1, $u^{s,f}(s, \epsilon)$ is also an SBR transfer function. This proves part 1 of the theorem. Part 2 follows from [9, Theorem 4.1].

QED

V CONCLUSION

In this note we have considered a version of the NP interpolation problem. We have obtained conditions which guarantee a TFS solution. We have formulated two smaller NP interpolation problems and have shown that they can be solved in parallel. We have reduced the solvability condition in terms of the solvability conditions for these two smaller problems. The immediate gain here is the reduction in the verification process and hence the computer time. We have used the solutions obtained from these two smaller problems and have constructed a solution which can become arbitrarily close in the H_{∞} norm to the solution of the original NP problem. The results of this note should prove useful both from the computational standpoint as well as in the areas such as robust stabilization problem for TFS systems.

Multiscale Smoothing Error Model

Mark R. Luetgten and Alan S. Willsky

Abstract—A class of multiscale stochastic models used in recursive dynamics on trees has recently been introduced. These models are interesting because they can be used to represent a wide class of physical phenomena and because they lead to efficient algorithms for estimation and likelihood calculation. In this paper, we provide a complete statistical characterization of the error associated with smoothed estimates of the multiscale stochastic processes described by these models. In particular, we show that the smoothing error is itself a multiscale stochastic process with parameters that can be explicitly calculated.

I INTRODUCTION

A class of multiscale models describing stochastic processes indexed by the nodes of a tree has recently been introduced in [1]–[2]. These models can be used to capture a surprisingly rich class of physical phenomena. For instance, experimental results in [2] illustrate that they can be used to model the statistical self-similarity exhibited by stochastic processes with generalized power spectra of the form $1/f^{\alpha}$ and in [3] we describe how they can be used to represent any 1-D Markov process or 2-D Markov random field. Moreover, this class of models leads to efficient algorithms for estimation and likelihood calculation and as a result provides a useful framework for a variety of signal and image processing problems [1]–[2], [4]–[6].

Knowledge of the error statistics of smoothed estimates of such processes is essential for the development of a number of important new applications, including for instance so-called mapping problems [7], the multiscale counterpart to the model validation problem in [8], and certain oceanographic problems [9]. Several such applications have been developed in the context of 1-D Gauss–Markov models by exploiting relatively recent results that show that the smoothing error processes associated with Gauss–Markov models are themselves Gauss–Markov processes [7], [8], [10], [11].¹ In this paper, we derive a dynamic model for the smoothing error process associated with multiscale stochastic models. In particular, we show that the smoothing error is itself a multiscale stochastic process with parameters that can be explicitly computed. These results generalize previous results for Gauss–Markov processes, since these processes correspond to a degenerate form of the multiscale models, and provide the necessary framework for applications such as those mentioned above.

This paper is organized as follows. In Section II we briefly review the class of multiscale stochastic models of interest here and the scale recursive estimation algorithm associated with them. In Section III we derive a multiscale model for the smoothing error process.

¹More generally, Levy *et al.* [12] have recently shown that the smoothing error processes associated with the class of Gaussian reciprocal processes, which contains the class of Gauss–Markov processes, are themselves Gaussian reciprocal. See also [13] for similar results corresponding to 2-D Gauss–Markov random fields.

Fig. 1. Multiscale stochastic processes are indexed by a q th-order tree. The parent of a node s on the tree is denoted $s\bar{\gamma}$, and its q offspring are denoted $s\alpha_1, \dots, s\alpha_q$.

II. MULTISCALE STOCHASTIC MODELING AND OPTIMAL ESTIMATION

The models presented in this section describe multiscale Gaussian stochastic processes indexed by nodes on a tree. A q th order tree is a pyramidal structure of nodes connected such that each node of the tree has q offspring (see Fig. 1). We denote nodes on the tree with an abstract index s , and define an upward (fine-to-coarse) shift operator $\bar{\gamma}$ such that $s\bar{\gamma}$ is the parent of node s . We also define a corresponding set of downward shift operators $\alpha_1, \dots, \alpha_q$ such that $s\alpha_1, \dots, s\alpha_q$ are the offspring of node s . In addition, we denote the set of nodes on the tree as \mathcal{T} and the set of nodes that includes node s and all of its descendants as \mathcal{T}_s , i.e., $\mathcal{T}_s = \{\sigma | \sigma = s \text{ or } \sigma \text{ is a descendant of } s\}$. Also, the complement of \mathcal{T}_s is denoted \mathcal{T}_s^c . The statistical characterization of the model state $x(s) \in \mathcal{R}^n$ is then given by

$$x(s) = A(s)x(s\bar{\gamma}) + B(s)w(s) \quad (1)$$

under the assumptions that $x(0) \sim \mathcal{N}(0, P(0))$, $w(s) \sim \mathcal{N}(0, I)$, $A(s)$ and $B(s)$ are matrices of appropriate size, and $s = 0$ is the root node at the top of the tree. The driving noise $w(s) \in \mathcal{R}^m$ is white, i.e., $w(s)$ and $w(\sigma)$ are independent if $s \neq \sigma$, and independent of the initial condition $x(0)$. The class of models (1) has a statistical structure that can be exploited to develop efficient signal processing algorithms. In particular, note that any given node on the q th-order tree can be viewed as a boundary between $q + 1$ subsets of nodes (q corresponding to paths leading towards offspring and one corresponding to a path leading towards a parent). An important property of the model (1) is that, conditioned on the value of the state at any node, the values of the state corresponding to the $q + 1$ subsets of nodes are independent. This fact is the basis for the development in [1], [2] of an algorithm for computing smoothed estimates of $x(s)$ based on noisy measurements $y(s) \in \mathcal{R}^p$ of the form

$$y(s) = C(s)x(s) + v(s) \quad (2)$$

where $v(s) \sim \mathcal{N}(0, R(s))$, and is independent of both $w(s)$ and $x(0)$. The algorithm for computing the smoothed estimates of $x(s)$ is a generalization to q th-order trees of the well-known Rauch–Tung–Striebel algorithm for smoothing 1-D Gauss–Markov processes. We briefly review the multiscale smoothing algorithm next, and then derive a model for the error associated with the smoothed estimates.

We denote the set of states defined at nodes in \mathcal{T}_s as X_s , i.e., $X_s = \{x(\sigma) | \sigma \in \mathcal{T}_s\}$, and similarly $Y_s = \{y(\sigma) | \sigma \in \mathcal{T}_s\}$. The set of measurements in the subtree strictly below s is denoted Y_s^+ , i.e., $Y_s^+ = \{y(\sigma) | \sigma \text{ is a descendant of } s\}$. We also define $\hat{x}(s|Y)$ as the expected value of $x(s)$ given measurements in the set Y and the corresponding error covariance as $P(s|Y)$.

The upward sweep of the smoothing algorithm begins with the initialization of $\hat{x}(s|Y_s^+)$ and $P(s|Y_s^+)$ at the finest level. In particular,

for every s at this finest scale we set $\hat{x}(s|Y_s^+)$ to zero and $P(s|Y_s^+)$ to the solution at the finest level of the tree of the Lyapunov equation:

$$P(s) = A(s)P(s\bar{\gamma})A^T(s) + B(s)B^T(s) \quad (3)$$

where $P(s)$ denotes the covariance of the process $x(s)$ at node s . Suppose then that we have $\hat{x}(s|Y_s^+)$ and $P(s|Y_s^+)$ at a given node s . This estimate is *updated* to incorporate the measurement $y(s)$ according to the following:

$$\hat{x}(s|Y_s) = \hat{x}(s|Y_s^+) + K(s)[y(s) - C(s)\hat{x}(s|Y_s^+)] \quad (4)$$

$$P(s|Y_s) = [I - K(s)C(s)]P(s|Y_s^+) \quad (5)$$

where $K(s) = P(s|Y_s^+)C^T(s)[C(s)P(s|Y_s^+)C^T(s) + R(s)]^{-1}$.

Suppose next that we have the updated estimates $\hat{x}(s\alpha_i|Y_{s\alpha_i})$ at all of the immediate descendants of node s . The next step involves the use of these estimates to predict $x(s)$ at the next coarser scale, i.e., to compute $\hat{x}(s|Y_{s\alpha_i})$. Using the following *upward* model for the multiscale process [1], [2]:

$$x(s\bar{\gamma}) = F(s)x(s) + \bar{w}(s) \quad (6)$$

with the measurement equation again given by (2), and where $F(s) = P(s\bar{\gamma})A^T(s)P(s)^{-1}$ and $E[\bar{w}(s)\bar{w}^T(s)] = P(s\bar{\gamma}) - P(s\bar{\gamma})A^T(s)P(s)^{-1}A(s)P(s\bar{\gamma}) \equiv Q(s)$, we compute the fine-to-coarse *predicted* estimates:

$$\hat{x}(s|Y_{s\alpha_i}) = F(s\alpha_i)\hat{x}(s\alpha_i|Y_{s\alpha_i}) \quad (7)$$

$$P(s|Y_{s\alpha_i}) = F(s\alpha_i)P(s\alpha_i|Y_{s\alpha_i})F^T(s\alpha_i) + Q(s\alpha_i). \quad (8)$$

The estimates $\hat{x}(s|Y_{s\alpha_i})$, $i = 1, \dots, q$ are then *merged* to obtain

$$\hat{x}(s|Y_s^+) = P(s|Y_s^+) \sum_{i=1}^q P^{-1}(s|Y_{s\alpha_i}) \hat{x}(s|Y_{s\alpha_i}) \quad (9)$$

$$P(s|Y_s^+) = \left[(1-q)P(s)^{-1} + \sum_{i=1}^q P^{-1}(s|Y_{s\alpha_i}) \right]^{-1}. \quad (10)$$

We assume here that $P(s)$ and $P(s\bar{\gamma}|Y_s)$ are invertible for all s so that the upward model given by (6) and the merge operation given by (9), (10) are well-defined. As discussed at the end of the next section, this restriction can be removed.

The recursion given by the update, predict and merge equations proceeds up the tree until one obtains the smoothed estimate of the root node, $\hat{x}(0|Y_0)$. This estimate initializes a *downward sweep* in which $\hat{x}(s|Y_0)$ is computed according to

$$\hat{x}(s|Y_0) = \hat{x}(s|Y_s) + J(s)[\hat{x}(s\bar{\gamma}|Y_0) - \hat{x}(s\bar{\gamma}|Y_s)] \quad (11)$$

$$P(s|Y_0) = P(s|Y_s) + J(s)[P(s\bar{\gamma}|Y_0) - P(s\bar{\gamma}|Y_s)]J^T(s) \quad (12)$$

$$J(s) = P(s|Y_s)F^T(s)P^{-1}(s\bar{\gamma}|Y_s). \quad (13)$$

Note that (12) characterizes the smoothing error covariance at any given lattice site s , but does not provide information about the correlation structure of the error process. The goal in the next section is to provide a multiscale model for the smoothing error process, i.e., to show that the error satisfies a recursion of the form (1), and to calculate the associated model parameters. This then provides the complete statistical characterization of the smoothing error that we seek.

III. MULTISCALE SMOOTHING ERROR MODELS

Given two nodes s and $\sigma \in \mathcal{T}_s^c$ on the tree, we can represent $x(\sigma)$ in terms of $x(s\bar{\gamma})$ and an additive noise term $\varphi_{\sigma, s\bar{\gamma}}$:

$$x(\sigma) = \Phi_{\sigma, s\bar{\gamma}}x(s\bar{\gamma}) + \varphi_{\sigma, s\bar{\gamma}} \quad (14)$$

with $\varphi_{\sigma, s\bar{\gamma}}$ independent of the set of states $x(s\bar{\gamma}) \cup X_s$ and the corresponding set of measurements $y(s\bar{\gamma}) \cup Y_s$, by tracing a path

from σ to s^- and using the upward dynamics (6) and downward dynamics (1) to eliminate state variables along the way. The state transition matrix Φ_{σ, s^-} in this construction is a function of the upward and downward prediction matrices A and F along the path, whereas φ_{σ, s^-} is a linear function of the upward and downward driving noises u and π . Since φ_{σ, s^-} is independent of the set of states $i(s^-) \cup \mathcal{Y}_s$, and the measurements $y(s^-) \cup \mathcal{Y}$, we have that $i(\sigma|\mathcal{Y}_s) = \Phi_{\sigma, s^-} i(s^-|\mathcal{Y}_s)$ which using (14) implies that

$$i(\sigma|\mathcal{Y}_s) = \Phi_{\sigma, s^-} i(s^-|\mathcal{Y}) + \varphi_{\sigma, s^-} \quad (15)$$

where we have defined the error in $i(s|\mathcal{Y})$ as $i(s|\mathcal{Y}) \equiv i(s) - i(s|\mathcal{Y})$. As a result we see that $i(s|\mathcal{Y})$ has the Markov property

$$\begin{aligned} E\{i(s|\mathcal{Y})|i(\sigma|\mathcal{Y})\} &= E\{i(s|\mathcal{Y}_s)|i(s^-|\mathcal{Y})\} \quad \{\varphi_{\sigma, s^-} \mid s \in \mathcal{I}_s\} \\ &= E\{i(s|\mathcal{Y})|i(s^-|\mathcal{Y})\} + E\{i(s|\mathcal{Y})|\{\varphi_{\sigma, s^-} \mid s \in \mathcal{I}\}\} \\ &= E\{i(s|\mathcal{Y})|i(s^-|\mathcal{Y})\} \end{aligned} \quad (16)$$

The first equality in (16) follows from (15), the second from the orthogonality of φ_{σ, s^-} to $i(s^-)$ and \mathcal{Y} , and the last from the orthogonality of φ_{σ, s^-} to $i(s)$ and \mathcal{Y} . Now using the upward dynamics (6), the upward sweep prediction equation (7), and standard linear least squares formulas we can write

$$i(s|\mathcal{Y}) = J(s)i(s^-|\mathcal{Y}) + u(s) \quad (17)$$

where $J(s)$ is given by (13) and where from (16) $u(s)$ is independent of $\{i(\sigma|\mathcal{Y})|\sigma \in \mathcal{I}\}$ and has covariance

$$P(s|\mathcal{Y}) = P(s|\mathcal{Y})F^T(s)P^{-1}(s^-|\mathcal{Y})F(s)P(s|\mathcal{Y}) \quad (18)$$

Next note that the independence of $u(s)$ and $\{i(\sigma|\mathcal{Y})|\sigma \in \mathcal{I}\}$ implies that $u(s)$ is also independent of the residual information about $i(s)$ that is contained in the set of all available measurements \mathcal{Y}_s , but not contained in \mathcal{Y} . In particular, at each node in \mathcal{T} , a residual component $r(\sigma)$ that is orthogonal to the measurements in the set \mathcal{Y} can be defined as

$$\begin{aligned} r(\sigma) &= y(\sigma) - E\{y(\sigma)|\mathcal{Y}\} \\ &= C(\sigma)i(\sigma|\mathcal{Y}) + v(\sigma) \end{aligned} \quad (19)$$

Denoting $r = \{r(\sigma)|\sigma \in \mathcal{I}\}$ it is clear that $\text{span } \mathcal{Y} = \text{span } \{r\}$ that $r \perp \mathcal{Y}$ and that $r \perp u(s)$. Taking the expected value of both sides of (17) conditioned on r we obtain

$$E\{i(s|\mathcal{Y})|r\} = J(s)E\{i(s^-|\mathcal{Y})|r\} \quad (20)$$

Finally noting that

$$i(s|\mathcal{Y}_s) = i(s|\mathcal{Y}) + E\{i(s|\mathcal{Y})|r\} \quad (21)$$

and then subtracting (20) from (17) results in

$$i(s|\mathcal{Y}_0) = J(s)i(s^-|\mathcal{Y}_0) + u(s) \quad (22)$$

which is a multiscale model for the smoothing error of precisely the same form as (1).

This model is, of course, consistent with the error covariance computation in (12). In particular, using the Lyapunov equation for (22) we obtain

$$\begin{aligned} P(s|\mathcal{Y}_0) &= J(s)P(s^-|\mathcal{Y}_0)J^T(s) + P(s|\mathcal{Y}) \\ &= P(s|\mathcal{Y}_s)F^T(s)P^{-1}(s^-|\mathcal{Y}_s)F(s)P(s|\mathcal{Y}_s) \\ &= P(s|\mathcal{Y}_s) + J(s)[P(s^-|\mathcal{Y}_0) - P(s^-|\mathcal{Y}_s)]J^T(s) \end{aligned} \quad (23)$$

In addition, on first-order trees, the model (1) reduces to a standard Gauss-Markov model and hence (22) generalizes to q th order trees the corresponding 1-D time series result. The derivation here is

related to but is in fact substantially simpler than the based on backwards prediction error models in [8].

Finally we note that it is possible to derive a multiscale error model without assuming invertibility of $I(s^-)$. We refer the reader to Appendix D of [14] for a detailed derivation of a likelihood calculation algorithm for (1)-(2) that allows for rank deficient $P(s)$ and $P(s^-|\mathcal{Y})$. A slight variation of the technique in that derivation can be used to show that a multiscale error model allowing for rank deficient $P(s)$ and $I(s^-|\mathcal{Y})$ can be written precisely as in (22) but with the gain $J(s)$ given by

$$J(s) = P(s|\mathcal{Y}_s)F^T(s)P^\dagger(s^-|\mathcal{Y}) \quad (24)$$

$$J(s) = P(s^-|\mathcal{Y})A^T(s)P(s)^{-1} \quad (25)$$

and the covariance of $u(s)$ given by

$$P(s|\mathcal{Y}) = P(s|\mathcal{Y})F^T(s)P^\dagger(s^-|\mathcal{Y}_s)F(s)P(s|\mathcal{Y}) \quad (26)$$

where the superscript \dagger denotes the Moore-Penrose pseudo-inverse [15].

A Generalized Popov-Belevitch-Hautus Test of Observability

Bijoy K. Ghosh and Joachim Rosenthal

Abstract—In this paper, an earlier result on the problem of observability of a linear dynamical system due to Popov-Belevitch-Hautus has been generalized and applied to the problem of observing the initial condition of a linear dynamical system described on the space of d dimensional affine planes in \mathbb{R}^n .

1. INTRODUCTION AND MOTIVATION

In this paper we generalize the well known Popov-Belevitch-Hautus test (see [3]) on the observability of a linear dynamical system. Let \mathbf{K} denote either the field of real ($\mathbf{K} = \mathbb{R}$) or the field of complex ($\mathbf{K} = \mathbb{C}$) numbers. Let A be an $n \times n$ matrix and let C be a $p \times n$ matrix defined over \mathbf{K} . Consider the linear time invariant system

$$\dot{x} = Ax, \quad y = Cx, \quad x \in \mathbf{K}^n, y \in \mathbf{K}^p. \quad (1.1)$$

The well-known Hautus test [3] gives a necessary and sufficient condition, when the state vector $x(t)$ can be observed from the output measurement $y(t)$. To be precise one has the following.

Theorem 1 (Hautus [3]): System (1.1) is observable over either \mathbb{R} or \mathbb{C} if, and only if

$$\text{rank} \begin{bmatrix} A - \lambda I \\ C \end{bmatrix} = n, \quad \text{for all } \lambda \in \mathbb{C}. \quad (1.2)$$

It may be remarked that the rank can only be less than n if λ is an eigenvalue of the matrix A .

In this paper we consider dynamical systems for which the output vector is not observed exactly but can be ascertained with an ambiguity restricted to a d -dimensional affine subspace. The problem that we propose to consider is to compute if possible the initial condition and hence the states of the dynamical system up to a d -dimensional affine subspace. Thus for the dynamical system (1.1), if we assume that the output vector $y(t)$ is observed up to a d -dimensional plane given by an equation of the form

$$\theta(t)y(t) = \eta(t) \quad (1.3)$$

where $\theta(t)$ is a $(p-d) \times n$ matrix function of time having full rank for all but countably many instances of time and $\eta(t)$ is a vector function of time. The problem is to derive conditions on A and C under which $x(0)$ can be observed up to a d -dimensional plane.

The above class of problem occurs in machine vision as has already been introduced in [6], [1]. Specifically if we consider a plane in \mathbb{R}^3 with coordinates (X, Y, Z) given by

$$sZ = pX + qY + r. \quad (1.4)$$

Let us assume that the points on the plane (1.4) satisfy a dynamical system

$$\dot{\chi} = A\chi + b \quad (1.5)$$

where A is an arbitrary 3×3 matrix and b is a 3×1 vector given by

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \quad (1.6)$$

$$b = (b_1 \ b_2 \ b_3)^T, \quad (1.7)$$

respectively, and where χ is given by

$$\chi = (X \ Y \ Z)^T.$$

One can compute a dynamical system for the shape parameters p, q, r , and s described as follows:

$$\frac{d}{dt} \begin{pmatrix} p \\ q \\ -s \\ r \end{pmatrix} = \begin{pmatrix} -A^T & 0 \\ -b^T & 0 \end{pmatrix} \begin{pmatrix} p \\ q \\ -s \\ r \end{pmatrix}. \quad (1.8)$$

Typically a point on the plane (1.4) is observed with the aid of a CCD camera that projects (X, Y, Z) perspectively onto an image plane. Let (η_1, η_2) be the coordinates of the image plane and assume that the perspective projection is defined as

$$\eta_1 = \frac{fX}{Z+f}, \quad \eta_2 = \frac{fY}{Z+f} \quad (1.9)$$

where f is the focal length of the camera. One can easily compute a differential equation that is satisfied by the coordinates (η_1, η_2) and is given by

$$\begin{aligned} \dot{\eta}_1 &= \eta_1 + \eta_1 \eta_1 + \eta_1 \eta_2 + \frac{1}{f}(\eta_1^2 + \eta_2^2) \\ \dot{\eta}_2 &= \eta_2 + \eta_2 \eta_2 + \eta_2 \eta_1 + \frac{1}{f}(\eta_1^2 + \eta_2^2) \end{aligned} \quad (1.10)$$

where

$$\begin{pmatrix} \dot{\eta}_1 \\ \dot{\eta}_2 \\ \dot{\eta}_3 \\ \dot{\eta}_4 \\ \dot{\eta}_5 \\ \dot{\eta}_6 \\ \dot{\eta}_7 \\ \dot{\eta}_8 \\ \dot{\eta}_9 \end{pmatrix} = \begin{pmatrix} 0 & 0 & -fb_1 & fa_{11} \\ 0 & 0 & -fb_2 & fa_{21} \\ -b'_1 & 0 & b_1 - fa_{11} & a_{11} - a_{33} \\ 0 & -b'_1 & -fa_{12} & a_{12} \\ -b'_2 & 0 & -fa_{21} & a_{21} \\ 0 & -b'_2 & b_2 - fa_{22} & a_{22} - a_{33} \\ -b'_3 & 0 & -fa_{31} & a_{31} \\ 0 & -b'_3 & -fa_{32} & a_{32} \\ 0 & 0 & -f & 1 \end{pmatrix} \begin{pmatrix} p \\ q \\ -s \\ r \end{pmatrix} \quad (1.11)$$

and where

$$b' = (b_1 - a_{13}f, b_2 - a_{23}f, b_3 - a_{33}f) \triangleq (b'_1, b'_2, b'_3). \quad (1.12)$$

The equation (1.10) is known as the "optical flow" and in the literature various algorithms exist as to how one can estimate $(\dot{\eta}_1, \dot{\eta}_2)$ for a given pair (η_1, η_2) (see Horn [4]).

For our purposes we would like to view (1.8), (1.11) as a linear system for which the output vector y is not observed but instead one observes the vector $(\dot{\eta}_1, \dot{\eta}_2, \eta_1, \eta_2)$ at various points on the image plane. Note that for almost every point on the image plane, (1.10) describes a homogeneous seven-dimensional plane in \mathbb{R}^9 . Thus if one observes $(\dot{\eta}_1, \dot{\eta}_2, \eta_1, \eta_2)$ for 3 points on the image plane, the output vector in (1.11) is observed up to a homogeneous 3-plane.

Manuscript received October 25, 1993; revised March 8, 1994 and May 14, 1994. B. K. Ghosh was supported in part by the Department of Energy under Grant DE-FG-02-90ER14140. J. Rosenthal was supported in part by the National Science Foundation under Grant DMS-9201263.

J. Rosenthal is with the Department of Mathematics, University of Notre Dame, Notre Dame, IN 46556 USA.

IEEE Log Number 9406983.

On the other hand, if 4 points are observed the output vector in (1.1) is observed up to a homogeneous line. Various other cases can be demonstrated likewise. Note in particular that by observing the vector $(\eta_1, \eta_2, \eta_3, \eta_4)$ for 1 or 2 points on the image plane, the output vector is observed up to respectively a seven- or five-dimensional plane in \mathbb{R}^9 . Such an observation does not shed any new information on the vector (p, q, s, t) . In practice if the vector (p, q, s, t) is recovered only up to a d -dimensional plane where $d > 1$ one would typically use multiple cameras to determine the exact value of (p, q, s, t) .

II. PROBLEM FORMULATION AND MAIN RESULT

In order to introduce the main result considered in this paper let $P_0 \subset \mathbb{K}^n$ be a d -dimensional affine subspace not necessarily passing through the origin. In this paper we shall use the expression ' d -dimensional affine subspace' to mean a ' d -dimensional plane'. We say that the dynamical system (1.1) observes P_0 if for any $0 \leq t_1 < t$ it is possible to calculate P_0 from the observation of the moving plane $C(P(t)) \triangleq C e^{-\lambda t} P_0$ in \mathbb{K}^n , $t_1 < t \leq t$. Our main theorem is described as follows.

Theorem 2 (Main Theorem) System (1.1) observes any d -dimensional affine subspace P_0 in \mathbb{K}^n if for any set of eigenvalues $\lambda_1, \dots, \lambda_d$ of A one has

$$\text{rank} \begin{bmatrix} (A - \lambda_1 I) & \cdots & (A - \lambda_d I) \\ C \end{bmatrix} = n \quad (2.1)$$

Moreover this condition is also necessary if $d = 0$ or if all eigenvalues of the matrix A are in \mathbb{K} .

Remark 3 Note that over the complex numbers \mathbb{C} condition (2.1) is necessary and sufficient. Moreover if $d = 0$ Theorem 2 reduces to Theorem 1. Finally if $d = 1$ this result implies the one given in [6] due to Wang, Martin, Dayawansa, and Ghosh.

The following two examples explain the ingredients of our result.

Example 4 Consider the real system

$$\dot{x} = Ax = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} x, \quad y = Cx = (1 \ 0)x, \quad x \in \mathbb{R}^2 \quad (2.2)$$

Because the eigenvalues of A are real, condition (2.1) in Theorem 2 is necessary and sufficient. In particular if $p_0 \in \mathbb{R}^2$ is a point it can be observed from $y(t) = C e^{-\lambda t} p_0$ because

$$\text{rank} \begin{bmatrix} -\lambda & 1 \\ 0 & -\lambda \\ 1 & 0 \end{bmatrix} = 2 \quad (2.3)$$

for all $\lambda \in \mathbb{R}$ including the case when λ is an eigenvalue of A . However if $l_0 \subset \mathbb{R}^2$ is a line, it cannot be observed from $l(t) = C e^{-\lambda t} l_0$ because for every pair of lines l_0 and l_1 in \mathbb{R}^2 and for all but a finite number of time instants t we have

$$\{\xi \mid \xi = C e^{-\lambda t} \delta \in l_0\} = \{\xi \mid \xi = C e^{-\lambda t} \delta \in l_1\} \quad (2.4)$$

Thus the lines l_0 and l_1 are both mapped to the entire real axis and therefore they cannot be observed. We also note that

$$\text{rank} \begin{bmatrix} \lambda_0 \lambda_1 & -\lambda_0 - \lambda_1 \\ 0 & \lambda_0 \lambda_1 \\ 1 & 0 \end{bmatrix} \neq 2 \quad \text{for every pair of eigenvalues } \lambda_0, \lambda_1 \text{ of } A \quad (2.5)$$

In fact for $\lambda_0 = \lambda_1 = 0$ rank drops to 1.

Remark 5 Note that the equality of the two sets l_0 and l_1 for all but possibly a finite number of time instants t does not correctly conclude from this that in principle observations can be ascertained on the basis of these finitely many t . However we would still like to say that the lines l_0 and l_1 are unobservable on the basis of any arbitrary time interval.

Example 6 Consider the fourth order system

$$\dot{x} = Ax = \begin{pmatrix} -81 & -56 & 57 & 11 \\ 146 & 102 & -106 & 20 \\ 62 & 13 & -46 & 9 \\ 203 & 138 & -149 & 31 \end{pmatrix} x, \quad y = Cx = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} x, \quad x \in \mathbb{R}^4 \quad (2.6)$$

A direct computation shows that the pair (A, C) is observable and the matrix A has eigenvalues $0, 1, 2, 3$. Since for any 2 eigenvalues λ_0, λ_1 the nullspace of $(A - \lambda_0 I)(A - \lambda_1 I)$ is equal to the sum of the eigenspaces $\text{Ker}(A - \lambda_0 I)$ and $\text{Ker}(A - \lambda_1 I)$ and none of those sums contains the vector $(0, 0, 0, 1)^T \in \text{Ker}(C)$ it follows from Theorem 2 that if $l_0 \subset \mathbb{R}^4$ is a line in \mathbb{R}^4 it can be observed from $l(t) = C e^{-\lambda t} l_0$ which is a motion of lines in \mathbb{R}^4 . On the other hand one immediately verifies that

$$l(A - I)(A - 2I) = \begin{pmatrix} -3 & -1 & 3 & 0 \\ 8 & 8 & -8 & 0 \\ -1 & -1 & 1 & 0 \\ -23 & -23 & 23 & 0 \end{pmatrix}$$

It therefore follows that certain two planes $P_0 \subset \mathbb{R}^4$ cannot be observed from $C e^{-\lambda t} P_0 \subset \mathbb{R}^4$. Specifically consider the vectors $v_0 = (-12, 20, 8, 28)^T$, $v_1 = (35, -60, -25, -55)^T$ and $v_2 = (-23, 40, 17, 58)^T$. One immediately verifies that v_0, v_1, v_2 are eigenvectors corresponding to the eigenvalues $0, 1$ and 2 . Also note that $v_0 + v_1 + v_2 = (0, 0, 0, 1)^T$. Let P be the three dimensional subspace in \mathbb{R}^4 spanned by the vectors v_0, v_1 and v_2 . It can be verified that for all but a finite set of values of t $C e^{-\lambda t} P$ is a two dimensional plane in \mathbb{R}^4 . To see this note that $C e^{-\lambda t} v_j = C e^{-\lambda_j t} v_j$ for $j = 0, 1, 2$ where λ_j is the eigenvalue corresponding to the eigenvector v_j . Since $C v_0, C v_1, C v_2$ are linearly dependent it follows that $C e^{-\lambda t} v_0, C e^{-\lambda t} v_1, C e^{-\lambda t} v_2$ are linearly dependent as well. Thus for any $0 \leq t_1 < t$ and for almost every pair of two dimensional planes Q_1 and Q_2 such that $Q_1 \neq Q_2$ and $Q_1 \subset P, Q_2 \subset P$ we have

$$C e^{-\lambda t} Q_1 = C e^{-\lambda t} Q_2$$

for $t_1 \leq t \leq t$. Hence the planes Q_1 and Q_2 cannot be observed.

III. AN ASSOCIATED DYNAMICAL SYSTEM

The proof of Theorem 2 will be broken down in a sequence of lemmas. The proof is mainly based on a careful study of a dynamical system defined on the \mathbb{K} vector space $\wedge^k \mathbb{K}^n$ the k -fold wedge product of \mathbb{K}^n (see [2] for a reference). This system has also been used in [6] to derive the results there.

First recall that $\wedge^k \mathbb{K}^n$ is linearly generated by the vectors

$$\{e_{i_1} \wedge \cdots \wedge e_{i_k} \mid i_1 < \cdots < i_k\}$$

Addition in $\wedge^k \mathbb{K}^n$ is multilinear and alternating in the components. If $\{e_{i_1}, \dots, e_{i_k}\}$ is a basis of \mathbb{K}^n then it follows from the multilinearity and the alternating property of the wedge product that

$$\mathcal{B} = \{e_{i_1} \wedge \cdots \wedge e_{i_k} \mid 1 \leq i_1 < \cdots < i_k \leq n\}$$

is a basis of $\bigwedge^k \mathbb{K}^n$. In particular one has $\dim \bigwedge^k \mathbb{K}^n = \binom{n}{k}$. If a vector $v \in \bigwedge^k \mathbb{K}^n$ has a representation $v = x_1 \wedge \cdots \wedge x_k$ for some particular vectors $x_i \in \mathbb{K}^n$, $i = 1, \dots, k$, one says that v is a *decomposable* vector. The coordinates of a decomposable vector with respect to the canonical basis \mathcal{B} are sometimes called the Plücker coordinates of v .

Next define linear maps

$$\begin{aligned} \hat{A}: \bigwedge^k \mathbb{K}^n &\rightarrow \bigwedge^k \mathbb{K}^n \\ x_1 \wedge \cdots \wedge x_k &\mapsto \sum_{i=1}^k x_1 \wedge \cdots \wedge x_{i-1} \wedge Ax_i \wedge x_{i+1} \wedge \cdots \wedge x_k \end{aligned} \quad (3.1)$$

and

$$\begin{aligned} C': \bigwedge^k \mathbb{K}^n &\rightarrow \bigwedge^k \mathbb{K}^q \\ x_1 \wedge \cdots \wedge x_k &\mapsto C'x_1 \wedge \cdots \wedge C'x_k. \end{aligned} \quad (3.2)$$

\hat{A} and C' induce the dynamical system

$$\dot{X} = \hat{A}X, \quad \dot{Y} = C'X. \quad (3.3)$$

The state space of (3.3) is the vector space $\bigwedge^k \mathbb{K}^n$ and the output space is the vector space $\bigwedge^k \mathbb{K}^q$. We would like to remark that if the trajectories $C'x_1(t), \dots, C'x_k(t)$ are solutions of the system (1.1) then $\hat{C}(x_1(t) \wedge \cdots \wedge x_k(t))$ is a solution of system (3.3). It is our goal to show that, provided the eigenvalues of A are in \mathbb{K} , (2.1) is equivalent to a particular notion of observability of the system (3.3) and that this condition is also necessary and sufficient for the observability of P_0 under the output function $C'e^{-t}P_0$. The following lemmas prepare for this result.

Lemma 7: The (unique) solution of the initial value problem

$$\begin{aligned} \frac{d}{dt}(x_1(t) \wedge \cdots \wedge x_k(t)) &= \hat{A}(x_1(t) \wedge \cdots \wedge x_k(t)) \\ x_1(0) \wedge \cdots \wedge x_k(0) &= v_1 \wedge \cdots \wedge v_k \end{aligned}$$

is given through

$$x_1(t) \wedge \cdots \wedge x_k(t) = e^{t\hat{A}} v_1 \wedge \cdots \wedge e^{t\hat{A}} v_k. \quad (3.4)$$

Proof: Differentiate (3.4) and recall the definition of \hat{A} . Q.E.D.

Lemma 8: Let $x_1, \dots, x_k \in \mathbb{K}^n$ be vectors and $c_1, c_2, \dots, c_k \in \mathbb{K}$ be scalars. Let $v \triangleq c_1 + c_2 + \cdots + c_k$. Then it follows that

$$\begin{aligned} (\hat{A} - vI)(x_1 \wedge x_2 \wedge \cdots \wedge x_k) &= \sum_{i=1}^k x_1 \wedge \cdots \wedge x_{i-1} \wedge (\hat{A} - c_i I)x_i \wedge x_{i+1} \wedge \cdots \wedge x_k. \end{aligned} \quad (3.5)$$

Proof. Note that

$$\begin{aligned} &(\hat{A} - vI)(x_1 \wedge x_2 \wedge \cdots \wedge x_k) \\ &= (Ax_1 \wedge x_2 \wedge \cdots \wedge x_k) \\ &\quad - c_1(x_1 \wedge x_2 \wedge \cdots \wedge x_k) \\ &\quad + (x_1 \wedge Ax_2 \wedge \cdots \wedge x_k) \\ &\quad - c_2(x_1 \wedge x_2 \wedge \cdots \wedge x_k) \\ &\quad + \cdots \\ &\quad - c_k(x_1 \wedge x_2 \wedge \cdots \wedge x_k) \\ &= \sum_{i=1}^k x_1 \wedge \cdots \wedge x_{i-1} \wedge (\hat{A} - c_i I)x_i \wedge x_{i+1} \wedge \cdots \wedge x_k. \end{aligned} \quad \text{Q.E.D.}$$

Lemma 9: Let $\{x_1, \dots, x_n\} \subset \mathbb{K}^n$ be a \mathbb{K} -basis of generalized eigenvectors of the matrix A having corresponding eigenvalues $\{\lambda_1, \dots, \lambda_n\}$ (possibly repeated) then

$$\{x_{i_1} \wedge \cdots \wedge x_{i_k} \mid 1 \leq i_1 < \cdots < i_k \leq n\} \quad (3.6)$$

is a \mathbb{K} -basis of generalized eigenvectors of the matrix \hat{A} with corresponding eigenvalues $\lambda_{i_1} + \cdots + \lambda_{i_k}$.

Proof: Clearly the set of vectors (3.6) are linearly independent and therefore form a basis. Assume that the vectors x_{i_1}, \dots, x_{i_k} have a nilpotency index m_{i_1}, \dots, m_{i_k} , i.e.,

$$(A - \lambda_{i_k} I)^{m_{i_k}-1} x_{i_k} \neq 0, \quad (A - \lambda_{i_k} I)^{m_{i_k}} x_{i_k} = 0. \quad (3.7)$$

In particular, if $m_{i_k} = 1$ it follows that x_{i_k} is an eigenvector with λ_{i_k} being the corresponding eigenvalue. Let us define

$$q = m_{i_1} + \cdots + m_{i_k} + 1 - k \quad (3.8)$$

it is trivial to verify using Lemma 8 that

$$(\hat{A} - (\lambda_{i_1} + \cdots + \lambda_{i_k})I)^q x_{i_1} \wedge \cdots \wedge x_{i_k} = 0. \quad (3.9)$$

Q.E.D.

Lemma 10: Let N be a nilpotent operator acting on \mathbb{K}^q . For every vector $v \in \mathbb{K}^q$ there is a unique $u \in \mathbb{K}^q$ such that

$$v = u + Nu + \cdots + N^{q-1}u.$$

Moreover if m is the nilpotency index of v then $\{u, \dots, N^{m-1}u\}$ are linearly independent.

Proof: The unique vector u is given through $u := (I - N)v$. The linear independence is clear. Q.E.D.

Before we state the next result we note the following.

Remark 11: Note that not every vector in the vector space $\bigwedge^k \mathbb{K}^n$ is of the form $x_1 \wedge \cdots \wedge x_k$ and those that are, would be known as decomposable vectors.

The next result establishes the crucial relation between the observability of the pair (\hat{A}, C') and the condition (2.1).

Proposition 12: Assume that the eigenvalues of the matrix A are in \mathbb{K} . Then the following conditions are equivalent:

1) There are eigenvalues $\lambda_{i_1}, \dots, \lambda_{i_k}$ of A and a nonzero vector $v \in \mathbb{K}^n$ such that

$$\left((A - \lambda_{i_1} I) \cdots (A - \lambda_{i_k} I) \right)_{C'} v = 0. \quad (3.10)$$

2) There is a $\lambda \in \mathbb{K}$ and a decomposable vector $z_1 \wedge \cdots \wedge z_k \in \bigwedge^k \mathbb{K}^n$ such that

$$\left(\frac{A - \lambda I}{C'} \right) z_1 \wedge \cdots \wedge z_k = 0. \quad (3.11)$$

3) The dynamical system (3.3) has a decomposable vector $\alpha_1 \wedge \cdots \wedge \alpha_k \in \bigwedge^k \mathbb{K}^n$ in its unobservable subspace.

Proof: 1) \rightarrow 2): Let $\lambda_1, \dots, \lambda_k$ be the eigenvalues of A and let

$$\mathbb{K}^n = \bigoplus_{i=1}^s V_{\lambda_i} \quad (3.12)$$

be the decomposition into generalized eigenspaces. This decomposition induces a decomposition

$$v = v_1 + \cdots + v_s.$$

Let $\Lambda = \{\lambda_1, \dots, \lambda_p\}$ be the eigenvalues appearing in the product

$$P := (A - \lambda_{i_1} I) \cdots (A - \lambda_{i_k} I)$$

and denote by $m(\lambda_1), \dots, m(\lambda_p)$ their multiplicity, i.e., we have

$$P = (A - \lambda_1 I)^{m(\lambda_1)} \cdots (A - \lambda_p I)^{m(\lambda_p)}.$$

From the A invariance of the generalized eigenspaces V_{λ_i} it follows that $v_h = 0$ if $h \notin \Lambda$. Moreover if $h \in \Lambda$ then v_h has nilpotency

index at most $m(h)$. In the following we restrict ourselves to the case when v_h has nilpotency index $m(h)$. The (easier) other cases are similar. By Lemma 10 we have an expansion

$$v = \sum_{j_1=0}^{m(l_1)-1} (A - l_1 I)^{j_1} u_{l_1} + \cdots + \sum_{j_p=0}^{m(l_p)-1} (A - l_p I)^{j_p} u_{l_p}. \quad (3.13)$$

In this summation there are $m(l_1) + \cdots + m(l_p) = k$ summands which we like to denote by j_1, \dots, j_k . By Lemma 10 those vectors are linearly independent and from Lemma 9 it follows that $j := j_1 \wedge \cdots \wedge j_k$ is an eigenvector of \hat{A} with corresponding eigenvalue $\lambda := \lambda_{l_1} + \cdots + \lambda_{l_k}$. Finally, from (3.10) it follows that $\{Cj_1, \dots, Cj_k\}$ is a linearly dependent set. It follows

$$\left(\hat{A} - (\lambda_{l_1} + \cdots + \lambda_{l_k})I \right) j_1 \wedge \cdots \wedge j_k = 0. \quad (3.14)$$

2) \rightarrow 3): The vector $j_1 \wedge \cdots \wedge j_k$ is necessarily an eigenvector of \hat{A} and therefore in the unobservable subspace U of the system (3.3).

3) \rightarrow 1): The fact that condition 3) implies condition 1) is nontrivial. Our proof follows mainly ideas already developed in [6] and in principle it should be possible to generalize the proof given in [6]. This however amounts to a large case by case search. In order to avoid those tedious arguments we will deviate at a crucial point from this program.

The proof is structured as follows. Consider the decomposable vector $\alpha := \alpha_1 \wedge \cdots \wedge \alpha_k$ in the unobservable subspace U of the system (3.3) whose existence we assume. Using the fact that U is \hat{A} invariant we will construct a polynomial $f(x) \in \mathbb{K}[x]$ which has the property that $f(\hat{A})\alpha$ is a decomposable eigenvector of \hat{A} . $f(\hat{A})\alpha$ is then necessarily in the unobservable subspace U and this implies 2) and from there we will imply 1). The details are now described as follows.

Consider the set of eigenvalues $\{\lambda_1, \dots, \lambda_k\} \subset \mathbb{K}$ of \hat{A} and arrange the order such that

$$\operatorname{Re} \lambda_i < \operatorname{Re} \lambda_{i+1}$$

or

$$\operatorname{Re} \lambda_i = \operatorname{Re} \lambda_{i+1}$$

and

$$\operatorname{Im} \lambda_i < \operatorname{Im} \lambda_{i+1}.$$

Let us choose a set of generalized eigenvectors $\{x_1, \dots, x_n\}$ of \hat{A} and consider the decomposition of \mathbb{K}^n into generalized eigenspaces given through $\mathbb{K}^n = \bigoplus_{i=1}^k V_{\lambda_i}$. Arrange the order of $\{x_1, \dots, x_n\}$ in such a way that $\{x_1, \dots, x_{l_1}\}$ forms a basis of V_{λ_1} , $\{x_{l_1+1}, \dots, x_{l_1+l_2}\}$ forms a basis of V_{λ_2} and so on.

Let $\alpha := \alpha_1 \wedge \cdots \wedge \alpha_k$ be a decomposable vector in the unobservable subspace U . Expand $\alpha_j = \sum_{i=1}^n b_{ji} x_i$, $j = 1, \dots, k$, in terms of this basis. In this way we associate to α a coefficient matrix $B = b_{ij}$ whose entries are unique up to premultiplication by an element of the special linear group $SL_k := \{T \in \operatorname{Mat}_{k \times k} | \det(T) = 1\}$. Without loss of generality we can therefore assume that the matrix B is in echelon form.

Consider now the decomposition of $\bigwedge^k \mathbb{K}^n$ into generalized eigenspaces.

$$\bigwedge^k \mathbb{K}^n = \bigoplus_{\lambda = \lambda_{i_1} + \cdots + \lambda_{i_k}} W_{\lambda}. \quad (3.15)$$

If w_{λ} denotes the component of $\alpha_1 \wedge \cdots \wedge \alpha_k$ in W_{λ} then

$$w_{\lambda} = \sum v_{i_1} \wedge \cdots \wedge v_{i_k}, \quad (3.16)$$

where v_{i_j} is the component of α_j in $V_{\lambda_{i_j}}$ and where the is taken over all indexes (i_1, \dots, i_k) having the property $\lambda_{i_1} + \cdots + \lambda_{i_k} = \lambda$.

From the fact that the matrix B is assumed to be in echelon and from the assumption that $\lambda_1, \dots, \lambda_k$ are ordered, it follows that there is one eigenvalue μ such that the component w_{μ} of $\alpha_1 \wedge \cdots \wedge \alpha_k$ in W_{μ} is nonzero and decomposable, i.e.,

$$w_{\mu} = v_{i_1} \wedge \cdots \wedge v_{i_k}. \quad (3.17)$$

Indeed, v_{i_j} can be chosen in the following way. For $j = 1, \dots, k$ consider the decomposition

$$\alpha_j = \sum_{i_j=1}^{n_j} v_{i_j} \quad (3.18)$$

induced by the eigenspace decomposition (3.12). Then choose i_j as the first index with the property, that $v_{i_j} \neq 0$. By definition $v_{i_1} \wedge \cdots \wedge v_{i_k}$ is nonzero, decomposable, and it represents the component of $\alpha_1 \wedge \cdots \wedge \alpha_k$ in W_{μ} .

Let m be the order of w_{μ} . It is our goal to calculate the eigenvector $(\hat{A} - \mu I)^{m-1} w_{\mu}$ and to show that this vector is decomposable as well. For this consider the initial value problem

$$\begin{aligned} \frac{d}{dt}(x_1(t) \wedge \cdots \wedge x_k(t)) &= (A - \mu I)(x_1(t) \wedge \cdots \wedge x_k(t)) \\ x_1(0) \wedge \cdots \wedge x_k(0) &= v_{i_1} \wedge \cdots \wedge v_{i_k}. \end{aligned}$$

Using Lemma 7 and Lemma 8 one verifies that the solution is given through

$$e^{(A - \mu I)t} w_{\mu} = e^{(\lambda_{i_1} - \mu)t} v_{i_1} \wedge \cdots \wedge e^{(\lambda_{i_k} - \mu)t} v_{i_k}. \quad (3.19)$$

Because $v_{i_j} \in V_{\lambda_{i_j}}$, $j = 1, \dots, k$, we have a polynomial expansion

$$e^{(\lambda_{i_j} - \mu)t} v_{i_j} = \sum_{h_j=0}^{m(j)-1} (A - \lambda_{i_j} I)^{h_j} t^{h_j} v_{i_j}, \quad (3.20)$$

where $m(j)$ is the nilpotency index of v_{i_j} .

Expanding each v_{i_j} in terms of the standard basis $\{x_1, \dots, x_n\} \subset \mathbb{K}^n$ we get an expansion

$$e^{(A - \mu I)t} w_{\mu} = \sum_{1 \leq i_1 < \cdots < i_k \leq n} f_{(i_1, \dots, i_k)}(t) x_{i_1} \wedge \cdots \wedge x_{i_k}. \quad (3.21)$$

In this summation $f_{(i_1, \dots, i_k)}(t)$ are the Plücker coordinates of the vector $e^{(A - \mu I)t} w_{\mu}$ and we will abbreviate them by $f_i(t)$. By (3.20) it follows that $f_i(t)$ are all polynomials of degree at most $\sum_{j=1}^k m(j) - k$.

If fact we can say more. Differentiating both sides in (3.19) $m-1$ times and substituting $t = 0$ results in the eigenvector $(A - \mu I)^{m-1} w_{\mu}$ on the left side of the equality sign. On the right side this operation results in

$$(m-1)! \sum_{1 \leq i_1 < \cdots < i_k \leq n} g_i x_{i_1} \wedge \cdots \wedge x_{i_k},$$

where g_i is the coefficient of the monom t^{m-1} in the polynomial $f_i(t)$. By definition we have $(A - \mu I)^{m-1} w_{\mu} \neq 0$ and $(A - \mu I)^m w_{\mu} = 0$. We conclude that each polynomial $f_i(t)$ has degree at most $m-1$ and some coefficients g_i are nonzero. In addition note that the vector $e^{(A - \mu I)t} w_{\mu}$ is a decomposable vector at all time $t \geq 0$ and the Plücker relations (compare to [5, Section 3])

$$(QR) \quad \sum_{n-k+1}^{p+1} (-1)^k \cdot f_{(i_1, \dots, i_{p-k+1}, j_k)}(t) \cdot f_{(j_1, \dots, j_{k-1}, i_{p-k+1})}(t) = 0 \quad (3.22)$$

have therefore to be satisfied for all $t \geq 0$ as well. By doing the same argument as in [5, Theorem 3.6 and Example 3.7] we conclude

that the Plücker coordinates are also satisfied for the coordinates g_i . But this means that $(A - \mu I)^{m-1} w_\mu$ is a decomposable eigenvector which we denote by

$$j_1 \wedge \cdots \wedge j_k.$$

Consider once more the eigenspace decomposition

$$\alpha_1 \wedge \cdots \wedge \alpha_k = \sum_{\lambda} w_\lambda$$

as induced by the decomposition (3.15). Let $m(\lambda)$ be the nilpotency index of w_λ and define the operator

$$f(\dot{A}) := (A - \mu I)^{m-1} \prod_{\lambda \neq \mu} (A - \lambda I)^{m(\lambda)}. \quad (3.23)$$

A direct calculation shows that

$$f(\dot{A})\alpha_1 \wedge \cdots \wedge \alpha_k = \prod_{\lambda \neq \mu} (\mu - \lambda)^{m(\lambda)} j_1 \wedge \cdots \wedge j_k. \quad (3.24)$$

We conclude that the decomposable eigenvector $j_1 \wedge \cdots \wedge j_k$ is in the unobservable subspace U of the system (3.3) and this implies 2).

Actually we have shown more: $j_i \in V_i$, and if the coefficient r_j is repeated m times in the set $\{r_1, \dots, r_k\}$ then j_i has nilpotency index at most m . But this means that

$$(A - \lambda_{j_1} I) \cdots (A - \lambda_{j_k} I) j_i = 0$$

for $j = 1, \dots, k$.

By linear dependence of the set $\{C' j_1, \dots, C' j_k\}$ there exist scalars c_1, \dots, c_k not all zero such that

$$c_1 C' j_1 + \cdots + c_k C' j_k = 0.$$

But then

$$w \triangleq c_1 j_1 + \cdots + c_k j_k$$

has all required properties for 1).

Q.E.D.

A direct consequence is the following Lemma whose proof is clear.

Lemma 13: If for any set of eigenvalues $\lambda_1, \dots, \lambda_k$ of A one has

$$\text{rank} \begin{bmatrix} (A - \lambda_1 I) \cdots (A - \lambda_k I) \\ C' \end{bmatrix} = n \quad (3.25)$$

then there is no real decomposable vector in the unobservable subspace U of the system (3.3).

Remark 14: In general the converse is not true as it is demonstrated through an example in [6].

IV. PROOF OF THE MAIN THEOREM

Proof: We first show the sufficiency of the criterion (2.1). Let $P_0, Q_0 \subseteq \mathbb{K}^n$ be two d -dimensional planes with $P_0 \neq Q_0$. Let $q_0 \in Q_0$ be a point having the property that $q_0 \notin P_0$. Let $\{x_0, \dots, x_d\} \subseteq P_0$ be a set of points chosen in such a way that the decomposable vector

$$w \triangleq (q_0 - x_0) \wedge (x_1 - x_0) \wedge \cdots \wedge (x_d - x_0)$$

is nonzero. If the rank condition (2.1) holds, it follows from Proposition 12 and Lemma 13 that there is no decomposable vector in the unobservable subspace U of "the augmented system" (3.3). It therefore follows that

$$C'w(t) = (C'e^{-At}q_0 - C'e^{-At}x_0) \wedge (C'e^{-At}x_1 - C'e^{-At}x_0) \cdots \wedge (C'e^{-At}x_d - C'e^{-At}x_0)$$

is nonzero for all time t with the exception of a set of measure zero. But then we have that $C'e^{-At}q_0 \notin C'e^{-At}P_0$ for almost all time t . In other words $C'e^{-At}Q_0 \neq C'e^{-At}P_0$.

In order to prove the necessity part assume that all eigenvalues of A are in \mathbb{K} . Assume that there is a set of eigenvalues $\lambda_0, \dots, \lambda_d$ of A such that the rank condition (2.1) is not satisfied. Furthermore assume that for any set of eigenvalues μ_0, \dots, μ_{d-1} of A

$$\text{rank} \begin{bmatrix} (A - \mu_0 I) \cdots (A - \mu_{d-1} I) \\ C' \end{bmatrix} = n. \quad (4.1)$$

If this (technical) condition is not satisfied we will be able to show at the end of the proof that $(d-1)$ -dimensional subspaces cannot be observed in general.

By Proposition 12 there exists a nonzero, decomposable vector $x_0 \wedge x_1 \wedge \cdots \wedge x_d$ in the unobservable subspace U of "the augmented system" (3.3) (assuming $k = d+1$). Define $V := \text{span}\{x_0, \dots, x_d\}$ and let $P_0, Q_0 \subset V$ be two d -dimensional subspaces satisfying $P_0 \neq Q_0$. By the assumption it follows that

$$\text{span}\{C'e^{-At}x_0, \dots, C'e^{-At}x_d\}$$

is a d -dimensional subspace for t almost everywhere. But this means that the two different subspaces P_0 and Q_0 in \mathbb{K}^n produce the same moving plane $C'e^{-At}P_0 = C'e^{-At}Q_0$ in \mathbb{K}^n for all time t with the possible exception of a set of measure zero.

Assume now that (4.1) is not satisfied and let \hat{d} be the largest integer having the property that

$$\text{rank} \begin{bmatrix} (A - \lambda_0 I) \cdots (A - \lambda_{\hat{d}} I) \\ C' \end{bmatrix} < n \quad (4.2)$$

for some eigenvalues $\lambda_0, \dots, \lambda_{\hat{d}}$ but

$$\text{rank} \begin{bmatrix} (A - \mu_0 I) \cdots (A - \mu_{\hat{d}-1} I) \\ C' \end{bmatrix} = n \quad (4.3)$$

for all eigenvalues $\mu_0, \dots, \mu_{\hat{d}-1}$ of A . Using the same argument as before one shows the existence of two subspaces \tilde{P}_0 and \tilde{Q}_0 of dimension \hat{d} which cannot be distinguished in the observation. This completes the proof. Q.E.D.

ACKNOWLEDGMENT

The first author would like to thank Prof. C. Martin for many interesting advice on the perspective observability problem. Comments made by three anonymous referees on an earlier version of this paper is gratefully acknowledged. Finally we would like to thank A. A. Stoorvogel for making numerous suggestions and comments to improve the presentation of the paper.

A Note on Robust Pole Placement

Marek K. Solak and Albert C. Peng

Abstract— Pole placement algorithm in single input–single output (SISO) systems is discussed with respect to the corresponding, real stability radius of the resulting closed loop polynomial

I. INTRODUCTION

Various robust stability problems are discussed in terms of stability radius [1], [2], [9]–[14]. This approach is attractive because only one variable (stability radius) describes stability margin in a parameter space. Numerous methods exist to calculate stability radius (structured and unstructured) [1], [2], [9]–[14] and in many cases these methods allow to determine destabilizing direction of perturbation. Real stability radius appears also as a practical tool in designing robust stabilizing controllers for various control systems [1], [2].

This note provides a useful suggestion how pole placement of a closed loop system affects robust stability measured by its real stability radius. It is also interesting to notice when root localization of a given Hurwitz polynomial is known then complicated numerical minimization of its distance d_∞ from the set of polynomials with roots on the imaginary axis can be avoided in many cases. d_∞ may have many spikes and local minima over $[0, \infty)$.

Consider a nominal Hurwitz polynomial

$$p_{i-1}(s) = a_0^{i-1}s^n + a_1^{i-1}s^{n-1} + \dots + a_{n-1}^{i-1}s + a_n^{i-1} = p_{i-1}'(s), \quad S(s) \quad (1)$$

$$S(s) = [s^n \quad s^{n-1} \quad \dots \quad s \quad 1] \quad (2)$$

perturbed by a polynomial

$$h(s) = \delta_0 s^n + \delta_1 s^{n-1} + \dots + \delta_{n-1} s + \delta_n = \delta' S(s) \quad (3)$$

The real unstructured stability radius for $p_{i-1}(s)/p_{i-1}'(s)$ can be calculated via various methods. All of these methods are based on the paper of Fam and Meditch [16]. Define

$$p_{i-1}(s) = p_{i-1}'(s) + \kappa p_{i-1}''(s) \quad (4)$$

Theorem 1 [1], [9]–[14]

$$r_{i-1} = r_{i-1}(p_{i-1}(s)) = \min(|a_0^{i-1}|, |a_n^{i-1}|, d_\infty) \quad (5)$$

$$d_\infty = \inf_{\omega} \left\{ \frac{[p_{i-1}(j\omega)]^2}{1 + \omega^{2n} + \dots + \omega^{2(n-1)}} + \frac{[p_{i-1}(j\omega)]^2}{1 + \omega^{2n} + \dots + \omega^{2(n-1)}} \right\} \quad n = 2p \quad (6a)$$

$$d_\infty = \inf_{\omega} \left\{ \frac{[p_{i-1}(j\omega)]^2}{1 + \omega^{2n} + \dots + \omega^{2(n-1)}} + \frac{[p_{i-1}(j\omega)]^2}{1 + \omega^{2n} + \dots + \omega^{2(n-1)}} \right\} \quad n = 2p + 1 \quad (6b)$$

where $|a_0^{i-1}|$ denotes the distance of $p_{i-1}(s)$ from a zero at infinity, $|a_n^{i-1}|$ denotes the distance from a zero at the origin, and d_∞ denotes

the distance from the set of polynomials with roots on the imaginary axis at $\pm j\omega$.

In many pole placement algorithms we are able to calculate [6], localization of $p_{i-1}(s)$ via (state space) feedback, closed loop polynomial

$$p_i(s) = p_{i-1}(s) - f(s)$$

is generated [1], [3]. Some other feedback controllers (cf. Section II) require solution of a diophantine polynomial equation

$$p(s)a(s) + q(s)b(s) = n_{i-1}(s)$$

where $n_{i-1}(s)$ is a polynomial with arbitrary location of roots within the left complex half plane. At this stage an open question remains of how to select either $f(s)$ or $n_{i-1}(s)$ to assure maximum value of the corresponding stability radius. On the other hand, many practical problems impose specific regions (cf. [7]) in the left complex half plane where roots of $p_i(s)$ or $n_{i-1}(s)$ shall be located.

This note discusses a connection between real unstructured stability radius of a given Hurwitz polynomial and its root localization.

II. ROBUST POLE PLACEMENT

Presentation of the main result of this note will require additional definitions. Let $S^-(p)$ denote the set of all Hurwitz polynomials with roots outside interior of the unit circle (single or multiple roots on the circumference of the unit circle are allowed). Additionally let $\mathcal{HP}^-(p)$ denote the set of all Hurwitz polynomials with roots in the region bounded by the hyperbola (including roots on the hyperbola)

$$\frac{\alpha^2}{\left(\frac{1}{\sqrt{\alpha}}\right)^2} - \frac{\beta^2}{\left(\frac{1}{\sqrt{\alpha}}\right)^2} = 1 \quad (7)$$

where α denotes real part of the root and β denotes complex part of the root.

The main result of this note is formulated in the following theorem. The proof is a little complicated and is carried out in the next section.

Theorem 2 If

$$p_{i-1}(s) \in S^-(p) \cap \mathcal{HP}^-(p)$$

then

$$r_{i-1}(p_{i-1}(s)) = |a_0^{i-1}| \quad (8)$$

Remark 1

The condition $p_{i-1}(s) \in S^-(p)$ can be easily verified. Assuming that $p_{i-1}(s)$ has no roots at infinity we can easily see that $p_{i-1}(s) \in S^-(p)$ iff

$$q(s) = s p_{i-1}(1/s) \in S^-(p)$$

where $S^-(p)$ denotes the set of all Schur polynomials (polynomials with all roots inside the unit circle). There is a fair number of algebraic procedures to check if $q(s) \in S^-(p)$ (cf. [4], [15]). Applying the method in [15] we are also able to check if $p_{i-1}(s) \in \mathcal{HP}^-(p)$.

It is important to notice that stabilization algorithms are mainly based on an *a priori* localization of roots of a nominal closed loop system characteristic polynomial within the left complex half plane and do not require application of G stability polynomial tests (cf. [15]).

Fig. 1 Root localization of polynomials destabilized through zero at infinity

III. PROOF OF THEOREM 2

The proof will be subdivided into a few steps. In the first step the well known Rouché theorem will be extended to accommodate Hurwitz polynomials (a nonclosed Jordan curve, imaginary axis, will be considered). Then a simple approximation of d_+ will be provided. An elementary induction argument will conclude the proof.

Proposition 1 Extension of the Rouché' theorem for nonclosed Jordan curves (cf. [4], [8])

For a given Hurwitz polynomial $p_{n-1}(s) = p'_{n-1}(s)$ a perturbed polynomial

$$p_n(s) = p_{n-1}(s) + \delta(s) = (p'_{n-1} + \delta)S(s) \quad (9)$$

is Hurwitz as well if

$$\delta(jt)\delta(-jt) < p_{n-1}(jt)p_{n-1}(-jt) \quad t \geq 0 \quad (10)$$

Proof The proof follows directly from the zero exclusion principle. Consider a parametrized polynomial, cf. [4, Exercise 10 p. 5]

$$F(s, \lambda) = p_{n-1}(s) + \lambda\delta(s) \quad \lambda \in [0, 1] \quad (11)$$

In case of finite zeros of $F(s, \lambda)$ let us assume that condition (10) holds, but the polynomial

$$F(s, 1) = p_n(s) = p_{n-1}(s) + \delta(s) \quad (12)$$

is unstable. Due to continuity principle [8], [17] there exists $\lambda_0 \in [0, 1]$ and $t_0 \geq 0$ such that

$$F(jt_0, \lambda_0) = p_{n-1}(jt_0) + \lambda_0\delta(jt_0) = 0 \quad (13)$$

$$0 \leq |\lambda_0|^2 = \frac{|p_{n-1}(jt_0)|^2}{|\delta(jt_0)|^2} = \frac{p_{n-1}(jt_0)p_{n-1}(-jt_0)}{\delta(jt_0)\delta(-jt_0)} \leq 1 \quad (14)$$

and the latter condition contradicts (10). $F(s, \lambda)$ can also be destabilized through a zero at infinity. $F(s, \lambda)$ has a zero at infinity iff $sF(1/s, \lambda)$ has a zero at the origin. In this particular case there exists $\lambda_0 \in [0, 1]$ such that for $s_0 = 0$

$$s_0 F(1/s_0, \lambda_0) = s_0^n [p_{n-1}(1/s_0) + \lambda_0\delta(1/s_0)] = 0 \quad (15)$$

$$p_0^{n-1} + \lambda_0\delta_0 = 0 \quad \deg p_{n-1}(s) = \deg \delta(s) \quad (16)$$

where p_0^{n-1} and δ_0 are the highest term coefficients of $p_{n-1}(s)$ and $\delta(s)$

$$0 \leq |\lambda_0|^2 = \frac{|p_0^{n-1}|^2}{|\delta_0|^2} \leq 1 \quad (17)$$

Once again (17) contradicts (10) for $t_0 = 0$. If $\delta_0 = 0$, $|p_0^{n-1}|^2 > 0$ and (16) never happens. \square

To prove the main result of this note we shall need the following matrix

$$\Xi(jt) = S(jt)S'(-jt) \quad t \in (-\infty, \infty) \quad (18)$$

where $\sigma[\Xi(jt)]$ denotes the set of all eigenvalues of $\Xi(jt)$

Proposition 2

$$\Xi(jt) \text{ is a Hermitian matrix} \quad (19)$$

$$\text{rank } \Xi(jt) = 1 \quad t \in (-\infty, \infty) \quad (20)$$

$$\sigma[\Xi(jt)] = \{\lambda(t), 0, \dots, 0\} \quad (21)$$

$$\lambda(t) = \sum_{k=0}^n t^k = \begin{cases} \frac{1-t^{n+1}}{1-t} & t \neq \pm 1 \\ n+1 & t = \pm 1 \end{cases} \quad (22)$$

The corresponding eigenvectors are

$$\begin{aligned} v_1(jt) &= S(jt) \\ v_k(jt) &\in \ker S'(-jt) \\ k &= 1, \dots, n \end{aligned} \quad (23)$$

Proof It is easily verified that $\Xi(jt)$ is a Hermitian matrix of rank 1. Hence $\Xi(jt)$ has n eigenvalues equal to 0 and one nonzero eigenvalue $\lambda(t)$. Moreover, in this particular case

$$\lambda(t) = \text{tr } \Xi(jt)$$

and the proposition follows. \square

Proposition 3 If

$$\|\delta\| < [1/\lambda(t)]p_{n-1}(jt)p_{n-1}(-jt) \quad t \geq 0 \quad (24)$$

and the polynomial $p_{n-1}(s) = p'_{n-1}(s)$ is Hurwitz, then the polynomial

$$p_n(s) = (p'_{n-1} + \delta')S(s) \quad (25)$$

is Hurwitz as well.

Proof First let us observe, that according to Proposition 1

$$p_n(s) = (p'_{n-1} + \delta')S(s)$$

is stable if

$$p'_{n-1}\Xi(jt)p_{n-1} > \delta'\Xi(jt)\delta \quad t \geq 0 \quad (26)$$

According to the Rayleigh principle for Hermitian matrices [17, Section 6.2]

$$\delta'\Xi(jt)\delta \leq \lambda(t)\|\delta\|^2 \quad (27)$$

and we have the thesis of Proposition 3. \square

Proof of Theorem 2 From (24) we have (cf. [22])

$$r_{\min}^2(p_{nom}) \geq \inf_{t>0} \left[\frac{1}{\lambda(t)} p_{nom}(jt) p_{nom}(-jt) \right] \quad (28)$$

and in particular

$$r_{\omega}^2 \geq \inf_{t>0} \left[\frac{1}{\lambda(t)} p_{nom}(jt) p_{nom}(-jt) \right] \quad (29)$$

Our intention is to show that all Hurwitz polynomials with roots outside the unit circle (including circumference) and within the hyperbola (7) are destabilized by the zero at infinity, i.e., $r_{\min} = a_0^{1/m}$. The proof will use the induction argument with respect to the polynomial degree n . Coefficient "nom" notion will be omitted (case $n = 1$)

$$p_{nom}^1(s) = a_0 s + a_1 \quad (30)$$

If $s = -a_1/a_0$ satisfies $|s| \geq 1$ then $r_{\min} = \min(|a_0|, |a_1|) = |a_0|$

Case $n = 2$ $p_{nom}^2(s)$ is a nominal, Hurwitz polynomial of degree 2 and two cases can occur

1) $p_{nom}^2(s)$ has two complex, conjugate roots

2) $p_{nom}^2(s)$ has two real roots

In case 1)

$$p_{nom}^2(s) = a_0[(s + \alpha)^2 + \beta^2] \quad (31)$$

$$\begin{aligned} \frac{1}{\lambda_2(t)} p_{nom}^2(jt) p_{nom}^2(-jt) &= a_0^2 \frac{t^4 + 2t(\alpha^2 - \beta^2) + (\alpha^2 + \beta^2)t^2}{t^4 + t^2 + 1} \\ &\geq a_0^2 \frac{t^4 + t^2 + 1}{t^4 + t^2 + 1} = a_0^2 \end{aligned} \quad (32)$$

if $2(\alpha^2 - \beta^2) \geq 1$ ($\alpha^2 + \beta^2 \geq 1$)

Hence in view of (28)

$$r_{\min}^2 \geq a_0^2 \quad (33)$$

On the other hand, $r_{\min} \leq |a_0|$ and case 1) has been proved for complex roots. Case 2) is an immediate consequence of Case 1)

Assume that Theorem 2 holds for a polynomial $p_{nom}(s)$ of degree n we have to prove its validity for a polynomial of degree $n + 1$. First, let us assume that

$$p_{nom}^{n+1}(s) = p_{nom}(s)(s + \alpha), \quad \alpha \geq 1$$

$$\begin{aligned} \frac{1}{\lambda_{n+1}(t)} [p_{nom}^{n+1}(jt) p_{nom}^{n+1}(-jt)] &= \frac{p_{nom}(jt) p_{nom}(-jt) (t^2 + \alpha^2)}{1 + t^2 + \frac{t^{2(n+1)}}{t^{2(n+1)}}} \\ &= \frac{p_{nom}(jt) p_{nom}(-jt)}{1 + t^2 + \frac{t^{2n}}{t^{2(n+1)}}} \frac{1 + t^2 + \frac{t^{2n}}{t^{2(n+1)}}}{1 + t^2 + \frac{t^{2n}}{t^{2(n+1)}}} (t^2 + \alpha^2) \\ &\geq a_0^2 \frac{1 + t^2 + \frac{t^{2n}}{t^{2(n+1)}}}{1 + t^2 + \frac{t^{2n}}{t^{2(n+1)}}} (t^2 + \alpha^2) \geq a_0^2 \quad \alpha^2 \geq 1 \end{aligned} \quad (34)$$

If $p_{nom}^{n+2}(s) = p_{nom}^n(s)[(s + \alpha)^2 + \beta^2]$, then

$$\begin{aligned} \frac{1}{\lambda_{n+2}(t)} [p_{nom}^{n+2}(jt) p_{nom}^{n+2}(-jt)] &= \frac{p_{nom}^n(jt) p_{nom}^n(-jt)}{1 + t^2 + \frac{t^{2n}}{t^{2(n+2)}}} \frac{1 + t^2 + \frac{t^{2n}}{t^{2(n+2)}}}{1 + t^2 + \frac{t^{2n}}{t^{2(n+2)}}} \\ &\quad [t^4 + 2t^2(\alpha^2 - \beta^2) + (\alpha^2 + \beta^2)] \\ &\geq a_0^2 \end{aligned} \quad (35)$$

It is obvious, under assumptions of Theorem 2 that $a_0^2 \leq a_n^2$, and Theorem 2 is proved. \square

Fig. 2 A feedback control system

IV. ROBUST STABILIZING CONTROLLER DESIGN

A standard feedback stabilization problem is to design (for a proper, possibly unstable transfer function) a proper controller such that the denominator of the closed loop transfer function is stable

$$t(s) = p^{-1}(s)q(s) \quad (36)$$

$$p(s) = p_0 s^{n_1} + p_1 s^{n_1-1} + \dots + p_{n_1} \quad (37a)$$

$$q(s) = q_0 s^{n_2} + q_1 s^{n_2-1} + \dots + q_{n_2}, \quad n_1 \geq n_2 \quad (37b)$$

$$c(s) = a^{-1}(s)b(s) \quad (38)$$

$$a(s) = a_0 s^{m_1} + a_1 s^{m_1-1} + \dots + a_{m_1} \quad (39a)$$

$$b(s) = b_0 s^{m_2} + b_1 s^{m_2-1} + \dots + b_{m_2}, \quad m_1 \geq m_2 \quad (39b)$$

The transfer function of the closed loop system is

$$T_r(s) = \frac{a(s)q(s)}{p(s)a(s) + q(s)b(s)} = \frac{m(s)}{n(s)} \quad (40)$$

$$n(s) = n_0 s^{n_1+m_1} + \dots + n_{n_1+m_1} \quad (41a)$$

$$n_0 = \begin{cases} p_0 a_0 + q_0 b_0 & n_1 = n, m_1 = m \\ p_0 a_0 & \text{otherwise} \end{cases} \quad (41b)$$

Under very mild assumptions concerning $p(s)$ and $q(s)$ (p, q -coprime [3], [18]) a proper controller can always be determined such that roots of $n(s)$ are located arbitrarily in the left complex half plane [1], [3], [18]. If parameters of the plant are uncertain, for instance, cf. (37)

$$p^{min} \leq p \leq p^{max}, \quad q^{min} < q \leq q^{max} \quad (42)$$

it is quite reasonable to find a controller $c(s)$ (38) such that roots of the nominal polynomial $n_{nom}(s)$ (40)–(41) are located within appropriate region G of the left complex half plane and

$$n_{nom}(s) = p_{nom}(s)a(s) + q_{nom}(s)b(s) \quad (43)$$

a stability hypersphere of $n_{nom}(s)$ contains all uncertain polynomials $n(s)$ (40)–(42)

Usually, as a nominal polynomial $n_{nom}(s)$ a polynomial is selected such that its roots are all located within a specified region G of the left complex half plane, possibly contained within the hyperbola (7) and outside the unit circle centered at the origin. If $p_{nom}(s)$ and $q_{nom}(s)$ are coprime [3] a compensator $c(s) = a^{-1}(s)b(s)$ (38) can always be established, such that (43) holds

$$\begin{aligned} n_{nom}(s) &= n_0^{n_1+m_1} \prod_{i=1}^k (s + s_i) \prod_{j=1}^m [(s + \alpha_j)^2 + \beta_j^2] \\ n &= \deg n_{nom}(s) = 2m + k \end{aligned} \quad (44)$$

$$s_i \geq 1, s_i \in \mathcal{R}, i = 1, 2, \dots, k$$

$$\frac{\alpha_i^2}{\left(\frac{1}{\sqrt{2}}\right)^2} - \frac{\beta_i^2}{\left(\frac{1}{\sqrt{2}}\right)^2} \geq 1, \quad \alpha_i^2 + \beta_i^2 \geq 1,$$

$$i = 1, 2, \dots, m.$$

Theorem 3: Stability radius of $n_{\text{nom}}(s)$ (44) [cf. (40), (41) and (43)]

$$r_{\max}[n_{\text{nom}}(s)] = |n_0^{\text{nom}}|. \quad (45)$$

Proof: The proof is a direct consequence of Theorem 2. \square

Remark 2: Formulas (44) and (45) can be used to design proper, stabilizing robust feedback controllers for uncertain, single input single output systems (36). Parameters a_0, b_0 can be selected to provide an appropriate value of (45).

V. CONCLUSION AND DISCUSSION

This note presented a connection between pole placement in single input-single output systems and robust stability measure provided by real stability radius.

Pole Assignment for Uncertain Systems in a Specified Disk by State Feedback

Germain Garcia and Jacques Bernussou

Abstract—This paper presents a method for assigning the poles in a specified disk by state feedback for a linear discrete or continuous time uncertain system, the uncertainty being norm bounded. For this the "quadratic d stabilizability" concept which is the counterpart of quadratic stabilizability in the context of pole placement is defined and a necessary and sufficient condition for quadratic d stabilizability derived. This condition expressed as a parameter dependent discrete Riccati equation enables to design the control gain matrix by solving iteratively a discrete Riccati equation.

1. INTRODUCTION

Among the different ways for defining performance specifications, one of the most popular is to put some constraints on the poles location for the closed loop transfer matrix. In practice, the exact pole location is not required and it is often sufficient to locate them in a prescribed region in the left half complex plane for continuous time systems or in the unit disk for discrete time ones.

In this paper, the problem of pole assignment in a specified disk for linear discrete or continuous time uncertain system is addressed. In [1], the authors use a method based on conformal mapping which leads to a complex control law determination. In [2], another method working with the discrete Riccati equation for control law design is proposed. More recently, matricial algebraic tests for the spectrum of the state matrix to be clustered in a subregion of the complex plane were developed. In this direction, efforts to construct a modified Lyapunov matrix equation leading to efficient synthesis procedures have been made [3]–[6]. Unlike previous works, in the most recent works, uncertain systems are considered. A sufficient condition for disk location in the case of continuous or discrete systems is given in [5]. Robustness issues are discussed and margins for disk location are provided. In [4] and [3] conditions for pole placement in several regions (circle, vertical strip, sector...) are stated for uncertain systems, the parameter uncertainty being defined through convex bounded polytopes. The control law is derived via convex programming.

Here, following the same ideas as for quadratic stabilizability, a similar concept for pole assignment referred as "quadratic d stabilizability" is defined. First, a necessary and sufficient condition for quadratic d stabilizability is given for uncertainty affecting only the dynamical matrix. Expressed as a parameter dependent discrete Riccati equation, it leads to an algorithm allowing the state feedback gain design. The condition generalizes the sufficient condition given in [5]. The necessary and sufficient condition is extended to systems with uncertainty in both state and input matrices. This condition, although more involved, can be stated as a parameter dependent "augmented" Riccati equation. The paper ends with numerical examples illustrating the theory.

II PRELIMINARIES

Let us consider a continuous or discrete time system described by

$$\delta[\dot{x}(t)] = (A + \Delta A)x(t) + Bu(t) \quad (1)$$

here $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $u(t) \in \mathbb{R}^m$ is the input and $x(t) \in \mathbb{R}^n$ is the state. δ is the derivation operator in the continuous time case [i.e., $\delta[x(t)] = \dot{x}(t)$] and the delay operator for the discrete time one [i.e., $\delta[x(t)] = x(t+1)$]. ΔA is the uncertainty of norm bounded type written as

$$\Delta A = DFF^T \quad (2)$$

where $D \in \mathbb{R}^{n \times n}$, $E \in \mathbb{R}^{n \times r}$ define the structure of the uncertainty and the parameter uncertainty F belongs to the set

$$\mathcal{K} = \{F \in \mathbb{R}^{r \times n} : F^T F \leq I\} \quad (3)$$

Throughout this paper the expression $(\bullet) \succ 0$ ($\prec 0$) means that matrix (\bullet) is positive definite (negative definite) and I denotes the identity matrix of appropriate dimension. The problem to be addressed is to determine the state feedback

$$u(t) = Kx(t) \quad (4)$$

such that the closed loop system poles lie in the disk $D(\alpha, r)$ with center $\alpha + j0$ and radius r . For the sake of simplicity let us introduce the following notations

$$\begin{aligned} A &= A + BK, & A &= (A - \alpha I)/r \\ A &= (A + BK - \alpha I)/r \\ \Delta A &= \Delta A/r \\ A_\Delta &= A + BK + \Delta A \end{aligned} \quad (5)$$

From the general result on matrix root clustering presented in [7] the following theorem can be deduced

Theorem 1 Let $A \in \mathbb{R}^{n \times n}$ be a given matrix. The eigenvalues of A belong to $D(\alpha, r)$ if and only if there exists a symmetric matrix $P \in \mathbb{R}^{n \times n}$ such that

$$\begin{pmatrix} -P^{-1} & A \\ A^T & -P \end{pmatrix} \prec 0 \quad (6)$$

Proof The proof is obtained from the standard Schur complement result and from [7].

From now on only the stable $D(\alpha, r)$ location cases are considered i.e. the one where $D(\alpha, r)$ belongs to the left half complex plane for continuous systems and to the unit disk for discrete systems. A concept related to Theorem 1 which follows the same philosophy is the quadratic stabilizability [8] can be introduced. This concept referred in the sequel as "quadratic d stabilizability" extends the condition of Theorem 1 to the case of uncertain system in a similar way as quadratic stabilizability extends the concept of stability to uncertain system.

Definition 1 The system (1) is a 'quadratically d stabilizable' by a linear state feedback $u(t) = Kx(t)$ if and only if there exists a symmetric matrix $P \in \mathbb{R}^{n \times n}$ such that

$$\forall \left(\begin{pmatrix} -P^{-1} & A + \Delta A \\ A^T + \Delta A^T & -P \end{pmatrix} \right) \prec 0 \quad (7)$$

for all $\Delta \in \mathbb{R}^{2n}$ and $F \in \mathcal{K}$

The above definition states that a system is quadratically d stabilizable if there exists a single matrix P satisfying (7) for all Δ in the uncertainty domain. It should be interesting to relate P to a Lyapunov matrix. The existence of a single Lyapunov matrix for all the systems in the uncertainty domain ensures the quadratic system stability for time varying uncertainties.

Theorem 2 If the system (1) is quadratically d stabilizable, it is quadratically stabilizable and P is a Lyapunov matrix for systems in the uncertainty domain.

Proof First, obviously $P \succ 0$. For continuous systems $\alpha = 0$ and $r < |\alpha|$. Developing (7) we obtain

$$(A + \Delta A)^T P + P(A + \Delta A) - \alpha^{-1}(A + \Delta A)P(\alpha I + \Delta A) + \alpha^{-1}(r - \alpha)I \prec 0$$

and then

$$(A + \Delta A)^T P + P(A + \Delta A) \prec \alpha^{-1}(A + \Delta A)^T P(\alpha I + \Delta A) - \alpha^{-1}(r - \alpha)P \prec 0$$

Thus the system is quadratically stabilizable.

For discrete systems the relation with quadratic stabilizability is not so straightforward. In fact the difficulty is due to the presence in the equation of the term

$$-\alpha[(\alpha I + \Delta A)^T P + P(\alpha I + \Delta A)]$$

Suppose that system (1) is quadratically d stabilizable. Using notations (7) is written

$$\begin{pmatrix} -P^{-1} & A_\Delta - \alpha I \\ A_\Delta - \alpha I & -P \end{pmatrix} \prec 0 \quad (8)$$

Let us first consider the case $\alpha > 0$. The circles in the unit disk are then characterized by $\alpha + r < 1$. Multiplying (8) on the left and on the right by the symmetric matrix

$$\begin{pmatrix} -\alpha P & \mathbf{1} \\ \mathbf{1} & P^{-1}/r \end{pmatrix}$$

we obtain

$$\begin{pmatrix} \bullet & \bullet \\ \bullet & T_1 \end{pmatrix} \prec 0$$

where T_1 satisfies $P T_1 P = -2P - 2\alpha P/r + 1/r(A_\Delta^T P + P A_\Delta) \prec 0$ with $r > 0$, $\alpha > 0$. This implies $-\alpha(A_\Delta^T P + P A_\Delta) > -2\alpha(\alpha + r)P$ and thus

$$\begin{aligned} A_\Delta^T P A_\Delta + (\alpha - r)P - 2\alpha(\alpha + r)P \\ = A_\Delta^T P A_\Delta - (\alpha + r)^2 P \\ < A_\Delta^T P A_\Delta + (\alpha^2 - r)P - \alpha(A_\Delta^T P + P A_\Delta) \\ < 0 \end{aligned}$$

But as $0 < \alpha + r < 1$ we conclude that

$$A_\Delta^T P A_\Delta - P < A_\Delta^T P A_\Delta - (\alpha + r)P < 0$$

The system is quadratically stabilizable and P is a Lyapunov matrix.

The case $\alpha < 0$ with $\alpha - r > -1$ is treated in much the same way as for $\alpha > 0$ beginning by multiplying (8) on the left and on the right by

$$\begin{pmatrix} -\alpha P & \mathbf{1} \\ \mathbf{1} & -P^{-1}/r \end{pmatrix} \quad (9)$$

III. MAIN RESULT

We are now in a position to give the main result of this paper. Denoting by

$$E_i = E/\sqrt{r}, \quad D_i = D/\sqrt{r}, \\ 4_{ii} = (A - a\mathbf{1})/r, \quad B_i = B/r$$

the following theorem can be stated.

Theorem 3: Let Q and R two positive definite symmetric matrices of appropriate dimension. The system (1) is quadratically d stabilizable by a linear state feedback $u(t) = Kx(t)$ if and only if there exist $\epsilon > 0$ and a positive definite symmetric matrix $P \in \mathcal{R}^{n \times n}$ satisfying the following discrete Riccati equation:

$$A'_{ii}(P^{-1} + B_i R^{-1} B'_i - \epsilon D_i D'_i)^{-1} A_{ii} \\ - P + \epsilon^{-1} E'_i E_i + Q = 0 \quad (9)$$

with

$$\epsilon^{-1} \mathbf{1} - D'_i P D_i > 0. \quad (10)$$

Then the control gain matrix K is given by

$$K = -R^{-1} B'_i (P^{-1} + B_i R^{-1} B'_i - \epsilon D_i D'_i)^{-1} A_{ii}. \quad (11)$$

Remark. Let $P = \epsilon P$ and using the matrix inversion lemma, the Riccati equation (9) can be written in a more "classical form":

$$A'_{ii} \hat{P} A_{ii} - \hat{P} - A'_{ii} \hat{P} (B_i - D_i) \\ \cdot \begin{pmatrix} \epsilon R + B'_i \hat{P} B_i & B'_i \hat{P} D_i \\ D'_i \hat{P} B_i & D'_i \hat{P} D_i - \mathbf{1} \end{pmatrix}^{-1} \begin{pmatrix} B'_i \\ D'_i \end{pmatrix} \hat{P} A_{ii} \\ + E'_i E_i + \epsilon Q = 0.$$

The Riccati equation (9) is of a type which also arises in linear quadratic differential games (discrete time case) in which the cost functional is (see [9])

$$J_i(u_k, v_k) = \sum_{k=0}^{\infty} [y'_k y_k + \epsilon x'_k Q x_k + \epsilon u'_k R u_k - v'_k v_k]$$

where u_k is the minimizing control, v_k is the maximizing control, and the system under consideration is described by state equation

$$x_{k+1} = A_{ii} x_k + B_i u_k + D_i v_k \\ y_k = E_i x_k.$$

Proof of Theorem 3 For the proof, some technical lemmas are necessary. In what follows, we give almost all them without proofs which can be found in the quoted references.

Lemma 1 [10] Let S, Y , and Z be given by $k \times k$ symmetric matrices such that $S \geq 0$, $Y < 0$, and $Z \geq 0$. Furthermore, assume that

$$(\eta' Y \eta)^2 - 4(\eta' S \eta)(\eta' Z \eta) > 0$$

for all nonzero $\eta \in \mathcal{R}^k$. Then, there exists a constant $\lambda > 0$ such that the matrix $\lambda^2 S + \lambda Y + Z$ is negative definite. •

Lemma 2 (Finsler Lemma). Let X be a $k \times k$ symmetric matrix and $B_i \in \mathcal{R}^{k \times m}$ such that $\eta' X \eta < 0$ for all $\eta \neq 0$ satisfying $B'_i \eta = 0$. Then there exists a positive definite symmetric matrix $Y \in \mathcal{R}^{k \times k}$ such that the matrix $X - B_i Y B'_i$ is negative definite. •

Lemma 3 [10], [11] Given $x \in \mathcal{R}^n$, $y \in \mathcal{R}^m$,

$$\text{Max} \{ (x' D_i F E_i y) : F' F \leq \mathbf{1} \} = x' D_i D'_i x y' E'_i E_i y. \quad (12)$$

Lemma 4 [11] Let Q and R be two positive symmetric matrices such that the Riccati equation (9) has positive definite symmetric solution for $\epsilon^* > 0$. Then for any given positive definite symmetric matrices \hat{Q} and \hat{R} , there exists $\hat{\epsilon} > 0$ such that (9) has a definite positive symmetric solution for all $\epsilon \in (0, \hat{\epsilon})$ with R replaced by \hat{R} and Q by \hat{Q} . •

The above lemma states that the existence of a matrix P satisfying the conditions of Theorem 3 does not depend upon the choice of the R and Q matrices.

Lemma 5: Let D_i, A_i, E_i be matrices of appropriate dimension. Let $F \in \mathcal{N}$ and P be a positive definite symmetric matrix satisfying

$$\epsilon^{-1} \mathbf{1} - D'_i P D_i > 0, \quad \epsilon > 0.$$

Then,

$$A' P D_i F E_i + E'_i F' D'_i P A_i + E'_i F' D'_i P D_i F E_i \\ \leq A' P D_i (\epsilon^{-1} \mathbf{1} - D'_i P D_i)^{-1} D'_i P A_i + \epsilon^{-1} F'_i E_i. \quad \bullet$$

Proof If we define

$$Y = (\epsilon^{-1} \mathbf{1} - D'_i P D_i)^{-1/2} D'_i P A_i - (\epsilon^{-1} \mathbf{1} - D'_i P D_i)^{1/2} F E_i.$$

We have $Y' Y \geq 0$ and then

$$A' P D_i (\epsilon^{-1} \mathbf{1} - D'_i P D_i)^{-1} D'_i P A_i - A' P D_i F E_i \\ - E'_i F' D'_i P A_i + E'_i F' (\epsilon^{-1} \mathbf{1} - D'_i P D_i) F F_i \geq 0.$$

Rearranging some terms, the lemma is proved. □

Necessity: Suppose the system (1) quadratically d stabilizable by a state feedback $u(t) = Kx(t)$. Then, there exists a positive definite symmetric matrix $P \in \mathcal{R}^{n \times n}$ such that for all $X \in \mathcal{R}^{2n}$ and $F \in \mathcal{N}$:

$$X' \begin{pmatrix} -P^{-1} & A_{ii} + D_i F E_i + B_i K \\ A'_{ii} & -P \end{pmatrix} X < 0$$

which can be written

$$X' \begin{pmatrix} -P^{-1} & A_{ii} \\ A'_{ii} & -P \end{pmatrix} X + X' \begin{pmatrix} 0 & B_i K \\ K' B'_i & 0 \end{pmatrix} X \\ + X' \begin{pmatrix} 0 & D_i F E_i \\ E'_i F' D'_i & 0 \end{pmatrix} X < 0. \quad (13)$$

And then for all $X \neq 0$ such that $[B'_i \ 0]X = 0$, we have

$$X' \begin{pmatrix} -P^{-1} & A_{ii} \\ A'_{ii} & -P \end{pmatrix} X + X' \begin{pmatrix} 0 & D_i F E_i \\ E'_i F' D'_i & 0 \end{pmatrix} X < 0.$$

This implies that

$$X' \begin{pmatrix} -P^{-1} & A_{ii} \\ A'_{ii} & -P \end{pmatrix} X \\ < - \left\{ \text{Max } X' \begin{pmatrix} 0 & D_i F E_i \\ E'_i F' D'_i & 0 \end{pmatrix} X : F' F \leq \mathbf{1} \right\} \leq 0$$

for all $X \neq 0$ such that $[B'_i \ 0]X = 0$. And hence

$$\left(X' \begin{pmatrix} -P^{-1} & A_{ii} \\ A'_{ii} & -P \end{pmatrix} X \right)^2 \\ > \left\{ \text{Max } X' \begin{pmatrix} 0 & D_i F E_i \\ E'_i F' D'_i & 0 \end{pmatrix} X : F' F \leq \mathbf{1} \right\}^2$$

for all $X \neq 0$ such that $[B'_i \ 0]X = 0$. Writing $X = [x' y']'$ and by Lemma 3 we obtain

$$\left(X' \begin{pmatrix} -P^{-1} & A_{ii} \\ A'_{ii} & -P \end{pmatrix} X \right)^2 \\ > 4 X' \begin{pmatrix} D_i D'_i & 0 \\ 0 & 0 \end{pmatrix} X X' \begin{pmatrix} 0 & 0 \\ 0 & E'_i E_i \end{pmatrix} X \quad (14)$$

all $\lambda \neq 0$ such that $[B' \ 0]\lambda = 0$. Now denoting by Γ a matrix whose columns form a set of basis vector for the linear space $\in \mathcal{R}^{2n}$ $[B' \ 0]\lambda = 0$ and defining

$$\begin{aligned} \zeta &= \Gamma' \begin{pmatrix} D & D' & 0 \\ 0 & 0 & 0 \end{pmatrix} \Gamma \geq 0 \\ \gamma &= \Gamma' \begin{pmatrix} -P^{-1} & 4 \\ 4' & -P \end{pmatrix} \Gamma < 0 \\ \mathcal{Z} &= \Gamma' \begin{pmatrix} 0 & 0 \\ 0 & F'F \end{pmatrix} \Gamma \geq 0 \end{aligned}$$

It follows by Lemma 1 that there exists a constant $\epsilon > 0$ such that

$$\begin{aligned} \lambda \begin{pmatrix} D & D' & 0 \\ 0 & 0 & 0 \end{pmatrix} \lambda + \lambda \begin{pmatrix} -P^{-1} & 4 \\ 4' & -P \end{pmatrix} \lambda \\ + \frac{1}{\epsilon} \lambda \begin{pmatrix} 0 & 0 \\ 0 & F'F \end{pmatrix} \lambda < 0 \end{aligned}$$

for all $\lambda \neq 0$ such that $[B' \ 0]\lambda = 0$. By Lemma 2 there exists a positive definite symmetric matrix $W = R^{-1}$ such that the matrix

$$\begin{pmatrix} -P^{-1} + \epsilon D D' & 4 \\ 4' & -P + \epsilon F'F \end{pmatrix} = \begin{pmatrix} B R^{-1} B & 0 \\ 0 & 0 \end{pmatrix}$$

is negative definite. P being positive definite by hypothesis. This implies

$$4 (P^{-1} + B R^{-1} B - \epsilon D D')^{-1} 4 - P + \epsilon^{-1} F'F < 0$$

And there exists $Q = Q' > 0$ such that

$$4 (P^{-1} + B R^{-1} B - \epsilon D D')^{-1} 4 - P + \epsilon^{-1} F'F < -Q < 0$$

It remains to show the following inequality

$$\epsilon^{-1} \mathbf{1} - D P D' > 0 \quad (15)$$

Following the same development as above we obtain

$$\begin{aligned} \epsilon \lambda \begin{pmatrix} D & D' & 0 \\ 0 & 0 & 0 \end{pmatrix} \lambda + \lambda \begin{pmatrix} P^{-1} & 4 \\ 4' & -P \end{pmatrix} \lambda \\ + \frac{1}{\epsilon} \lambda \begin{pmatrix} 0 & 0 \\ 0 & F'F \end{pmatrix} \lambda < 0 \end{aligned}$$

for all $\lambda \neq 0$ such that $[0 \ B \ K]\lambda = 0$. Now from Lemma 2 there exists a matrix $V = V' > 0$ such that

$$\begin{pmatrix} -P^{-1} + \epsilon D D' & 4 \\ 4' & -P + \epsilon F'F \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & K B V B K \end{pmatrix} < 0$$

which implies that $P^{-1} - \epsilon D D' > 0$ or equivalently $\epsilon^{-1} \mathbf{1} - D P D' > 0$

Sufficiency Suppose that condition of Theorem 3 is satisfied and let

$$\mathcal{L} = (4' + \Delta 4') P (4' + \Delta 4') - P$$

Using Lemma 5 and (5), we have

$$\begin{aligned} \mathcal{L} &\leq [4' \ P 4' - P + 4' P D (\epsilon^{-1} \mathbf{1} - D' P D)^{-1} D' P 4' \\ &\quad + \epsilon^{-1} L' F] \\ &= [4' (P^{-1} - \epsilon D D')^{-1} 4' - P + \epsilon^{-1} F'F] \end{aligned} \quad (16)$$

By the conditions of Theorem 3

$$P = 4' (P^{-1} + B R^{-1} B' - \epsilon D D')^{-1} 4' + \epsilon^{-1} I' L + Q$$

Replacing in (16) leads to

$$\begin{aligned} \mathcal{L} &\leq [4' (P^{-1} - \epsilon D D')^{-1} 4' \\ &\quad - 4' (P^{-1} + B R^{-1} B' - \epsilon D D')^{-1} 4' - Q] \end{aligned} \quad (17)$$

Now denoting $\Gamma = (P^{-1} + B R^{-1} B' - \epsilon D D')^{-1} 4'$ that

$$\begin{aligned} 4' (P^{-1} + B R^{-1} B' - \epsilon D D')^{-1} 4' \\ = \Gamma' B R^{-1} B' \Gamma + I^{-1} \end{aligned}$$

(17) is now given by

$$\begin{aligned} \mathcal{L} &= [4' (P^{-1} - \epsilon D D')^{-1} 4' - Q] \\ &\quad - \Gamma' B R^{-1} B' \Gamma - I^{-1} (P^{-1} - \epsilon D D')^{-1} 4' \end{aligned}$$

A simple calculation shows that with K given by (11)

$$4' (P^{-1} - \epsilon D D')^{-1} 4' = \Gamma' (P^{-1} - \epsilon D D')^{-1} I = 0$$

and then

$$\mathcal{L} < -[Q + K' R K] < -Q < 0$$

Then the system is quadratically d stabilizable and the proof is completed \square

A d Stabilization Algorithm

Theorem 3 gives a condition which allows to derive the d stabilization algorithm presented below

- Step 1 Choose any positive definite symmetric weighting matrices $Q \in \mathcal{R}^{n \times n}$ and $R \in \mathcal{R}^{m \times m}$ and initialize ϵ to some starting value
- Step 2 Determine whether the Riccati equation (9) has positive definite solution satisfying (10). If such a solution exists the algorithm succeeds and a control law is determined by (11). If not go to step 3
- Step 3 Take $\epsilon = \epsilon/2$. If ϵ is less than some computational accuracy ϵ stop the algorithm fails. Otherwise go to step 2

Remark In order to solve the Riccati equation in step 2 some standard methods can be used see for example [12] [13]

B Comparison to a Previous Result

In this paragraph we examine the relation between the results given in this paper and the results in [5]. First suppose that system (1) is well known (i.e. $D = 0$ and $I = 0$) that is

$$\delta[x(t)] = Ax(t) + Bu(t) \quad (18)$$

Following the same steps as for the proof of Theorem 3 the result below can be proved

Corollary 1 Let Q and R be two positive definite symmetric matrices of appropriate dimension. The system (18) is d stabilizable by a linear state feedback $u(t) = Kx(t)$ (i.e. all poles of the closed loop system lie in $D(\alpha)$) if and only if there exists a positive definite symmetric matrix $P' \in \mathcal{R}^{n \times n}$ satisfying the following discrete Riccati equation

$$4 (P^{-1} + B R^{-1} B')^{-1} 4' = P + Q < 0 \quad (19)$$

Then the control gain matrix K is given by

$$\begin{aligned} K &= -R^{-1} B' (P^{-1} + B R^{-1} B')^{-1} 4' \\ &= -(I^* R + B' P B)^{-1} B' P (4 - \alpha \mathbf{1}) \end{aligned} \quad (20)$$

Thus the sufficient condition stated in [5] is also necessary

IV UNCERTAINTY IN BOTH THE STATE AND INPUT MATRICES

In this section, the problem of uncertainty on both state and input matrices is investigated. Let the system

$$\dot{x}(t) = (A + \Delta A)x(t) + (B + \Delta B)u(t) \quad (21)$$

with

$$[\Delta A \quad \Delta B] = DF[\Gamma_1 \quad \Gamma_2]$$

We begin by defining an "extended system" [14]

$$\dot{X}(t) = (F + \Delta F)X(t) + B_F u(t) \quad (22)$$

$$F = \begin{pmatrix} A & B \\ 0 & 0 \end{pmatrix}$$

$$B_F = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad \Delta F = D_F F E_F \quad D_F = \begin{pmatrix} D/\sqrt{\gamma} \\ 0 \end{pmatrix}$$

$$\Delta B = \Delta B/\gamma \quad E_F = (E_1/\sqrt{\gamma} \quad E_2/\sqrt{\gamma}) \quad \rho = n + m$$

Theorem 4 Let $Q_F \in \mathbb{R}^{(n+m) \times (n+m)}$ and $R_F \in \mathbb{R}^{m \times m}$ be positive definite symmetric matrices. The system (21) is quadratically d stabilizable by a linear state feedback $u(t) = Kx(t)$ if and only if there exist $\eta > 0$ and a positive definite symmetric matrix $\Pi \in \mathbb{R}^{(n+m) \times (n+m)}$ satisfying the following discrete Riccati equation

$$F'(\Pi^{-1} + B_F R_F^{-1} B_F' - \eta D_F D_F')^{-1} F - \Pi + \eta^{-1} F' F + Q_F = 0 \quad (23)$$

with

$$\eta^{-1} \mathbf{1} - D_F' S D_F > 0 \quad (24)$$

The control gain matrix is then given by

$$u = S^{-1} x_1 \quad (25)$$

where $S = \Pi^{-1}$ is partitioned as follows

$$S = \begin{pmatrix} S_1 & S_2 \\ S_2' & S_3 \end{pmatrix} \quad S_1 \in \mathbb{R}^{n \times n} \quad S_3 \in \mathbb{R}^{m \times m} \quad \bullet$$

For the proof we need the following lemmas

Lemma 6 Let a d stable system (i.e. all its modes are in $D(n, \gamma)$) be given by

$$\dot{x}(t) = Ax(t) \quad (26)$$

Thus there exists a definite positive symmetric matrix Γ such that

$$\Gamma \Gamma' - \Gamma < 0$$

Then

$$A \Gamma \Gamma' - \Gamma < 0$$

is satisfied with $\Pi = \Gamma^{-1}$ •

Lemma 7 The system (21) is quadratically d stabilizable if and only if there exists $\mathcal{W} = \mathcal{W}' > 0$ such that

$$(1 \quad 0)[(F + \Delta F)\mathcal{W}(F + \Delta F)' - \mathcal{W}]\begin{pmatrix} 1 \\ 0 \end{pmatrix} < 0 \quad \bullet$$

Proof The system (21) is quadratically d stabilizable by a linear state feedback $u(t) = Kx(t)$ if and only if there exists a positive definite symmetric matrix P such that

$$[(1 \quad 0 + \Delta A/\gamma) + (B/\gamma + \Delta B/\gamma)K]P[(1 \quad 0 + \Delta A/\gamma)' + (B/\gamma + \Delta B/\gamma)K]' - P < 0$$

This is equivalent to

$$(1' \quad 0) \left[(F + \Delta F) \begin{pmatrix} P & PK' \\ K'P & K'PK' \end{pmatrix} (F + \Delta F)' - \begin{pmatrix} P & PK' \\ K'P & K'PK' \end{pmatrix} \right] \begin{pmatrix} 1 \\ 0 \end{pmatrix} < 0$$

and then there exists $\rho > 0$ (sufficiently small) such that

$$(1' \quad 0) \left[(F + \Delta F) \underbrace{\begin{pmatrix} P & PK' \\ K'P & K'PK' + \rho \mathbf{1} \end{pmatrix}}_W (F + \Delta F)' - \underbrace{\begin{pmatrix} P & PK' \\ K'P & K'PK' + \rho \mathbf{1} \end{pmatrix}}_W \right] \begin{pmatrix} 1 \\ 0 \end{pmatrix} < 0$$

For the converse see [15]

Proof of Theorem 4 From Lemma 7 the necessity is derived in a similar way as for Theorem 3. We prove only the sufficiency. Suppose that the condition of theorem is satisfied and let

$$H = [A + \Delta A \quad (B + \Delta B)S^{-1}] S_1 [A + \Delta A \quad (B + \Delta B)S^{-1}]' - S_1$$

Developing this expression leads to

$$H = (A + \Delta A)S_1(A + \Delta A)' - S_1 + (B + \Delta B)S_2(1 + \Delta A)' + (A + \Delta A)S_2(B + \Delta B) + (B + \Delta B)S_2' S_1^{-1} S_2(B + \Delta B)$$

But by definite positivity of S we have

$$S_1 - S S_1^{-1} S_2 > 0$$

and then

$$H \leq (1 \quad 0) \left[\begin{pmatrix} A + \Delta A & B + \Delta B \\ 0 & 0 \end{pmatrix} \begin{pmatrix} S_1 & S_2 \\ S_2' & S_3 \end{pmatrix} \begin{pmatrix} A + \Delta A & B + \Delta B \\ 0 & 0 \end{pmatrix}' - \begin{pmatrix} S_1 & S_2 \\ S_2' & S_3 \end{pmatrix} \right] \begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

or

$$H < (1 \quad 0)[(F + \Delta F)S(F + \Delta F)' - S](1 \quad 0)'$$

By Lemma 5 we have

$$H \leq (1 \quad 0)[F(S^{-1} - \eta^{-1}F'F'F)^{-1}F' - S + \eta D_F D_F'](1 \quad 0)'$$

with by (23)

$$\eta \mathbf{1} - F' S F' > 0$$

Because of the structure of B_F and by (23) it is now easy to see that the condition above can be written as follows

$$H \leq (1 \quad 0)[F(S^{-1} - \eta^{-1}F'F'F)^{-1}F' - S - B_F R_F^{-1} B_F' + \eta D_F D_F'](1 \quad 0)' < 0$$

Fig. 1 Closed loop modes

and it follows that the system

$$\delta[\dot{x}(t)] = [(A + \Delta A) + (B + \Delta B)S_1^{-1}]x(t)$$

is quadratically d stabilizable for all uncertainty in the uncertainty domain. By Lemma 6, the system

$$\delta[\dot{x}(t)] = [(A + \Delta A) + (B + \Delta B)S_1^{-1}]x(t)$$

is quadratically d stabilizable over the uncertainty domain. \square

V. NUMERICAL EXAMPLES

A Continuous System [16] Let the continuous time uncertain system

$$\dot{x}(t) = (A + \Delta A)x(t) + Bu(t) \quad (27)$$

$$A = \begin{pmatrix} 0.52 & 17.76 & 90.21 \\ 0.17 & -0.75 & 11.10 \\ 0 & 0 & -2.50 \end{pmatrix} \quad B = \begin{pmatrix} -0.124 \\ 0 \\ 2.50 \end{pmatrix}$$

The uncertainty structure is described by

$$D = \begin{pmatrix} 0.5 \\ -0.25 \\ 0 \end{pmatrix} \quad F = [0.10 \quad 0.10 \quad 1.00] \quad I = f \in \mathfrak{R}$$

We want to place the poles in a disk centered at $\alpha = -5$ and with a radius $r = 4.5$. This problem was treated in [4] for convex bounded uncertainties. The Q and R matrices are chosen to be

$$Q = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad R = 1$$

The algorithm is initialized with $\epsilon = 10$. After 3 iterations, for $\epsilon = 1.25$

$$P = \begin{pmatrix} 3.219 & 13.462 & -11.887 \\ 13.462 & 89.288 & -95.452 \\ -11.887 & -95.452 & 111.425 \end{pmatrix}$$

$$\epsilon^{-1} \mathbf{1} - D'PD = 0.295$$

The control gain matrix is then given by

$$K = [0.0016 \quad 0.0173 \quad 0.9178]$$

Fig. 2 Closed loop modes

Fig. 1 shows the closed loop modes for 200 values of t such that $-1 \leq f \leq 1$.

A Discrete System Let the discrete time uncertain system

$$x(t+1) = (A + \Delta A)x(t) + Bu(t) \quad (28)$$

$$A = \begin{pmatrix} -0.50 & 1.00 & 1.00 \\ 1.25 & -0.25 & -1.00 \\ -2.25 & -0.25 & 0.50 \end{pmatrix} \quad B = \begin{pmatrix} 1 \\ -1 \\ 0 \end{pmatrix}$$

The uncertainty structure is described by

$$D = \begin{pmatrix} 0.3333 \\ 0.1667 \\ 0.1667 \end{pmatrix} \quad F = [0.1944 \quad 0.0833 \quad 0.1389]$$

$$I = f \in \mathfrak{R}$$

This nominal system has an uncontrollable stable mode at 0.75. We try to place the poles in the circle centered at $\alpha = 0$ with a radius $r = 0.5$. For the Q and R matrices, we take

$$Q = 1 \quad R = 1$$

The algorithm is initialized with $\epsilon = 10$. After 7 iterations, $\epsilon = 0.0781$ and

$$P = \begin{pmatrix} 50.151 & 2.138 & -0.351 \\ 2.138 & 2.916 & 1.409 \\ -0.351 & 1.309 & 2.491 \end{pmatrix}$$

$$\epsilon^{-1} \mathbf{1} - D'PD = 0.514$$

The control gain matrix is then given by

$$K = [1.0421 \quad -1.0133 \quad -0.9996]$$

Fig. 2 shows the closed loop modes for 200 values of t such that $-1 \leq f \leq 1$.

VI. CONCLUSION

In this paper, pole assignment in a specified disk for discrete or continuous time uncertain systems has been investigated. The condition derived is expressed as a parameter dependent discrete Riccati equation leading to a simple procedure for the design of the state feedback gain matrix. Numerical examples for continuous and discrete time systems have been presented showing the efficiency of the proposed method. The results of this paper are based on the strong assumption of state availability. In practice, for most systems, only partial state being available the problem of pole assignment by output feedback is of great interest. This problem will be addressed in the near future.

ACKNOWLEDGMENT

We would like to acknowledge Reviewer 1 for helpful comments on the numerical examples.

Modified Output Error Identification—Elimination of the SPR Condition

Amir Betser and Ezra Zeheb

Abstract—In this note, we present a modified adaptive output error algorithm for identification. We refer to both the continuous time and the discrete time cases. In the standard algorithm, stability requires that a certain transfer function should be Strictly Positive Real (SPR); however, in the present algorithm, the SPR condition, which is difficult to satisfy, is eliminated. This is achieved by adding a fixed feedback gain. When there exists an *a priori* partial knowledge about the parameters of the plant, we provide a simple procedure to design that gain. An illustrative example comparing the modified algorithm to the standard one is provided.

I. INTRODUCTION

A sufficient condition for asymptotic stability of the adaptive output error algorithm for identification is that a certain transfer function should be a Strictly Positive Real (SPR) rational function [1]–[3]. A drawback of the algorithm is the need to determine the SPR function. This is a very difficult task which has not yet been satisfactorily solved. Although the numerator of that function is an arbitrary polynomial which is chosen by the designer of the system, the denominator of the function must be the denominator of the transfer function of the plant, which is either unknown or only partially known.

Several papers give necessary and sufficient conditions to check whether a transfer function, with uncertain parameters, is a SPR transfer function [4]–[8]. Some papers treated the design problem, where there exists an *a priori* knowledge about the plant, i.e., it is assumed that the denominator $a(s)$ of the transfer function of the plant belongs to a certain set of stable polynomials. In the continuous time case, only sufficient conditions were found for the existence of a fixed polynomial $g(s)$ such that $g(s)/a(s)$ is an SPR transfer function, where $a(s)$ is the above-mentioned denominator [4], [9]–[11]. As mentioned above, the design of such a polynomial $g(s)$ is (for degrees higher than 3), difficult and not yet satisfactorily solved even when there is an *a priori* knowledge about the plant. In the discrete time case, necessary and sufficient conditions were found for the existence of a fixed polynomial $c(z^{-1})$ such that $c(z^{-1})/a(z^{-1})$ is a Discrete SPR transfer function where $a(z^{-1})$ is the denominator of the transfer function of the plant, which belongs to a certain stable set of polynomials [9].

In this note, we present a modified output error algorithm, pertaining to both the continuous time and the discrete time cases. The modification includes a fixed gain feedback which, if designed properly, eliminates the SPR requirement.

The modified algorithms are presented in Sections II and III for the continuous time and the discrete time cases, respectively. In Section IV, we use the modified algorithms to solve the design problem, where the denominator of the plant belongs to the same set of stable polynomials mentioned above. In Section V, we give an illustrative example where the advantages of the modified algorithm are evident. Section VI is the conclusion.

II MODIFIED ALGORITHM—CONTINUOUS TIME CASE

We start by following the derivation described in [2] of the output error algorithm. Consider the identification problem of a single input single output, linear time invariant system described by the transfer function

$$P(s) = \frac{b(s)}{a(s)} = \frac{\sum_{i=0}^m b_i s^i}{s^n + \sum_{i=1}^n a_i s^i} \quad m < n \quad (1)$$

Denote the input and the output of the system by $u(t)$ and $y(t)$, respectively. We assume that $a(s)$ is a stable polynomial (i.e., all the zeros of $a(s)$ are in the open left half plane). Let $F_i(s) \triangleq s^i / q(s)$, $i = 1, 2, \dots, n$ where $q(s) = s^n + \sum_{i=1}^n q_i s^i$ is a stable arbitrary polynomial. The input-output relationship can be expressed as follows

$$y(t) = c_0^T(t) \theta_0 \quad (2)$$

where

$$c_0^T(t) = [F_1 u \quad F_2 u \quad \dots \quad F_n u \quad -F_1 y \quad \dots \quad -F_n y] \quad (3)$$

$$\theta_0^T = [b_0 \quad b_1 \quad \dots \quad b_m \quad a_1 - q_1 \quad \dots \quad a_n - q_n] \quad (4)$$

and $F_i u$, $F_i y$ are the outputs of the stable filters $F_i(s)$ with the inputs $u(t)$, $y(t)$ respectively. At this point, we depart from the standard output error algorithm. We define our output error as usually done by

$$e(t) = y(t) - \hat{y}(t) \quad (5)$$

However, our $\hat{y}(t)$ differs from the standard definition. We add a feedback gain as follows

$$\hat{y}(t) = c^T(t) \theta(t) + l_1(t) \quad l_1(t) = 0 \quad (6)$$

where

$$c^T(t) = [F_1 u \quad F_2 u \quad \dots \quad F_n u \quad -F_1 y \quad \dots \quad -F_n y] \quad (7)$$

$$\theta^T(t) = [b_0 \quad b_1 \quad \dots \quad b_m \quad a_1 - q_1 \quad \dots \quad a_n - q_n] \quad (8)$$

$l_1(t) = 0$, $1 \leq m$ and $a_i - q_i$, $i = 1, 2, \dots, n$ are the estimated values. Notice that in the standard algorithm $\hat{y}(t) = c^T(t) \theta(t)$, i.e., $l_1(t) = 0$.

The adaptive algorithm is

$$\dot{\theta}(t) = \epsilon c(t) \theta(t) \quad \epsilon > 0 \quad (9)$$

We will now state and prove a theorem, on which our modified output error identification algorithm is based and justified.

Theorem 1 There exists a scalar $l^* > 0$ such that for all $l > l^*$ the modified output error algorithm described by (2)–(9) is asymptotically stable when the input $u(t)$ is bounded, i.e., all the signals in the system are bounded and $\lim_{t \rightarrow \infty} e(t) = 0$. If in addition the input $u(t)$ is persistently excited (PE) then $\lim_{t \rightarrow \infty} \theta(t) = \theta_0$ exponentially fast.

To prove Theorem 1, we need the following lemma which appears in [12].

Lemma 1 Let $Q(s)$ be a rational function in the complex variable s with real coefficients

$$Q(s) = \frac{\sum_{i=0}^m c_i s^i}{\sum_{i=0}^d d_i s^i} \quad c_i, d_i \neq 0$$

having a positive leading coefficient c_m/d_m , and satisfying

$$Q(s) \neq 0 \quad \text{in } \mathbb{R} \quad \text{Re}[s] \geq 0 \quad (10)$$

Also, if $Q(s)$ vanishes at infinity, the multiplicity of the zero is not greater than 1, i.e., $m \geq n - 1$.

Fig. 1 (a) Estimated parameters versus sampling instants—modified algorithm, discrete time case. (b) Output error versus sampling instants—modified algorithm, discrete time case.

Let l be a positive finite number which is sufficiently large. Then the rational function $F(s)$ defined by

$$F(s) = \frac{Q(s)}{1 + lQ(s)} \quad (11)$$

is strictly positive real (SPR).

Proof of Theorem 1 For the case $l = 0$ it was shown in [2] that

$$\dot{e}(t) = -H(s)(c^T \theta) \quad (12)$$

where

$$H(s) = \frac{q(s)}{a(s)} \quad (13)$$

and

$$\theta = \theta_0 - \theta \quad (14)$$

A similar derivation, which will be omitted for the sake of brevity, reveals that for the case of $\hat{y}(t)$ as in (6) with $l > 0$, (13) should be replaced by

$$H(s) = \frac{q(s)}{a(s) + lq(s)} \quad (15)$$

It is well known [1]–[2] that if $H(s)$ is an SPR function, then the system is asymptotically stable. If, in addition, the input $u(t)$ is PE, then the parameters converge exponentially to their correct values, i.e., $\lim_{t \rightarrow \infty} \theta = \theta_0$ exponentially fast.

Define now $Q(s) \triangleq q(s)/u(s)$ which satisfies the conditions of Lemma 1. Then, (15) becomes $H(s) = Q(s)/(1 + lQ(s))$ and according to Lemma 1 we can find $l > 0$ sufficiently large such that $H(s)$ is SPR. \square

III. MODIFIED ALGORITHM—DISCRETE TIME CASE

We consider a plant described by

$$y(k) = -\sum_1^m a_i y(k-i) + \sum_{j=0}^n b_j u(k-j) \quad (16)$$

$$= c_0^l (k-1)\theta_l \quad (17)$$

where

$$c_0^l(l-1) = [u(k) \quad u(k-m) \quad y(k-1) \quad y(k-n)] \quad (18)$$

$$\theta_l^T = [b_l \quad b \quad -a_1 \quad -a] \quad (19)$$

The plant is assumed to be stable, i.e., all the zeros of $a(z^{-1}) \triangleq 1 + \sum_{i=1}^m a_i z^{-i}$ are in the open unit disk. The output error is

$$e(k) = y(k) - y(k) \quad (20)$$

As in the continuous time case, the standard $y(l)$ is modified by using feedback in the system's realization.

$y(k)$ is defined as

$$y(k) = \frac{1}{1+l} [\alpha^l (k-1)\theta(k) + l y(k)] \quad l > 0 \quad (21)$$

where

$$c_0^l(l-1) = [u(k) \quad u(k-m) \quad y(k-1) \quad y(k-n)] \quad (22)$$

$$\theta(l)^T = [b_0 \quad b \quad -a_1 \quad -a] \quad (23)$$

$b_i, i=0, 1, \dots, m$ and $a_i, i=1, 2, \dots, n$ are the estimated values. Notice that although (21) is algebraically equivalent to

$$y(k) = \alpha^l (k-1)\theta(k) + l y(k) \quad (24)$$

which is the form we actually desire for our stability analysis, (24) is not directly implementable, whereas (21) is readily implementable. The adaptation algorithm is

$$\theta(k+1) = \theta(k) - \frac{e(k)}{1 + \frac{e(k)}{c_0^l(k)} c_0^l(k)} [c_0^l(k)^T \theta(k) - y(k+1)] \quad (25)$$

We state and prove Theorem 2 which is the discrete time analog of Theorem 1.

Theorem 2 There exists a scalar $l^* > 0$ such that for all $l > l^*$ the modified output error algorithm described by (16)–(25) is asymptotically stable when the input $u(l)$ is bounded, i.e., all the signals in the system are bounded and $\lim_{k \rightarrow \infty} e(k) = 0$. If, in addition, the input $u(l)$ is persistently excited (PE), then $\lim_{k \rightarrow \infty} \theta(k) = \theta_0$ exponentially fast.

To prove Theorem 2 we need the following lemma which appears in [13].

Lemma 2 The discrete transfer function

$$Q(z^{-1}) = \frac{1}{1 + \sum_{i=1}^n a_i z^{-i}} \quad (26)$$

is SPR if

$$\sum_i |a_i| < 1 \quad (27)$$

Proof of Theorem 2 A similar derivation to the one carried out in [2], for the case $l = 0$, yields for the proposed case of $y(k)$, as in (21) with $l > 0$ the following expression

$$e(k) = -H(z^{-1})(\alpha^l (k-1)\theta(k)) \quad (28)$$

$$H(z^{-1}) = \frac{\frac{1}{1+l}}{1 + \frac{1}{1+l} \sum_{i=1}^n a_i z^{-i}} \quad (29)$$

where

$$\theta(k) = \theta(k) - \theta_0 \quad (30)$$

It is well known [1]–[3] that if $H(z^{-1})$ is an SPR function, then the system is asymptotically stable. If, in addition, the input $u(k)$ is PE, then the parameters converge exponentially to their correct values, i.e., $\lim_{k \rightarrow \infty} \theta(k) = \theta_0$ exponentially fast.

Obviously, there exists a sufficiently large l such that $1/(1+l) \sum_{i=1}^n |a_i| < 1$ and according to Lemma 2, $H(z^{-1})$ in (29) is SPR for such an l . \square

IV. THE DESIGN PROCEDURE

We assume now that we have some *a priori* knowledge about the denominator of the plant. We will point out how this knowledge allows us to design the feedback gain l which eliminates the SPR requirement.

In the continuous time case, we assume that $a(s)$, the denominator of the plant, belongs to the set of interval stable polynomials \mathbf{K} , i.e.,

$$a(s) = s^n + \sum_{i=1}^n a_i s^{n-i} \quad (31)$$

$$a_i \in [\underline{a}_i, \bar{a}_i] \quad i=1, 2, \dots, n \quad (32)$$

and $\underline{a}_i, \bar{a}_i, i=1, 2, \dots, n$ are given real numbers satisfying $\underline{a}_i < \bar{a}_i, i=1, 2, \dots, n$. The first step of the design procedure is to choose an arbitrary stable polynomial $q(s)$ of degree n . As discussed in [12], if

$$l > - \min_{\mathbf{K}} \left\{ \operatorname{Re} \left[\frac{a(j\omega)}{q(j\omega)} \right] \right\} \quad (33)$$

then the function $H(s)$ in (15) is SPR, and the adaptive system is asymptotically stable. Now let the four Kharitonov polynomials which are associated with the set \mathbf{K} [14] be denoted by $a_i(s), i=1, 2, 3, 4$. It has been proved in [15] that

$$\min_{\mathbf{K}} \left\{ \operatorname{Re} \left[\frac{a(j\omega)}{q(j\omega)} \right] \right\} = \min_{i=1, 2, 3, 4} \left\{ \operatorname{Re} \left[\frac{a_i(j\omega)}{q(j\omega)} \right] \right\} \quad (34)$$

Therefore, any feedback gain l which satisfies

$$l > - \min_{i=1, 2, 3, 4} \left\{ \operatorname{Re} \left[\frac{a_i(j\omega)}{q(j\omega)} \right] \right\} \quad (35)$$

guarantees the asymptotic stability of the adaptive system.

The right hand side of (35) can readily be computed, since it consists of four distinct fixed coefficients functions of a single variable ω .

In a more general case, where the denominator of the plant $a(s)$ belongs to a convex polytope of stable polynomials, it is evident that the coefficients can be bounded by a box, and the procedure carried out as in the interval case.

The design procedure in the discrete time case is carried out in a similar way and will be omitted for the sake of brevity.

Remark In [13], [16], and [17], a criterion was given for the asymptotic stability of the output error algorithm ([13] was generalized in [18]). This criterion states that for a large enough adaptation gain and/or input signal magnitude the system is asymptotically stable. In the present note, there are no restrictions on the adaptation gain or the input signal magnitude.

V SIMULATION RESULTS

In the discrete-time case, we investigate the example in [19], note that it is only the example which is being used and not the technique proposed in [19]. The boundedness conjecture in [19] was disproved in [20]. The plant is a second-order one with two unknown parameters, a_1, a described by

$$\begin{aligned} y(l) &= -a_1 y(k-1) - a y(k-2) + u(l) \\ &= 1.6y(k-1) - 0.8y(k-2) + u(k) \end{aligned} \quad (36)$$

The true parameter vector is $\theta^T = [-a_1 \ -a] = [1.6 \ -0.8]$. The transfer function of the error system in the original algorithm is $H(z^{-1}) = 1/1 - 1.6z^{-1} + 0.8z^{-2}$ which is not an SPR transfer function. It can be shown that for $l > 1.4$ the modified $H(z^{-1})$ is SPR. For convenience we chose $l = 3$. Now $H(z^{-1}) = 0.25/1 - 0.1z^{-1} + 0.2z^{-2}$ is an SPR transfer function.

In [19] it was found (by trial and error) that if the adaptation gain $\epsilon = 0.001773$ then the output error algorithm is not stable. We simulate this example with $\epsilon = 0.001$. Fig. 1(a) contains the plots of the estimated parameters versus time $\theta(l)$. Fig. 1(b) contains the plot of the output error versus time $e(l)$. This figure shows that, contrary to the original algorithm, in the modified algorithm the parameters converge to their correct values and the output error approaches zero.

VI CONCLUSION

The SPR condition is a major drawback of the output error algorithm because the denominator of the SPR transfer function has to be the denominator of the unknown plant. In the discrete time case it is possible to overcome this condition while in the continuous time case only sufficient conditions were found to satisfy the SPR condition. In the present note it was shown that by a slight modification of the output error algorithm we eliminate the SPR condition both in the continuous and discrete time cases. An *a priori* knowledge about the denominator of the plant allows us to design a feedback gain which guarantees the asymptotic stability of the algorithm. The design algorithm is very simple and by simulation we demonstrate the advantages of the modified algorithm over the original one.

Comments on "Explicit Asymmetric Bounds for Robust Stability of Continuous and Discrete-Time Systems" and

Jian Xiao

Abstract—This note comments the results of a recent paper,¹ we point out that Theorem 2 is incorrectly stated. A correct version of the theorem is provided.

In the recent note,¹ the authors gave sufficient conditions for the robust stability of systems with parameter uncertainty. Since both the signs and the ranges of the uncertain parameters are taken into consideration, the proposed criterions are less conservative than the previous results.

In this note, we identify a minor error in their Theorem 2. In this theorem, the authors pointed out, for discrete time system

$$x(k+1) = (A + F)x(k) \quad (1)$$

with $F = \sum_{j=1}^m f_j F_j$, F is asymptotically stable if

$$\sum_k \lambda_k + \sum_j k f_j f_{j,j} < 1$$

where

$$\lambda_k = \begin{cases} \lambda_{\max}(P) & \text{for } k \geq 0 \\ \lambda_{\min}(P) & \text{for } k < 0 \end{cases} \quad (2)$$

$$f_{j,j} = \begin{cases} \lambda_{\max}(F_j) & \text{for } k, k_j \geq 0 \\ \lambda_{\min}(F_j) & \text{for } k, k_j < 0 \end{cases}$$

Manuscript received September 6, 1994.

The author is with the Department of Electrical Engineering, Southwest Jiaotong University, Chengdu 610031, Sichuan, P. R. China.

IEEE Log Number 9407005.

¹Z. Gao and P. J. Antsaklis, *IEEE Trans. Automat. Contr.*, vol. 38, pp. 332–335, 1993.

$$P = (E_i^T P A + A^T P E_i)/2, \quad i = 1, \dots, m$$

$$I_{i,j} = F_i^T P E_j/2, \quad i, j = 1, \dots, m$$

P is the solution of equation

$$A^T P A - P + 2I = 0$$

Since $F_{i,j}$ is generally not a Hermitian matrix, Lemma 2¹ is not valid here, and the theorem is generally not true. To give a correct statement, we first define two kind of matrices:

$$F_{i,j} = (F_i^T P F_j + L_i^T P E_j)/2, \quad i, j = 1, \dots, m, \quad i < j$$

$$G_i = F_i^T P E_i/2, \quad i = 1, \dots, m$$

note that both $F_{i,j}$ and G_i are Hermitian matrices, and

$$\sum_i G_i + \sum_{i,j} F_{i,j} = \sum_j F_j$$

We can give the correct version of this theorem as follows:

Theorem 1 The system in (1) is asymptotically stable if

$$\sum_k \lambda_k + \sum_i k q_i + \sum_{i,j} k, k_j f_{i,j} < 1$$

where λ_k is defined by (2) and

$$q_i = \lambda_{\max}(G_i), \quad i = 1, 2, \dots, m$$

$$f_{i,j} = \begin{cases} \lambda_{\max}(F_{i,j}) & \text{for } k, k_j \geq 0 \\ \lambda_{\min}(F_{i,j}) & \text{for } k, k_j < 0 \end{cases}, \quad i, j = 1, \dots, m, \quad i < j$$

Adaptive Control of Plants with Unknown Hystereses, *Wang and Kokotovic*

This paper studies the problem of adaptively controlling systems with unknown hystereses. Hysteresis phenomena caused by stiction, magnetism or gears with backlash often severely limit system performance and give rise to inaccuracy or oscillations, even leading to instability. Since hysteresis characteristics are generally nondifferentiable nonlinearities, the existing results of adaptive control theory which deal primarily with linear or differentiable nonlinear systems are not applicable to systems with hysteresis. The authors develop a new method to parameterize the unknown variables of a hysteresis model and develop a hysteresis inverse. They present an adaptive method for a known linear plant following the hysteresis as well as for an unknown plant. An adaptive hysteresis inverse cascaded with the plant is employed to cancel the effects of hysteresis so that the remaining part of the controller can retain its linear structure. The analytical results prove the global boundedness of the closed loop signals for wide class of hysteresis models.

Robust Stability under A Class of Nonlinear Parametric Perturbations, *Fu, Dasgupta and Blondel*

In verifying robust stability in linear systems dependent on real valued uncertain parameters, there is a fundamental trade off between the generality of functional dependence on the unknown parameters and the complexity of the tests for verifying stability. Therefore a key engineering challenge in these problems is to identify structures of uncertainty that facilitate tractable analysis, while capturing practically important cases. This paper's contribution falls in this category. For a transfer function description of finite dimensional linear time invariant systems, the authors derive tractable necessary and sufficient conditions for robust stability when given a particular structure of nonlinear parameter dependence in the associated characteristic function. The authors motivate their structure as one that might commonly arise from a cascade of parameter dependent single input single output plants with a fixed controller. If each of these uncertain plants has a numerator and denominator that are powers of polynomials having affine dependence on independent parameters and the parameters themselves are restricted to a hyper rectangle in R^n , the structure considered in this paper results.

The necessary and sufficient conditions for robust Hurwitz stability on this structure are derived using the concept of the frequency dependent value set for the characteristic function of interest. In particular, the authors identify simple one dimensional subsets of the parameter set that must be tested to ensure robust stability over the entire parameter set. These subsets are the edges of the parameter set hyper rectangle and certain internal line segments that may be frequency dependent. Moreover, the paper shows special cases of this uncertainty for which these internal line segments remain independent of frequency. To facilitate construction of algorithms to test these geometric conditions, the authors go on to identify a complex-valued function of frequency with the property that its image avoids the negative real axis if and only if the original uncertain system is robustly Hurwitz stable.

Discrete-Time Observers for Singularly Perturbed Continuous-Time Systems, *Shouse and Taylor*

This paper deals with constructing observers for nonlinear continuous time singularly perturbed systems. The observer design concept adopted here is based on inversion of state to measurement maps. The two time scale nature of the systems is exploited by decomposing the problem into one of designing separate observers for the approximate slow and fast subsystem models. The resulting observers are of reduced order and are also implemented in a multirate fashion. As a result, significant savings in computational and/or memory requirements are obtained. Also, the stiffness inherent in a full order observer design is eliminated.

The development and analysis of stabilizing observer based control algorithms is not attempted in this paper. Nevertheless, the use of observer based feedback is utilized in a case study of velocity control of a two phase permanent magnet synchronous motor using only phase current measurements. It is demonstrated via simulations, that the reduced order observer designs proposed in this paper result in good performance.

Adaptive Back-Pressure Congestion Control Based on Local Information, *Tassiulas*

A new distributed control policy for a multiclass multistage queueing systems that models virtual circuit and datagram communication networks and a class of manufacturing systems is presented in this paper. The policy aims at controlling the congestion in the network by dynamically allocating the servers to the buffers, regulating the flows in the network, and routing the served traffic. The author proposes a policy called Adaptive Back Pressure (ABP) congestion policy that performs all these control functions in a distributed fashion based on local information. For arrival processes with bounded burstiness, the author shows that the ABP policy stabilizes the network in the sense that it ensures bounded backlog in the network as long as the utilization of each server is less than its service capacity. An adaptive version of the ABP policy is also discussed.

Stability of Queueing Networks and Scheduling Policies, *Kumar and Mevn*

The objective of this paper is to establish stability results for queueing networks that involve scheduling servers among several competing queues. Given that solutions to the stability problem (namely, by determining a steady state probability distribution) are rare outside the special class of queueing networks possessing a product form solution, the authors propose and develop a programmatic procedure for obtaining sufficient conditions for the stability of queueing networks operating under scheduling policies. This procedure uses linear programming to programmatically construct an appropriate quadratic Lyapunov function from which the stability results are deduced. This method can provide stability results that could be very difficult to obtain analytically, and it is applied very successfully to several example problems in the paper.

Second-order Properties of Families of Discrete-Event Systems, *Rajan and Agrawal*

This paper considers a class of timed discrete-event systems termed synchronous discrete event systems (SDFS). Any such system

*This section is written by the Transactions Editorial Board.

can be described directly in terms of a language/score space, as opposed to a state evolution mechanism. SDES provide a unified framework for modeling a large class of Petri nets and queueing systems including tandem, cycle, fork-join, and split-merge networks with general blocking and starvation. The objective of the paper is to study the concavity of the event counting process of SDES. In particular, the paper presents a sufficient condition on score spaces that ensures that the event counting process of one system dominates

the event counting processes of a collection of systems. This result may be applied to conflict-free Petri nets to deduce the concavity of the firing process as function of the initial marking or to the above-mentioned families of queueing networks to deduce concavity of the throughput as a function of various parameters such as buffer configuration, initial job configuration, and blocking parameters. Overall, the authors present a new and interesting perspective that covers and extends earlier results.

The 1994 George S. Axelby Outstanding Paper Award

(Covering the Period January 1992–December 1993)

THE George S. Axelby Outstanding Paper Award is given each year by the Control Systems Society to the authors of outstanding papers published in the IEEE TRANSACTIONS ON AUTOMATIC CONTROL during the two calendar years preceding the year of the Award. At most three papers can be selected each year. Papers are judged on their originality, their potential impact on the foundations of control, their importance and practical significance in applications, and on their clarity.

Nominations for the Award were solicited this year through announcements in the IEEE CONTROL SYSTEMS MAGAZINE and the TRANSACTIONS ON AUTOMATIC CONTROL. The Axelby Award Committee makes use of selected reviews and panel evaluations to evaluate and rank those papers which are nominated. As a result of this process, the following paper was selected this year to receive this prestigious Award:

Sheng-Luen Chung, Stéphane Lafortune, and Feng Lin,
"Limited lookahead policies in supervisory control of
discrete-event systems," vol. 37, no. 12, pp. 1921–1935,
Dec. 1992.

Prof. Chung is with the Electrical Engineering Technology Department of the National Taiwan Institute of Technology, Taipei, Republic of China. Prof. Lafortune is with the Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, Michigan, 48109 USA. Prof. Lin is with the Department of Electrical and Computer Engineering, Wayne State University, Detroit, Michigan, 48202 USA.

The authors received their Award during the Luncheon Award Ceremonies of the 33rd IEEE Conference on Decision and Control, at Lake Buena Vista, Florida, USA on December 15, 1994. The Award consists of a certificate and plaque and is named for George S. Axelby, founding editor of the IEEE TRANSACTIONS ON AUTOMATIC CONTROL.

The following "Scanning the Issue" paragraph, written by Associate Editor C. G. Cassandras, is reprinted here again as a service to the reader:

One approach toward controlling discrete-event systems involves the design of "supervisors" whose purpose it is, for example, to ensure that the system reaches certain desirable state sets or avoids undesirable ones.

The design of supervisors is based on finite automata models both for the system to be controlled and for the process that describes its desired behavior. For complex systems, however, this task becomes extremely difficult for a number of reasons; for instance, one cannot overcome the exponential growth of the state space that accompanies complexity. The authors introduce an on-line scheme based on the idea of projecting the behavior of the system for N steps into the future after every event occurrence and then selecting a control action based on this limited information. This gives rise to various "limited lookahead policies" (LLP) resulting in an LLP supervisor. The authors also introduce the notion of an "attitude" regarding the control action selected, and they analyze a conservative and an optimistic attitude, for which they derive a number of properties. Lower bounds on the number of steps N defining the lookahead horizon are provided such that the LLP scheme's performance is at least as good as an off-line scheme with complete information. Finally, a simplified subway system is used as an example to illustrate the applicability of LLP supervisory control and related implementation issues.

Nominations for the 1995 George S. Axelby Outstanding Paper Award, covering the period January 1993–December 1994, are already open. Any reader who wishes to nominate a paper is urged to do so by the closing date of May 15, 1995. No nomination form is required. A letter identifying the paper by title, author, and issue of publication and including a description of the contribution of the paper should be submitted. Alternatively, an electronic message carrying the above information would be sufficient. Please send nominations, by May 15, 1995, to

Michael K. Sain
Freimann Professor of Electrical Engineering

MICHAEL K. SAIN
1994 Axelby Award Chairman

Abstract—For a system with hysteresis, we present a parameterized hysteresis model and develop a hysteresis inverse. We then design adaptive controllers with an adaptive hysteresis inverse for plants with unknown hystereses. A new adaptive controller structure is introduced which is capable of achieving a linear parameterization and a linear error model in the presence of a hysteresis nonlinearity. A robust adaptive law is used to update the controller parameters and hysteresis inverse parameters, which ensures the global boundedness of the closed-loop signals for a wide class of hysteresis models. Simulations show that the use of the adaptive hysteresis inverse leads to major improvements of system performance.

I. INTRODUCTION

HYSTERESIS phenomena caused by stiction, magnetism, or gears with backlash commonly exist in physical systems [1]–[6], and often severely limit system performance such as giving rise to undesirable inaccuracy or oscillations, even leading to instability. Hysteresis characteristics are generally nondifferentiable nonlinearities and usually unknown. Most results of adaptive control theory are for linear or differentiable nonlinear systems, and are not applicable to systems with nondifferentiable nonlinearities.

It is a challenging task of major practical interest to develop adaptive control schemes for systems with unknown hystereses. In this paper, we will pursue this task. The controlled plant consists of a linear part preceded by a hysteresis characteristic, that is, the hysteresis is present at the actuator of a linear part. The linear part can be either known or unknown, and the hysteresis is assumed to be unknown. The objective is to achieve stabilization and tracking in the presence of the unknown hysteresis. To solve this problem, we will use the “adaptive inverse” approach which was proposed in [7]–[9] for adaptive control of plants with nondifferentiable nonlinearities such as dead-zone and backlash. In [7], an adaptive dead-zone inverse control scheme was proposed for systems having an unknown dead zone at the input, using full state measurement. In [8], adaptive dead-zone inverse control designs for systems with unknown dead zones were developed, using only the output measurements. In [9], the adaptive inverse approach is used for adaptive control of systems were designed: one for systems with an unknown backlash and a known linear part, and the other for both the backlash and the linear

part unknown. In this paper, we will employ an adaptive hysteresis inverse cascaded with the plant to cancel the effects of hysteresis so that the remaining part of the controller can retain its linear structure.

The paper is organized as follows. In Section II, we present a hysteresis model characterized by a set of parameters, and formulate the control problem. In Section III, we present a mathematical model of a hysteresis inverse and its implementation. In Section IV, we develop a parameterization for an estimate of the hysteresis inverse. In Section V, we design an adaptive controller for plants with a known linear part and an unknown hysteresis. In Section VI, we present a solution to the more general adaptive control problem in which both the linear part and hysteresis are unknown. In Section VII, we present simulation results for the proposed adaptive control schemes.

Models of backlash, electromagnetic, and other types of hysteresis can be found in [1]–[6]. However, a general hysteresis model would not be convenient because of its complexity. We will use a simplified hysteresis model which captures most of the hysteresis characteristics and is useful for parameter adaptive control. We will show that our hysteresis model has a parameterizable right inverse which cancels the effect of the hysteresis when cascaded with the hysteresis. An adaptive hysteresis inverse is implemented with parameters updated on-line by adaptive laws.

When the adaptive hysteresis inverse is used for control, the effect of the hysteresis may not be completely cancelled, and there is a control error we express in two parts: first, a parameterizable part, and second, an unknown but bounded part.

For plants with an unknown linear part, the usual linear controller structure is modified in order to achieve a linear parameterization and a linear error model, which are both crucial for the development of robust adaptive laws. As a result of the linear parameterization of the adaptive hysteresis inverse and the new controller structure, robust adaptive laws can now be used to guarantee the closed-loop signal boundedness for a wide class of hysteresis characteristics. Our simulations show that major improvements of system performance have been achieved by the adaptive hysteresis inverse.

II. PLANT AND CONTROL OBJECTIVE

The plant to be controlled has a linear part and a hysteresis characteristic $H(\cdot)$ as its input:

$$y(t) = G(s)[u](t), \quad u(t) = H(v(t)) \quad (2.1)$$

where $G(s) = k_p(Z(s)/P(s))$, $Z(s)$, $P(s)$ are monic polynomials, k_p is a constant scalar, $y(t)$ is the measured output, $v(t)$ is the control input, and $H(\cdot) \triangleq H(m_t, c_t, m_b, c_b, m_r$.

IEEE Log Number 9407562

Fig. 1. Hysteresis model.

$c_r, m_l, c_l; \cdot$) is parameterized by constants $m_l, c_l, m_b, c_b, m_r, c_r, m_l, c_l$ and described by two half-lines (see Fig. 1):

$$u(t) = m_l v(t) + c_l, \quad v(t) > v_1 = \frac{c_l + m_l c_l}{m_l - m_t} \quad (2.2)$$

$$u(t) = m_b v(t) + c_b, \quad v(t) < v_2 = \frac{c_b + m_r c_r}{m_r - m_b} \quad (2.3)$$

and two line segments:

$$u(t) = m_r(v(t) - c_r), \quad v_2 \leq v(t) < v_3 = c_l + m_r c_r \quad (2.4)$$

$$u(t) = m_l(v(t) - c_l), \quad \frac{c_b + m_l c_l}{m_l - m_t} = v_4 < v(t) \leq v_1 \quad (2.5)$$

where v_1, v_2, v_3, v_4 are the values of $v(t)$ at the four opposite "corners" of the quadrilateral.

Along the segments, the time derivatives of $u(t), v(t)$ are of constant sign, namely, $\dot{u}(t) > 0, \dot{v}(t) > 0$ for $u(t) = m_r(v(t) - c_r)$, and $\dot{u}(t) < 0, \dot{v}(t) < 0$ for $u(t) = m_l(v(t) - c_l)$.

The hysteresis phenomena occur inside the loop formed by the half-lines (2.2)–(2.3) and the segments (2.4)–(2.5). Inside the hysteresis loop, the relationship between $u(t)$ and $v(t)$ is

$$u(t) = \begin{cases} m_t v(t) + c_d(t) & \text{for } \dot{v}(t) < 0 \\ m_b v(t) + c_u(t) & \text{for } \dot{v}(t) > 0 \end{cases} \quad (2.6)$$

where $c_d(t) \in (c_l, c_1), c_u(t) \in (c_2, c_b)$ are piecewise constant functions which depend on the point where $\dot{v}(t)$ changes its sign and on the past trajectories of $(v(t), u(t))$, with

$$c_1 = \begin{cases} (m_b - m_t) \frac{c_b + m_l c_l}{m_l - m_b} + c_b & \text{for } m_t < m_b \\ (m_b - m_t) \frac{c_b + m_r c_r}{m_r - m_b} + c_b & \text{for } m_t > m_b \\ c_b & \text{for } m_t = m_b \end{cases} \quad (2.7)$$

$$c_2 = \begin{cases} (m_t - m_b) \frac{c_l + m_r c_r}{m_r - m_t} + c_l, & \text{for } m_t > m_b \\ (m_t - m_b) \frac{c_l + m_l c_l}{m_l - m_t} + c_l, & \text{for } m_t < m_b \\ c_l & \text{for } m_t = m_b. \end{cases} \quad (2.8)$$

The relationship (2.6) holds also for a part of one of the half-lines: when $m_t > m_b$, on the half-line (2.2) with

$v_1 < v(t) < v_3, u(t) = m_t v(t) + c_l$ for $\dot{v}(t) < 0$; when $m_t < m_b$, on the half-line (2.3) with $v_4 < v(t) < v_2, u(t) = m_b v(t) + c_b$ for $\dot{v}(t) > 0$.

The signs of $\dot{u}(t)$ and $\dot{v}(t)$ are not restricted on other parts of these two half-lines: $u(t) = m_t v(t) + c_l, v(t) \geq v_3$; $u(t) = m_b v(t) + c_b, v(t) \leq v_4$; and $u(t) = m_t v(t) + c_l, v_1 < v(t) < v_3$ when $m_t < m_b$ or $u(t) = m_b v(t) + c_b, v_4 < v(t) < v_2$ when $m_t > m_b$. For example, the half-line $u(t) = m_b v(t) + c_b$ is bidirectional when $m_t > m_b$.

The motion of $u(t)$ and $v(t)$ on the half-lines (2.2)–(2.3) and the segments (2.4)–(2.5) and inside the hysteresis loop can be mathematically described as

$$\begin{aligned} \dot{u}(t) = \begin{cases} m_t \dot{v}(t) & \text{if } v(t) \geq v_3, \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) < 0, \\ & u(t) \neq m_l(v(t) - c_l) \text{ and} \\ & u(t) \neq m_b v(t) + c_b, \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) < 0, \\ & u(t) = m_b v(t) + c_b \text{ and } m_t < m_b \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) > 0, \\ & u(t) = m_t v(t) + c_l \text{ and } m_t < m_b \\ m_b \dot{v}(t) & \text{if } v(t) \leq v_4, \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) > 0, \\ & u(t) \neq m_r(v(t) - c_r) \text{ and} \\ & u(t) \neq m_t v(t) + c_l, \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) > 0, \\ & u(t) = m_t v(t) + c_l \text{ and } m_t > m_b \\ & \text{or if } v_4 < v(t) < v_3, \dot{v}(t) < 0, \\ & u(t) = m_b v(t) + c_b \text{ and } m_t > m_b \\ m_r \dot{v}(t) & \text{if } v_4 < v(t) < v_3, \dot{v}(t) > 0 \text{ and} \\ & u(t) = m_r(v(t) - c_r) \\ m_l \dot{v}(t) & \text{if } v_4 < v(t) < v_3, \dot{v}(t) < 0 \text{ and} \\ & u(t) = m_l(v(t) - c_l) \\ 0 & \text{if } \dot{v}(t) = 0. \end{cases} \quad (2.9) \end{aligned}$$

The model of the hysteresis and its two typical minor loops are shown in Fig. 1. This model captures most of the hysteresis phenomena described by more elaborate models in [5], e.g., it is an extended approximation of the ferromagnetic hysteresis model with $m_l = m_r = \infty, m_t = m_b = 0$ [6]. When $m_t = m_b$, the major hysteresis is the out-loop hysteresis, and the inner loops degenerate into line segments. When $m_t = m_b, m_r = m_l, c_l = -c_b > 0, c_r = -c_l > 0$, the hysteresis model (2.2)–(2.8) becomes the approximation model of [6] for the ferromagnetic hysteresis.

The assumptions about the hysteresis characteristic $H(\cdot)$ are

1) the hysteresis output $u(t)$ is not available for measurement;

2) $m_t > 0, m_b > 0, m_r > \max\{m_t, m_b\}, m_l > \max\{m_t, m_b\}, c_l \geq c_b, c_r \geq c_l$, and the values of these hysteresis parameters are unknown.

The assumptions for the linear part $G(s)$ of the plant are

3) $G(s)$ is minimum phase;

4) the relative degree n^* of $G(s)$ is known;

5) the degree n of $P(s)$ is known;

6) the sign of k_p is known.

The control objective is to design a feedback control $v(t)$ so that all closed-loop signals are bounded and the plant output

$y(t)$ tracks the output $y_m(t)$ of the reference model:

$$y_m(t) = W_m(s)[r](t) \quad (2.10)$$

where $W_m(s)$ is a stable rational transfer function of relative degree n^* , and $r(t)$ is a bounded piecewise continuous signal. Without loss of generality, we take $W_m(s) = P_m^{-1}(s)$, where $P_m(s)$ is a monic Hurwitz polynomial of degree n^* .

A linear model reference controller structure could be used to achieve the stated control objective of the hysteresis were absent, that is, $u(t) = v(t)$. In the presence of hysteresis, a linear controller alone cannot achieve the control objective. We propose to use an adaptive hysteresis inverse developed in the next sections to cancel the effect of hysteresis.

III. HYSTERESIS INVERSE

Let $u_d(t)$ be a control signal to be designed. As the inverse of the hysteresis (2.2)–(2.6), we use the hysteresis-like characteristic $HI(\cdot)$:

$$\begin{aligned} v(t) &= HI(u_d(t)) \\ &\triangleq HI(m_t, c_t, m_b, c_b, m_l, c_l; u_d(t)) \end{aligned} \quad (3.1)$$

which is defined by the half-lines (see Fig. 2):

$$v(t) = \frac{1}{m_t}(u_d(t) - c_t), \quad u_d(t) > u_1 = \frac{m_l(m_t c_l + c_t)}{m_l - m_t} \quad (3.2)$$

$$v(t) = \frac{1}{m_b}(u_d(t) - c_b), \quad u_d(t) < u_2 = \frac{m_l(m_b c_l + c_b)}{m_l - m_b} \quad (3.3)$$

and the line segments:

$$v(t) = \frac{1}{m_t} u_d(t) + c_t, \quad u_2 \leq u_d(t) \leq u_3 = \frac{m_l(m_t c_l + c_t)}{m_l - m_t} \quad (3.4)$$

$$v(t) = \frac{1}{m_l} u_d(t) + c_l, \quad \frac{m_l(m_b c_l + c_b)}{m_l - m_b} = u_4 < u_d(t) \leq u_1. \quad (3.5)$$

Along the segments, the time derivatives of $v(t)$, $u_d(t)$ are of constant sign, namely, $\dot{u}_d(t) > 0$, $\dot{v}(t) > 0$ for $v(t) = (1/m_t)u_d(t) + c_t$, and $\dot{u}_d(t) < 0$, $\dot{v}(t) < 0$ for $v(t) = (1/m_l)u_d(t) + c_l$.

Inside the loop formed by the half-lines (3.2)–(3.3) and the segments (3.4)–(3.5), the output of the hysteresis inverse $v(t)$ is defined as

$$v(t) = \begin{cases} \frac{1}{m_t}(u_d(t) - \hat{c}_d(t)) & \text{for } \dot{u}_d(t) < 0 \\ \frac{1}{m_b}(u_d(t) - \hat{c}_u(t)) & \text{for } \dot{u}_d(t) > 0 \end{cases} \quad (3.6)$$

where $\hat{c}_d(t) \in (c_t, c_1)$, $\hat{c}_u(t) \in (c_2, c_b)$ are piecewise constant functions which depend on the point where $\dot{u}_d(t)$ changes its sign and on the past trajectories of $(v(t), u_d(t))$, with c_1 and c_2 defined in (2.7) and (2.8).

The relationship (3.6) holds also for a part of one of the half-lines of the hysteresis inverse $HI(\cdot)$: when $m_t > m_b$, on the common part of the half-line (3.2) and the hysteresis loop, $v(t) = (1/m_t)(u_d(t) - c_t)$ for $\dot{u}_d(t) < 0$; when $m_t < m_b$, on the common part of the half-line (3.3) and the hysteresis loop, $v(t) = (1/m_b)(u_d(t) - c_b)$ for $\dot{u}_d(t) > 0$. $u_d(t)$ and $\dot{v}(t)$

Fig. 2 Hysteresis inverse

are allowed to have both positive and negative signs on other parts of these two half-lines.

The model of the hysteresis inverse and its two typical minor loops are shown in Fig. 2.

The motion of $u_d(t)$ and $v(t)$ on the half-lines (3.2)–(3.3) and the segments (3.4)–(3.5) and inside the loop is mathematically described as

$$\dot{v}(t) = \begin{cases} \frac{1}{m_t} \dot{u}_d(t) & \text{if } u_d(t) \geq u_3, \\ & \text{or if } u_4 < u_d(t) < u_3, u_d(t) < 0, \\ & v(t) \neq \frac{1}{m_t} u_d(t) + c_t \text{ and} \\ & v(t) \neq \frac{1}{m_l} (u_d(t) - c_b), \\ & \text{or if } u_4 < u_d(t) < u_3, u_d(t) < 0, \\ & v(t) = \frac{1}{m_t} (u_d(t) - c_b) \text{ and } m_t < m_b \\ & \text{or if } u_4 < u_d(t) < u_3, u_d(t) > 0, \\ & v(t) = \frac{1}{m_l} (u_d(t) - c_t) \text{ and } m_l < m_b \\ \frac{1}{m_b} \dot{u}_d(t) & \text{if } u_d(t) < u_4, \\ & \text{or if } u_4 < u_d(t) < u_3, u_d(t) > 0, \\ & v(t) \neq \frac{1}{m_t} u_d(t) + c_t \text{ and} \\ & v(t) \neq \frac{1}{m_l} (u_d(t) - c_t), \\ & \text{or if } u_4 < u_d(t) < u_3, \dot{u}_d(t) > 0, \\ & v(t) = \frac{1}{m_t} (u_d(t) - c_t) \text{ and } m_t > m_b \\ & \text{or if } u_4 < u_d(t) < u_3, \dot{u}_d(t) < 0, \\ & v(t) = \frac{1}{m_b} (u_d(t) - c_b) \text{ and } m_t > m_b \\ \frac{1}{m_t} \dot{u}_d(t) & \text{if } u_4 < u_d(t) < u_3, u_d(t) > 0 \text{ and} \\ & v(t) = \frac{1}{m_t} u_d(t) + c_t \\ \frac{1}{m_l} \dot{u}_d(t) & \text{if } u_4 < u_d(t) < u_3, \dot{u}_d(t) < 0 \text{ and} \\ & v(t) = \frac{1}{m_l} u_d(t) + c_l \\ 0 & \text{if } \dot{u}_d(t) = 0. \end{cases} \quad (3.7)$$

The proposed hysteresis inverse has the following properties:

Proposition 3.1 (Hysteresis Inverse): The characteristic $HI(\cdot)$ defined by (3.2)–(3.6) is the right inverse of the characteristic $H(\cdot)$ defined by (2.2)–(2.6) in the sense that

$$H(HI(u_d(t_0))) = u_d(t_0) \Rightarrow H(HI(u_d(t))) = u_d(t), \quad \forall t \geq t_0 \quad (3.8)$$

for any piecewise continuous $u_d(t)$ and any $t_0 \geq 0$.

Fig. 3 Adaptive hysteresis inverse

The mapping (3.2)–(3.6) may fail to define a hysteresis inverse only if $u_d(t)$ is such that $v(t)$ and $u(t)$ never leave the hysteresis loop, that is, t_0 in (3.8) cannot be reached. Such a situation happens when $u_d(t)$ is inside the hysteresis inverse loop and $u(t) \neq u_d(t)$ initially and the motion of $u_d(t)$ is such that $u(t)$ never leaves the hysteresis loop to correct the error between $u_d(t)$ and $u(t)$. However, as $u_d(t)$ is the design signal at our disposal, an initialization of the hysteresis inverse by an appropriate choice of $u_d(t_0)$ can always make $v(t)$ and $u(t)$ leave the inside of the hysteresis loop at t_0 so that $u(t_0) = u_l(t_0)$ and then from Proposition 3.1 $u(t) = u_d(t)$ for any $t > t_0$.

In the adaptive control problem the hysteresis parameters are unknown so the exact hysteresis inverse (3.2)–(3.6) is not implementable. We propose to use an adaptive hysteresis inverse whose parameters are updated according to adaptive laws.

Let $\hat{m}_t, \hat{c}_t, \hat{m}_b, \hat{c}_b, \hat{m}_r, \hat{c}_r, \hat{m}_l, \hat{c}_l$ be the estimates of the unknown hysteresis parameters $m_t, c_t, m_b, c_b, m_r, c_r, m_l, c_l$. An estimated hysteresis inverse $\hat{HI}(\cdot)$ is defined as

$$v(t) = \hat{HI}(u_d(t)) = HI(\hat{m}_t, \hat{c}_t, \hat{m}_l, \hat{c}_b, \hat{m}_r, \hat{c}_r, \hat{m}_l, \hat{c}_l, u_d(t)) \quad (3.9)$$

Fig. 3 shows its characteristic with two typical minor loops, as well as two segments indicating two possible motion of $v(t)$ and $u_l(t)$ at point S . Now, $\hat{c}_u(t) \in (\hat{c}_r(t), \hat{c}_l(t))$, $\hat{c}_d(t) \in (\hat{c}_r(t), \hat{c}_l(t))$ depend on the point $(u_d(t), v(t))$ where $u_d(t)$ changes the sign, and on the past trajectories of the adaptive hysteresis inverse, where $\hat{c}_1(t)$ and $\hat{c}_2(t)$ are calculated from (2.5) and (2.6), but with the estimates of the hysteresis parameters.

For a fixed hysteresis inverse, the estimates $\hat{m}_t, \hat{c}_t, \hat{m}_b, \hat{c}_b, \hat{m}_r, \hat{c}_r, \hat{m}_l, \hat{c}_l$ are constants based on certain *a priori* knowledge of $m_t, c_t, m_b, c_b, m_r, c_r, m_l, c_l$. For an adaptive hysteresis inverse, $\hat{m}_t = \hat{m}_t(t)$, $\hat{c}_t = \hat{c}_t(t)$, $\hat{m}_b = \hat{m}_b(t)$, $\hat{c}_b = \hat{c}_b(t)$, $\hat{m}_r = \hat{m}_r(t)$, $\hat{c}_r = \hat{c}_r(t)$, $\hat{m}_l = \hat{m}_l(t)$, $\hat{c}_l = \hat{c}_l(t)$ are time-varying signals generated by an adaptive update law.

To ensure that (3.2)–(3.6) are implementable we require 7) positive constants $m_{t1}, m_{t2}, m_{b1}, m_{b2}, m_{r1}, m_{r2}, m_{l1}, m_{l2}$ and constants $c_{b1}, c_{b2}, c_{t1}, c_{t2}, c_{r1}, c_{r2}$ are known such that $m_{t1} \leq m_{t2}, m_{b1} \leq m_{b2}, m_{r1} \leq m_{r2}, m_{l1} \leq m_{l2}$, $\max\{m_{t2}, m_{l2}\} < m_{t0} \leq m_{t1}$ and $c_{t1} < c_{t2} < c_{r1} \leq c_{r2} < c_{b1} \leq c_{b2} < c_{l1} \leq c_{l2} < c_{d1} \leq c_{d2}$.

Even when not stated explicitly, we will use projection to ensure that the estimated hysteresis parameters satisfy the above inequalities.

A numerical scheme for implementing the estimated hysteresis inverse (3.8) is developed next.

At time $t = t_k$ we have the knowledge of $\hat{m}_t(t), \hat{c}_t(t), \hat{m}_b(t), \hat{c}_b(t), \hat{m}_r(t), \hat{c}_r(t), \hat{m}_l(t), \hat{c}_l(t), u_d(t), v(t)$ for $t = t_{k-1}$ and the knowledge of $u_d(t)$ for $t = t_k$. With the help of Fig. 3 where $S = (u_d(t_{k-1}), v(t_{k-1}))$ we introduce the quantities $u_{ll} \leq u_{dl} \leq u_{dl} \leq u_{dr}$

$$u_{dl} = \frac{\hat{m}_t(\hat{m}_l \hat{c}_l + \hat{c}_t)}{\hat{m}_l - \hat{m}_t} \quad (3.10)$$

$$\hat{c}_l = u_d(t_{k-1}) - \hat{m}_l v(t_{k-1}) \quad \hat{c}_u = u_l(t_{k-1}) - \hat{m}_l v(t_{k-1}) \quad (3.11)$$

$$\begin{aligned} & \frac{m_t(\hat{m}_l \hat{c}_l + \hat{c}_t)}{\hat{m}_l - \hat{m}_t} \quad \text{if } u_d(t_{k-1}) > u_l(t_k) \\ & \frac{m_t(\hat{m}_l \hat{c}_u + \hat{c}_t)}{\hat{m}_l - \hat{m}_t} \quad \text{if } u_d(t_{k-1}) < u_d(t_k) \end{aligned}$$

$$u_{dl} = \begin{cases} \frac{m_t(\hat{m}_l \hat{c}_l + \hat{c}_t)}{\hat{m}_l - \hat{m}_t} & \text{if } u_d(t_{k-1}) > u_d(t_k) \\ \frac{m_t(\hat{m}_l \hat{c}_u + \hat{c}_t)}{\hat{m}_l - \hat{m}_t} & \text{if } u_d(t_{k-1}) < u_d(t_k) \end{cases} \quad (3.12)$$

Then $v(t_k)$ is determined as

$$\begin{aligned} & v(t_{k-1}) \quad \text{if } u_d(t_k) = u_d(t_{k-1}) \\ & \frac{1}{m_t}(u_d(t_k) - \hat{c}_t) \quad \text{if } u_d(t_k) \geq u_{ll} \\ & \frac{m_t}{m_l}(u_d(t_k) - \hat{c}_l) \quad \text{if } u_d(t_k) < u_{ll} \\ & \frac{1}{m_t}u_d(t_k) + \hat{c}_r \quad \text{if } u_{ll} \geq u_d(t_k) \geq u_{dr} \\ & \frac{1}{m_t}u_d(t_k) + \hat{c}_l \quad \text{if } u_{dl} < u_l(t_k) \leq u_{ll} \\ & \frac{m_t}{m_l}(u_d(t_k) - \hat{c}_d) \quad \text{if } u_{dl} < u_l(t_k) < u_{dl} \text{ and } \\ & \quad \quad \quad u_d(t_{k-1}) > u_d(t_k) \\ & \frac{1}{m_t}(u_d(t_k) - \hat{c}_u) \quad \text{if } u_{dl} < u_d(t_k) < u_{dr} \text{ and } \\ & \quad \quad \quad u_l(t_{k-1}) < u_l(t_k) \end{aligned} \quad (3.13)$$

The implementation is dynamic because it uses not only $u_d(t_k)$ but also $u_d(t_{k-1})$ and $v(t_{k-1})$. It is important that this implementation does not need the knowledge of $u_d(t)$.

In our adaptive control schemes, the adaptive hysteresis inverse will be used in cascade with the plant with a hysteresis, and the signal $u_d(t)$ will be generated from a linear controller structure.

IV. PARAMETERIZATION

In the absence of the hysteresis, a linear controller generating $u(t)$ can be used to achieve the asymptotic tracking of $y_m(t)$ by $y(t)$. When the hysteresis is present, $v(t)$ is the accessible control which, by our design, is the output of the adaptive hysteresis inverse with input $u_d(t)$. A parameterization of the control error $u(t) - u_d(t)$ will help us to develop suitable

controller structures for generating $u_d(t)$ and adaptive laws for updating the estimates $\widehat{m}_t(t)$, $\widehat{c}_t(t)$, $\widehat{m}_b(t)$, $\widehat{c}_b(t)$, $\widehat{m}_r(t)$, $\widehat{c}_r(t)$, $\widehat{m}_l(t)$, $\widehat{c}_l(t)$ to implement an adaptive hysteresis inverse

To proceed, we define the following indicator functions

$$\chi_t(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_t v(t) + c_t\} \\ 0 & \text{otherwise} \end{cases} \quad (4.1)$$

$$\chi_b(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_b v(t) + c_b\} \\ 0 & \text{otherwise} \end{cases} \quad (4.2)$$

$$\chi_r(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_r(v(t) - c_r)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.3)$$

$$\chi_l(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_l(v(t) - c_l)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.4)$$

$$\chi_d(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_t v(t) + c_d(t)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.5)$$

$$\chi_u(t) = \begin{cases} 1 & \text{if } (v(t), u(t)) \in \{(v(t), u(t)) \mid u(t) \\ & = m_b v(t) + c_u(t)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.6)$$

$$\widehat{\chi}_t(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_t(t)}(u_d(t) - \widehat{c}_t(t))\} \\ 0 & \text{otherwise} \end{cases} \quad (4.7)$$

$$\widehat{\chi}_b(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_b(t)}(u_d(t) - \widehat{c}_b(t))\} \\ 0 & \text{otherwise} \end{cases} \quad (4.8)$$

$$\widehat{\chi}_r(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_r(t)}(u_d(t) + \widehat{m}_r(t)\widehat{c}_r(t))\} \\ 0 & \text{otherwise} \end{cases} \quad (4.9)$$

$$\widehat{\chi}_l(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_l(t)}(u_d(t) + \widehat{m}_l(t)\widehat{c}_l(t))\} \\ 0 & \text{otherwise} \end{cases} \quad (4.10)$$

$$\widehat{\chi}_d(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_t(t)}(u_d(t) - \widehat{c}_d(t)), \\ & \widehat{c}_b(t) < \widehat{c}_d(t) < \widehat{c}_t(t)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.11)$$

$$\widehat{\chi}_u(t) = \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_b(t)}(u_d(t) - \widehat{c}_u(t)), \\ & \widehat{c}_b(t) < \widehat{c}_u(t) < \widehat{c}_t(t)\} \\ 0 & \text{otherwise} \end{cases} \quad (4.12)$$

In defining these indicator functions, we do not repeatedly count any intersection of the half-lines and the segments, e.g., at the top right corner of $\widehat{HI}(\cdot)$ we define $\widehat{\chi}_l(t) = 1$ and $\widehat{\chi}_r(t) = 0$, and when it goes down passing the $\widehat{c}_b(t)$ point, we define $\widehat{\chi}_b(t) = 1$ and $\widehat{\chi}_d(t) = 0$. With this constraint, only one of these functions is nonzero at any given time t .

$$\widehat{\chi}_t(t) + \widehat{\chi}_b(t) + \widehat{\chi}_r(t) + \widehat{\chi}_l(t) + \widehat{\chi}_d(t) + \widehat{\chi}_u(t) = 1 \quad (4.13)$$

$$\widehat{\chi}_k^2(t) = \widehat{\chi}_k(t) \quad \widehat{\chi}_i(t)\widehat{\chi}_j(t) = 0 \quad i \neq j, i, j \in \{t, b, r, l, d, u\} \quad (4.14)$$

All the equalities in (4.1)–(4.12) are understood in the sense of (2.2)–(2.5) and the adaptive version of (3.2)–(3.5), that is, inequalities apply whenever they are feasible. We note that the condition 7) is necessary to ensure a well defined adaptive hysteresis inverse with the properties (4.13) and (4.14).

Using (2.2)–(2.6), (4.1)–(4.6), (4.13), we express $u(t)$ as

$$\begin{aligned} u(t) &= \chi_t(t)(m_t v(t) + c_t) + \chi_b(t)(m_b v(t) + c_b) \\ &\quad + \chi_r(t)(m_r(v(t) - c_r)) + \chi_l(t)(m_l(v(t) - c_l)) \\ &\quad + \chi_d(t)(m_t v(t) + c_d(t)) + \chi_u(t)(m_b v(t) + c_u(t)) \\ &= u_d(t) + \widehat{\chi}_t(t)(m_t v(t) + c_t - \widehat{\chi}_t(t)u_d(t)) \\ &\quad + \widehat{\chi}_b(t)(m_b v(t) + c_b - \widehat{\chi}_b(t)u_d(t)) \\ &\quad + \widehat{\chi}_r(t)(m_r(v(t) - c_r) - \widehat{\chi}_r(t)u_d(t)) \\ &\quad + \widehat{\chi}_l(t)(m_l(v(t) - c_l) - \widehat{\chi}_l(t)u_d(t)) \\ &\quad + \widehat{\chi}_d(t)(m_t v(t) + c_d(t) - \widehat{\chi}_d(t)u_d(t)) \\ &\quad + \widehat{\chi}_u(t)(m_b v(t) + c_u(t) - \widehat{\chi}_u(t)u_d(t)) + d_1(t) \end{aligned} \quad (4.15)$$

where

$$\begin{aligned} d_1(t) &= (\chi_t(t) - \widehat{\chi}_t(t))(m_t v(t) + c_t) \\ &\quad + (\chi_b(t) - \widehat{\chi}_b(t))(m_b v(t) + c_b) \\ &\quad + (\chi_r(t) - \widehat{\chi}_r(t))(m_r(v(t) - c_r)) \\ &\quad + (\chi_l(t) - \widehat{\chi}_l(t))(m_l(v(t) - c_l)) \\ &\quad + (\chi_d(t) - \widehat{\chi}_d(t))(m_t v(t) + c_d(t)) \\ &\quad + (\chi_u(t) - \widehat{\chi}_u(t))(m_b v(t) + c_u(t)) \end{aligned} \quad (4.16)$$

Since a projection based on the condition 7) ensures that all estimated hysteresis parameters are bounded, the adaptive hysteresis inverse loop is bounded. If $v(t)$ is large such that $(v(t), u_d(t))$ is outside the hysteresis inverse loop and $(u(t), v(t))$ is outside the hysteresis loop, then all $\chi(t)$'s and $\widehat{\chi}(t)$'s are zero except for $\chi_r(t)$ (or $\chi_l(t)$) and $\widehat{\chi}_r(t)$ (or $\widehat{\chi}_l(t)$), so that $d_1(t) = 0$ from (4.16). This implies that $d_1(t)$ is bounded whenever the estimated hysteresis parameters satisfy 7), which is crucial for our designs.

Using (3.2)–(3.6), (4.7)–(4.12), we express $v(t)$ as

$$\begin{aligned} v(t) = & \hat{\chi}_t(t) \left(\frac{1}{\widehat{m}_t(t)} (u_d(t) - \widehat{c}_t(t)) \right) \\ & + \widehat{\chi}_b(t) \left(\frac{1}{\widehat{m}_b(t)} (u_d(t) - \widehat{c}_b(t)) \right) \\ & + \widehat{\chi}_r(t) \frac{1}{\widehat{m}_r(t)} (u_d(t) + \widehat{m}_r(t) \widehat{c}_r(t)) \\ & + \widehat{\chi}_l(t) \left(\frac{1}{\widehat{m}_l(t)} (u_d(t) + \widehat{m}_l(t) \widehat{c}_l(t)) \right) \\ & + \widehat{\chi}_d(t) \left(\frac{1}{\widehat{m}_d(t)} (u_d(t) - \widehat{c}_d(t)) \right) \\ & + \widehat{\chi}_u(t) \left(\frac{1}{\widehat{m}_u(t)} (u_d(t) - \widehat{c}_u(t)) \right) \end{aligned} \quad (4.17)$$

In view of (4.14), from (4.17), we obtain

$$\widehat{\chi}_t(t) u_d(t) = \widehat{\chi}_t(t) (\widehat{m}_t(t) v(t) + \widehat{c}_t(t)) \quad (4.18)$$

$$\widehat{\chi}_b(t) u_d(t) = \widehat{\chi}_b(t) (\widehat{m}_b(t) v(t) + \widehat{c}_b(t)) \quad (4.19)$$

$$\widehat{\chi}_r(t) u_d(t) = \widehat{\chi}_r(t) (\widehat{m}_r(t) v(t) - \widehat{m}_r(t) \widehat{c}_r(t)) \quad (4.20)$$

$$\widehat{\chi}_l(t) u_d(t) = \widehat{\chi}_l(t) (\widehat{m}_l(t) v(t) - \widehat{m}_l(t) \widehat{c}_l(t)) \quad (4.21)$$

$$\widehat{\chi}_d(t) u_d(t) = \widehat{\chi}_d(t) (\widehat{m}_d(t) v(t) + \widehat{c}_d(t)) \quad (4.22)$$

$$\widehat{\chi}_u(t) u_d(t) = \widehat{\chi}_u(t) (\widehat{m}_u(t) v(t) + \widehat{c}_u(t)). \quad (4.23)$$

Introducing $\widehat{m}_r c_r(t) = \widehat{m}_r(t) \widehat{c}_r(t)$, $\widehat{m}_l c_l(t) = \widehat{m}_l(t) \widehat{c}_l(t)$, and

$$\theta_h(t) = (\widehat{m}_t(t), \widehat{c}_t(t), \widehat{m}_b(t), \widehat{c}_b(t), \widehat{m}_r(t), \widehat{m}_r c_r(t), \widehat{m}_l(t), \widehat{m}_l c_l(t))^T \quad (4.24)$$

$$\begin{aligned} \theta_h^* &= (m_t, c_t, m_b, c_b, m_r, m_r c_r, m_l, m_l c_l)^T, \\ \phi_h(t) &= \theta_h(t) - \theta_h^* \end{aligned} \quad (4.25)$$

$$\begin{aligned} \omega_h(t) = & (-\widehat{\chi}_t(t) + \widehat{\chi}_d(t)) v(t), -\widehat{\chi}_t(t), \\ & -(\widehat{\chi}_b(t) + \widehat{\chi}_u(t)) v(t), -\widehat{\chi}_b(t), -\widehat{\chi}_r(t) v(t), \\ & \widehat{\chi}_r(t), -\widehat{\chi}_l(t) v(t), \widehat{\chi}_l(t))^T \end{aligned} \quad (4.26)$$

from (4.15), (4.18)–(4.26), we have

$$u(t) = u_d(t) + \phi_h^T(t) \omega_h(t) + d_h(t) \quad (4.27)$$

where

$$\begin{aligned} d_h(t) = & d_1(t) + \widehat{\chi}_d(t) (c_d(t) - \widehat{c}_d(t)) \\ & + \widehat{\chi}_u(t) (c_u(t) - \widehat{c}_u(t)). \end{aligned} \quad (4.28)$$

Thus, we have expressed the control error $u(t) - u_d(t)$ as a sum of a parameterizable part and an unknown disturbance. The disturbance $d_h(t)$ has the following properties.

Proposition 4.1: The unparameterizable part $d_h(t)$ of the control error $u(t) - u_d(t)$ is bounded for any $t \geq 0$, and reduces to zero when the hysteresis parameter error $\phi_h(t) \rightarrow 0$.

The signals $\chi_t(t)$, $\chi_b(t)$, $\chi_r(t)$, $\chi_l(t)$, $\chi_d(t)$, and $\chi_u(t)$, which describe the motion of the hysteresis output $u(t) = H(v(t))$ [see the first expression for $u(t)$ in (4.15)], are not available for measurement. We choose to parameterize the control error $u(t) - u_d(t)$ in terms of the measured signals $\widehat{\chi}_t(t)$, $\widehat{\chi}_b(t)$, $\widehat{\chi}_r(t)$, $\widehat{\chi}_l(t)$, $\widehat{\chi}_d(t)$, and $\widehat{\chi}_u(t)$ [see the definition (4.26) for $\omega_h(t)$] which describe the motion of the adaptive hysteresis inverse output $v(t) = \widehat{H}(u_d(t))$ [see (4.17)].

The parameterization (4.27) can be made simpler for some special hysteresis characteristics.

Hysteresis with Equal Slopes $m_t = m_b$: The knowledge that $m_t = m_b$ can be used to choose $\widehat{m}_b(t) = \widehat{m}_t(t)$, $\widehat{c}_u(t) = \widehat{c}_d(t)$. In this case, we define

$$\theta_h^* = (m_t, c_t, c_b, m_r, m_r c_r, m_l, m_l c_l)^T \quad (4.29)$$

$$\begin{aligned} \theta_h(t) = & (\widehat{m}_t(t), \widehat{c}_t(t), \widehat{c}_b(t), \widehat{m}_r(t), \\ & \widehat{m}_r c_r(t), \widehat{m}_l(t), \widehat{m}_l c_l(t))^T \end{aligned} \quad (4.30)$$

$$\begin{aligned} \omega_h(t) = & (-\widehat{\chi}_t(t) + \widehat{\chi}_d(t) + \widehat{\chi}_b(t)) v(t), -\widehat{\chi}_t(t), -\widehat{\chi}_b(t), \\ & -\widehat{\chi}_r(t) v(t), \widehat{\chi}_r(t), -\widehat{\chi}_l(t) v(t), \widehat{\chi}_l(t))^T \end{aligned} \quad (4.31)$$

where

$$\begin{aligned} \widehat{\chi}_c(t) = & \begin{cases} 1 & \text{if } (u_d(t), v(t)) \in \{(u_d(t), v(t)) \mid v(t) \\ & = \frac{1}{\widehat{m}_r(t)} (u_d(t) - \widehat{c}_d(t)), \\ & \widehat{c}_b(t) < \widehat{c}_d(t) < \widehat{c}_t(t)\} \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \quad (4.32)$$

Symmetric Hysteresis: When the hysteresis is symmetric, $m_t = m_b$, $m_r = m_l$, $c_t = -c_b > 0$, $c_r = -c_l > 0$, we define

$$\theta_h^* = (m_t, c_t, m_r, m_r c_r)^T \quad (4.33)$$

$$\theta_h(t) = (\widehat{m}_t(t), \widehat{c}_t(t), \widehat{m}_r(t), \widehat{m}_r c_r(t))^T \quad (4.34)$$

$$\begin{aligned} \omega_h(t) = & (-\widehat{\chi}_t(t) + \widehat{\chi}_d(t) + \widehat{\chi}_b(t)) v(t), -(\widehat{\chi}_t(t) - \widehat{\chi}_b(t)), \\ & -(\widehat{\chi}_r(t) + \widehat{\chi}_l(t)) v(t), \widehat{\chi}_r(t) - \widehat{\chi}_l(t))^T \end{aligned} \quad (4.35)$$

where $\widehat{\chi}_c(t)$ is also defined by (4.32), but with $\widehat{c}_b(t) = -\widehat{c}_t(t)$. In both cases, (4.27) and Proposition 4.1 hold.

V. ADAPTIVE HYSTERESIS INVERSE FOR $G(s)$ KNOWN

In this section, we design an adaptive control scheme for the plant (2.1) with a known linear part.

We use the following linear controller to generate $u_d(t)$:

$$u_d(t) = \theta_1^{*T} \omega_1(t) + \theta_2^{*T} \omega_2(t) + \theta_{20}^* y(t) + \theta_3^* r(t). \quad (5.1)$$

There are two designs for θ_1^* , θ_2^* , θ_{20}^* , and θ_3^* and $\omega_1(t)$ and $\omega_2(t)$.

I) For $a(s) = (1, s, \dots, s^{n-2})^T$, $\Lambda(s)$ being any monic Hurwitz polynomial of degree $n - 1$

$$\omega_1(t) = \frac{a(s)}{\Lambda(s)} [u_d](t), \quad \omega_2(t) = \frac{a(s)}{\Lambda(s)} [y](t) \quad (5.2)$$

$\theta_3^* = k_p^{-1}$, and $\theta_1^*, \theta_2^* \in R^{n-1}$, $\theta_{20}^* \in R$ satisfying the following Diophantine equation

$$\theta_1^{*T} a(s)P(s) + (\theta_2^{*T} a(s) + \theta_{20}^* \Lambda(s))k_p Z(s) = \Lambda(s)(P(s) - k_p \theta_3^* Z(s)P_m(s)). \quad (5.3)$$

II) For $a(s) = (1, s, \dots, s^{n-1})^T$, $\Lambda(s)$ being any monic Hurwitz polynomial of degree n , $\omega_1(t)$ and $\omega_2(t)$ still have the form (5.2), and $\theta_3^* = k_p^{-1}$, $\theta_1^*, \theta_2^* \in R^n$, $\theta_{20}^* = 0$ satisfying (5.3).

Then the signal $u_d(t)$ is applied to the adaptive hysteresis inverse (3.8) to generate $v(t)$ as the control input to the plant (2.1) which has a hysteresis at input.

To implement an adaptive hysteresis inverse, we can use the adaptive version of the continuous-time hysteresis inverse (3.7) or the discrete-time version (3.13). For the controller II, both the continuous-time and discrete-time adaptive hysteresis inverses can be implemented because, from (5.1) with $\theta_{20}^* = 0$, the derivative of $u_d(t)$, $\dot{u}_d(t)$, which is needed for implementing (3.7), is also available (assuming that $\dot{v}(t)$ is bounded). For the controller II, one can only use the discrete-time inverse (3.13) since, in this case, $u_d(t)$ depends on $\dot{y}(t)$, which is not measured. For the discrete-time inverse, there is no need to assume the boundedness of $\dot{v}(t)$.

The parameter matching equation (5.3) can be used to derive

$$u(t) = \theta_1^{*T} \frac{a(s)}{\Lambda(s)} [v](t) + \theta_2^{*T} \frac{a(s)}{\Lambda(s)} [y](t) + \theta_{20}^* y(t) + \theta_3^* W_m^{-1}(s) [y](t). \quad (5.4)$$

Using (2.9), (4.27), (5.1), (5.4), introducing $v(t) = y(t) - y_m(t)$, $F(s) = \theta_1^{*-1} W_m(s)(1 - \theta_3^{*T} (a(s)/\Lambda(s)))$, we obtain the tracking error equation

$$v(t) = F(s)[\phi_h^T \omega_h](t) + F(s)[d_h](t). \quad (5.5)$$

We note that $F(s)$ is a stable, strictly proper, and known transfer function.

Introducing

$$\xi_h(t) = \theta_h^T(t) \zeta_h(t) - F(s)[\theta_h^T \omega_h](t), \quad \zeta_h(t) = F(s)[\omega_h](t) \quad (5.6)$$

$$e_h(t) = v(t) + \xi_h(t) \quad (5.7)$$

we use the following adaptive law to update $\theta_h(t)$

$$\dot{\theta}_h(t) = \frac{\Gamma_h \zeta_h(t) e_h(t)}{1 + \zeta_h^T(t) \zeta_h(t) + \xi_h^2(t)} - \Gamma_h \sigma(\theta_h, M_h, \sigma_0) \theta_h(t) \quad (5.8)$$

where $\Gamma_h = \Gamma_h^T > 0$, and σ is a "switching-sigma" signal [10] using *a priori* knowledge of an upper bound M_h on the Euclidean norm $\|\theta_h^*\|$ of θ_h^* and a design parameter $\sigma_0 > 0$:

$$\sigma(\theta_h, M_h, \sigma_0) = \begin{cases} \text{if } \|\theta_h(t)\| < M_h \\ \left(\frac{\|\theta_h(t)\|}{M_h} - 1 \right) \\ \text{if } M_h \leq \|\theta_h(t)\| < 2M_h \\ \sigma_0 \\ \text{if } \|\theta_h(t)\| \geq 2M_h. \end{cases} \quad (5.9)$$

This adaptive law has the following properties

Lemma 5.1: The adaptive law (5.8) guarantees

- 1) $\theta_h(t)$, $\dot{\theta}_h(t)$, $(\epsilon_h^2(t)/1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t)) \in L_\infty$;
- 2) for some constants $k_1 > 0$, $k_2 > 0$, and all $t_2 > t_1 \geq 0$,

$$\int_{t_1}^{t_2} \|\dot{\theta}_h(t)\|^2 dt \leq k_1 + \int_{t_1}^{t_2} \frac{k_2}{1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t)} dt \quad (5.10)$$

$$\int_{t_1}^{t_2} \frac{\epsilon_h^2(t)}{1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t)} dt \leq k_1 + \int_{t_1}^{t_2} \frac{k_2}{1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t)} dt. \quad (5.11)$$

Proof With the substitution of (5.5) and (5.6) in (5.7), the estimation error $e_h(t)$ becomes

$$e_h(t) = \phi_h^T(t) \zeta_h(t) + d(t), \quad d(t) = F(s)[d_h](t). \quad (5.12)$$

Using (5.8) and (5.12), we express the time derivative of the positive-definite function $V_h(\phi_h) = \frac{1}{2} \phi_h^T \Gamma_h^{-1} \phi_h$ along the trajectories of (5.8), as

$$\begin{aligned} \dot{V}_h \leq & -\frac{\epsilon_h^2(t)}{2(1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t))} \\ & + \frac{d^2(t)}{2(1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t))} \\ & \sigma(\theta_h, M_h, \sigma_0) \phi_h^T(t) \theta_h(t). \end{aligned} \quad (5.13)$$

Since $d(t)$ is bounded, it follows from (5.13) that $\theta_h(t) \in L_\infty$, and $(\epsilon_h(t)/\sqrt{1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t)}), \theta_h(t) \in L_\infty$.

The definition of the signal $\sigma(t) = \sigma(\theta_h, M_h, \sigma_0)$ implies

$$\begin{aligned} \sigma^2(t) \|\theta_h(t)\|^2 \|\Gamma_h\|^2 & \leq k_0 \sigma(t) \|\theta_h(t)\| (\|\theta_h(t)\| - \|\theta_h^*\|) \\ & \leq k_0 \sigma(t) \phi_h^T(t) \theta_h(t) \end{aligned} \quad (5.14)$$

for some constant $k_0 > 0$. Then, using (5.13) and

$$\begin{aligned} \|\dot{\theta}_h(t)\|^2 & \leq 2 \frac{\|\Gamma_h\|^2 \|\zeta_h(t)\|^2 \epsilon_h^2(t)}{(1 + \zeta_h^T(t)\zeta_h(t) + \xi_h^2(t))^2} \\ & \quad + \|\Gamma_h\|^2 \sigma^2(\theta_h, M_h, \sigma_0) \|\theta_h(t)\|^2 \end{aligned} \quad (5.15)$$

we have part (2) of the lemma. \square

Lemma 5.1 only shows the boundedness of $\theta_h(t)$ and the L^2 properties (5.10)–(5.11) of the adaptive law (5.8). While the signal boundedness of the adaptive control system with a general hysteresis is still under investigation, we present the stability results for some special cases.

Theorem 5.1: When the hysteresis $H(\cdot)$ in (2.1) has two equal slopes, $m_t = m_b$ and (4.30), (4.31) are used for adaptation and implementation of the adaptive hysteresis inverse, all closed-loop signals are bounded.

The proof for Theorem 5.1 is given in Appendix A.

This boundedness result holds for the symmetric hysteresis case where (4.34), (4.35) are used for adaptation and implementation of the adaptive hysteresis inverse with a reduced system order.

VI. ADAPTIVE HYSTERESIS INVERSE FOR $G(s)$ UNKNOWN

The problem of adaptively controlling the plant (2.1) with an unknown hysteresis $H(\cdot)$ as well as an unknown linear part $G(s)$ challenges us with the task of estimating two sets of parameters: one from the hysteresis inverse, and the other from a linear controller structure. In this case, the linear controller structure (5.1) results in a nonlinear parameterization which is not suitable for parameter estimation.

Facing this difficulty, we need to modify the linear structure (5.1). Using (4.13), (4.18)–(4.23), (4.25), we express the hysteresis inverse (3.2)–(3.6) as

$$u_d(t) = -\theta_h^{*T} \omega_h(t) + \widehat{\chi}_d(t) \widehat{c}_d(t) + \widehat{\chi}_u(t) \widehat{c}_u(t). \quad (6.1)$$

Hence, the term $\theta_1^{*T} \omega_1(t)$ in (5.1) becomes

$$\begin{aligned} \theta_1^{*T} \omega_1(t) = & -\theta_1^{*T} \frac{a(s)}{\Lambda(s)} [\theta_h^{*T} \omega_h(t) \\ & + \theta_1^{*T} \frac{a(s)}{\Lambda(s)} [\widehat{\chi}_d \widehat{c}_d + \widehat{\chi}_u \widehat{c}_u](t)]. \end{aligned} \quad (6.2)$$

Introducing new regressors and parameters as

$$\omega_4(t) = \frac{A(s)}{\Lambda(s)} [\omega_h(t)], \quad \theta_4^* = -\theta_1^* \otimes \theta_h^* \quad (6.3)$$

$$\omega_5(t) = \frac{a(s)}{\Lambda(s)} [\widehat{\chi}_d \widehat{c}_d + \widehat{\chi}_u \widehat{c}_u](t), \quad \theta_5^* = \theta_1^* \quad (6.4)$$

where \otimes denotes the Kronecker product, $A(s) = (I_p, sI_p, \dots, s^{n-2}I_p)^T$, I_p is the $p \times p$ identity matrix with p being the dimension of θ_h^* , from (6.2), we obtain

$$\theta_1^{*T} \omega_1(t) = \theta_4^{*T} \omega_4(t) + \theta_5^{*T} \omega_5(t). \quad (6.5)$$

We should note that the dimension of θ_4^* and its estimate $\theta_4(t)$ is $p(n-1)$ (pn) for the controller I (controller II) of Section V. It is this enlarged parameterization that enables us to obtain a linear parameterization of the error system, which is suitable for controller adaptation. Physically, the hysteresis has eight different regions, so that the feedforward part $\theta_1^{*T}(t)\omega_1(t)$ has eight different forms. A natural parameterization turns out to be the one given in (6.5), with the parameter vector θ_4^* .

This new parameterization brings us to a new controller structure for adaptive control

$$\begin{aligned} u_d(t) = & \theta_2^T(t) \omega_2(t) + \theta_{20}(t) y(t) + \theta_3(t) r(t) \\ & + \theta_4^T(t) \omega_4(t) + \theta_5^T(t) \omega_5(t). \end{aligned} \quad (6.6)$$

$\theta_{20}(t) = 0$ in (6.6) if $a(s)$, $\Lambda(s)$ are defined by the controller II of Section V.

In view of (4.27), (5.4), (6.1)–(6.6), the tracking error equation now has the form

$$e(t) = \rho^* W_m(s) [\phi^T \omega](t) + d(t) \quad (6.7)$$

where $\rho^* = \theta_3^{*-1}$, $\phi(t) = \theta(t) + \theta^*$, $d(t) = \rho^* W_m(s) (1 - \theta_1^{*T}(a(s)/\Lambda(s))) [d_h](t)$, and

$$\theta(t) = (\theta_2^T(t), \theta_{20}(t), \theta_3(t), \theta_4^T(t), \theta_5^T(t), \theta_h^T(t))^T \quad (6.8)$$

$$\theta^* = (\theta_2^{*T}, \theta_{20}^*, \theta_3^*, \theta_4^{*T}, \theta_5^{*T}, \theta_h^{*T})^T \quad (6.9)$$

$$\omega(t) = (\omega_2^T(t), y(t), r(t), \omega_4^T(t), \omega_5^T(t), \omega_h^T(t))^T$$

The expression of the tracking error allows us to use adaptive linear control theory [11], [12] to develop an adaptive law for updating parameters of the adaptive hysteresis inverse and adaptive linear controller structure which make up our adaptive controller for the nonlinear plant (2.1).

We note that θ_{20}^* , θ_h^* , $\theta_{20}(t)$, $\theta_h(t)$, $\omega_h(t)$ are defined in different ways when the different designs of Sections IV and V are used; see (4.24)–(4.35), and (5.1).

Starting with tracking error equation (6.7), we can design adaptive schemes to update the parameter vector $\theta(t)$. Next, we present two such schemes.

Adaptive Scheme I: Letting $\rho(t)$ be the estimate of ρ^* and $L(s)$ be any Hurwitz polynomial of degree $n^* - 1$ such that $W_m(s)L(s)$ is strictly positive real, and introducing

$$\begin{aligned} \zeta(t) = & L^{-1}(s) [\omega](t), \\ \xi(t) = & \theta^T(t) \zeta(t) - L^{-1}(s) [\theta^T \omega](t) \end{aligned} \quad (6.11)$$

we define the estimation error $\epsilon(t)$ from

$$\epsilon(t) = e(t) + W_m(s)L(s) [\rho \xi - \alpha \epsilon (\zeta^T \zeta + \xi^2)](t) \quad (6.12)$$

where $\alpha > 0$, and update $\theta(t)$ and $\rho(t)$ from

$$\dot{\theta}(t) = -\text{sign}[k_p] \Gamma^T \zeta(t) \epsilon(t) - \Gamma \sigma(\theta, M_\theta, \sigma_0) \theta(t) \quad (6.13)$$

$$\dot{\rho}(t) = -\gamma \xi(t) \epsilon(t) - \gamma \sigma(\rho, M_\rho, \sigma_0) \rho(t) \quad (6.14)$$

where $\Gamma = \Gamma^T > 0$, $\gamma > 0$, and σ is the switching signal defined by (5.9).

We then have the following properties of this adaptive law.

Lemma 6.1. The adaptive law (6.13)–(6.14) guarantees

- 1) $\theta(t)$, $\rho(t)$, $\epsilon(t) \in L_\infty$;
- 2) for some constants $k_3 > 0$, $k_4 > 0$, and all $t_2 > t_1 \geq 0$,

$$\int_{t_1}^{t_2} \|\dot{\theta}(t)\|^2 dt \leq k_3 + \int_{t_1}^{t_2} \frac{k_4}{1 + \zeta^T(t) \zeta(t) + \xi^2(t)} dt \quad (6.15)$$

$$\begin{aligned} & \int_{t_1}^{t_2} \epsilon^2(t) (1 + \zeta^T(t) \zeta(t) + \xi^2(t)) dt \\ & \leq k_3 + \int_{t_1}^{t_2} \frac{k_4}{1 + \zeta^T(t) \zeta(t) + \xi^2(t)} dt \end{aligned} \quad (6.16)$$

Proof. We rewrite (6.7) as

$$\begin{aligned} e(t) = & W_m(s)L(s) [\rho^* (L^{-1}(s) [\theta^T \omega] - \theta^{*T} L^{-1}(s) [\omega] \\ & + \rho^* (1 - \theta_1^{*T} \frac{a(s)}{\Lambda(s)}) L^{-1}(s) [d_h])](t). \end{aligned} \quad (6.17)$$

Substituting (6.12) in (6.17), we have

$$\epsilon(t) = W_m(s)L(s) [\rho^* \phi^T \zeta + \psi \xi - \alpha \epsilon (\zeta^T \zeta + \xi^2) + \tilde{d}](t) \quad (6.18)$$

where $\tilde{d}(t) = \rho^* (1 - \theta_1^{*T}(a(s)/\Lambda(s))) L^{-1}(s) [d_h](t)$, $\psi(t) = \rho(t) - \rho^*$.

Let $W_m(s)L(s)$ have a controllable realization (A_m, B_m, C_m) and $e_r(t)$ be its state variable. With this notation, from (6.18), we obtain

$$\dot{e}_r(t) = A_m e_r(t) + B_m \nu(t), \quad \epsilon(t) = C_m e_r(t) \quad (6.19)$$

where

$$\nu(t) = \rho^* \phi^T(t) \zeta(t) + \psi(t) \xi(t) - \alpha(t)(\zeta^T(t) \zeta(t) + \xi^2(t)) + \bar{d}(t). \quad (6.20)$$

Strict positive realness of $W_m(s)J(s)$ implies that there exist constant matrices $Q = Q^T > 0$, $P = P^T > 0$, vector q , and scalar $\delta > 0$ such that $A_m^T P + P A_m = -q q^T + \delta Q$, $P B_m = C_m^T$. Hence, the time derivative of $V(\rho, \phi, \psi) = e_c^T P e_c + |\rho^*| \phi^T \Gamma^{-1} \phi + \gamma^{-1} \psi^2$ is

$$\begin{aligned} \dot{V} \leq & -\alpha_1 \epsilon^2(t)(1 + \zeta^T(t) \zeta(t) + \xi^2(t)) \\ & + \alpha_2 \frac{d^2(t)}{1 + \zeta^T(t) \zeta(t) + \xi^2(t)} \\ & - 2|\rho^*| \sigma_\theta(t) \phi^T(t) \theta(t) - 2\sigma_\rho(t) \psi(t) \rho(t) \end{aligned} \quad (6.21)$$

for some constants $\alpha_1 > 0$, $\alpha_2 > 0$. This, together with a similar argument to (5.14) and (5.15), proves (1) and (2). \square

Adaptive Scheme II: Instead of a choice of $L(s)$ of degree $n^* - 1$, we choose $L(s) = P_m(s) = W_m^{-1}(s)$, of degree n^* , to obtain the estimation error as

$$\epsilon(t) = \frac{e(t) + \rho(t) \xi(t)}{1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))} \quad (6.22)$$

where $\zeta(t)$ and $\xi(t)$ are defined in (6.11) with this new $L(s)$. We then use (6.13) and (6.14) with the new $\epsilon(t)$ defined in (6.22) to update the estimates $\theta(t)$ and $\rho(t)$.

For this scheme, we have the following result.

Lemma 6.2: The adaptive (6.13), (6.14), (6.23) guarantees

- 1) $\theta(t)$, $\dot{\theta}(t)$, $\rho(t)$, $\dot{\rho}(t)$, $\epsilon^2(t)(1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))) \in L_\infty$;
- 2) for some constant $k_5 > 0$, $k_6 > 0$, and all $t_2 \geq t_1 \geq 0$,

$$\int_{t_1}^{t_2} \|\dot{\theta}(t)\|^2 dt \leq k_5 + \int_{t_1}^{t_2} \frac{k_6}{1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))} dt \quad (6.23)$$

$$\begin{aligned} & \int_{t_1}^{t_2} \epsilon^2(t)(1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))) dt \\ & \leq k_5 + \int_{t_1}^{t_2} \frac{k_6}{1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))} dt. \end{aligned} \quad (6.24)$$

Proof: With (6.7), (6.11), and (6.22), we write the time derivative of the positive-definite function $V(\phi, \psi) = \frac{1}{2}(|\rho^*| \phi^T \Gamma^{-1} \phi + \gamma^{-1} \psi^2)$ where $\psi(t) = \rho(t) - \rho^*$, along (6.13) and (6.14), as

$$\begin{aligned} \dot{V}(t) \leq & -\frac{1}{2} \epsilon^2(t)(1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t))) \\ & + \frac{d^2(t)}{2(1 + \alpha(\zeta^T(t) \zeta(t) + \xi^2(t)))} \\ & - |\rho^*| \sigma_\theta(t) \phi^T(t) \theta(t) \\ & - \sigma(\rho, M_\rho, \sigma_0) \psi(t) \rho(t). \end{aligned} \quad (6.25)$$

From this inequality, (6.13) and (6.14) with σ defined in (5.9), (1), and (2) follow. \square

Similar to Lemma 5.1, Lemmas 6.1 and 6.2 only show the boundedness of $\theta(t)$ and the L^2 properties (6.23)–(6.24) of the adaptive law (6.13)–(6.14). The signal boundedness of the adaptive control system with a general hysteresis is

still a research topic. However, for a wide class of hysteresis characteristics, we have the following stability results.

Theorem 6.1: If the hysteresis $H(\cdot)$ in (2.1) has two equal slopes, $m_t = m_b$, and (4.30), (4.31), (6.9), (6.10) are used for adaptation and implementation of the adaptive hysteresis inverse and the adaptive controller, then all closed-loop signals are bounded.

The proof for Theorem 6.1 is given in Appendix B.

This boundedness result applies to the symmetric hysteresis case where (4.34), (4.35), (6.9), and (6.10) are used for adaptation and implementation of the adaptive hysteresis inverse and the adaptive controller (6.6), with a reduced system order.

While analytically characterizing the tracking performance of the closed-loop system with an adaptive hysteresis inverse is an important future research topic, we will examine it by simulations and compare it with that of a control system without hysteresis inverse.

VII. SIMULATION RESULTS

In this section, we present an example with simulation results to illustrate the structure and effectiveness of the developed adaptive hysteresis control schemes.

We consider the plant with an unstable linear part $G(s) = 2.5/(s^2 + 2s - 4)$ and a symmetric hysteresis characteristic $H(m_t, c_t, m_b, c_b, m_r, c_r, m_l, c_l; \cdot)$ where $m_t = m_b = 1.8$, $m_r = m_l = 3$, $c_t = -c_b = 1.9$, $c_r = -c_l = 2.5$, and choose a model transfer function $W_m(s) = 1/(s^2 + 3s + 2)$.

We study the system performance in one of the five cases: a) a fixed linear controller without hysteresis inverse, for $G(s)$ known; b) an adaptive linear controller without hysteresis inverse, for $G(s)$ unknown; c) a fixed linear controller with a fixed inaccurate hysteresis inverse, for $G(s)$ known; d) a fixed linear controller with an adaptive hysteresis inverse, for $G(s)$ known; and e) an adaptive linear controller with an adaptive hysteresis inverse, for $G(s)$ unknown.

The controller a) has the structure

$$\begin{aligned} v(t) = & \theta_1^* \frac{1}{s+3} [v](t) + \theta_2^* \frac{1}{s+3} [y](t) \\ & + \theta_{20}^* y(t) + \theta_{31}^* r(t) \end{aligned} \quad (7.1)$$

where $\theta_1^* = -1$, $\theta_2^* = -0.4$, $\theta_{20}^* = -2.8$, $\theta_{31}^* = 0.4$, which are calculated from (5.3) with $G(s)$ known.

The controller b) is the adaptive version of a) for $G(s)$ unknown:

$$\begin{aligned} v(t) = & \theta_1(t) \frac{1}{s+3} [v](t) + \theta_2(t) \frac{1}{s+3} [y](t) \\ & + \theta_{20}(t) y(t) + \theta_3(t) r(t) \end{aligned} \quad (7.2)$$

where $\theta_1(t)$, $\theta_2(t)$, $\theta_{20}(t)$, $\theta_3(t)$ are updated from an adaptive law similar to (6.11)–(6.14) with a different $\theta(t) = (\theta_1(t), \theta_2(t), \theta_{20}(t), \theta_3(t))^T$, and with $\theta(0) = (-1.5, -0.8, -2, 0.8)^T$, $\rho(0) = 1.25$, and the choice of $L(s) = s + 2$, $\alpha = 1$, $\sigma_0 = 0.15$, $\Gamma = 10I$, $\gamma = 10$, $M_\theta = 5.53$, $M_\rho = 3$.

These two controllers, well known in the literature, ignore the existence of the hysteresis characteristic in the plant and have no compensation for the hysteresis $H(\cdot)$.

The controller c) is

$$v(t) = \bar{H}I(u_d(t)),$$

$$\bar{H}I(\cdot) = HI(\bar{m}_t, \bar{c}_t, \bar{m}_b, \bar{c}_b, \bar{m}_r, \bar{c}_r, \bar{m}_l, \bar{c}_l; \cdot) \quad (7.3)$$

$$u_d(t) = \theta_1^* \frac{1}{s+3} [u_d](t) + \theta_2^* \frac{1}{s+3} [y](t) + \theta_{20}^* y(t) + \theta_3^* r(t) \quad (7.4)$$

where $\bar{H}I(\cdot)$ is an accurate estimate of $HI(\cdot)$ defined in (3.2)–(3.6), with $\bar{m}_t = \bar{m}_b = 2.3$, $\bar{c}_t = -\bar{c}_b = 0.9$, $\bar{m}_r = \bar{m}_l = 2.5$, $\bar{c}_r = -\bar{c}_l = 0.5$, and θ_1^* , θ_2^* , θ_{20}^* , θ_3^* are the same as that in the controller a). This controller, with $\bar{H}I(\cdot)$, has a fixed but inaccurate compensation for the hysteresis $H(\cdot)$. The control law (7.4) was developed in (5.1).

The controller d) is with an adaptive hysteresis inverse for $G(s)$ known

$$v(t) = \widehat{H}I(u_d(t)), \quad \widehat{H}I(\cdot) = HI(\widehat{m}_t(t), \widehat{c}_t(t), \widehat{m}_b(t), \widehat{c}_b(t), \widehat{m}_r(t), \widehat{c}_r(t), \widehat{m}_l(t), \widehat{c}_l(t); \cdot) \quad (7.5)$$

where $u_d(t)$ is generated from the same structure as that in the controller c) [see (7.4)], and $\widehat{H}I(\cdot)$ is an adaptive estimate of $HI(\cdot)$, with initial parameter estimates $\widehat{m}_t(0) = \widehat{m}_b(0) = 2.3$, $\widehat{c}_t(0) = -\widehat{c}_b(0) = 0.9$, $\widehat{m}_r(0) = \widehat{m}_l(0) = 2.5$, $\widehat{c}_r(0) = -\widehat{c}_l(0) = 0.5$. The adaptive law for $\theta_h(t) = (\widehat{m}_t(t), \widehat{c}_t(t), \widehat{m}_r(t), \widehat{m}_l(t), \widehat{c}_r(t))^T$ is (5.8) with $\sigma_0 = 0.15$, $\Gamma_h = 10I$, $M_h = 11$.

The controller (e) is with an adaptive hysteresis inverse for $G(s)$ unknown

$$v(t) = \widehat{H}I(u_d(t)), \quad \widehat{H}I(\cdot) = HI(\widehat{m}_t(t), \widehat{c}_t(t), \widehat{m}_b(t), \widehat{c}_b(t), \widehat{m}_r(t), \widehat{c}_r(t), \widehat{m}_l(t), \widehat{c}_l(t); \cdot) \quad (7.6)$$

$$u_d(t) = \theta_2(t) \frac{1}{s+3} [y](t) + \theta_{20}(t) y(t) + \theta_3(t) r(t) + (\theta_{41}(t), \theta_{42}(t), \theta_{43}(t), \theta_{44}(t)) \frac{1}{s+3} [\omega_h](t) + \theta_5(t) \omega_5(t) \quad (7.7)$$

where $\widehat{H}I(\cdot)$ is an adaptive hysteresis inverse with the same initial parameter estimates as that in the controller d), and the adaptive law for $\theta(t) = (\theta_2(t), \theta_{20}(t), \theta_3(t), \theta_4^T(t), \theta_5(t), \theta_h^T(t))^T$ is (6.11)–(6.14) with the choice of $L(s) = s+2$, $\alpha = 1$, $\sigma_0 = 0.15$, $\Gamma = 10I$, $\gamma = 10$, $M_\theta = 17.38$, $M_\rho = 3$, $\rho(0) = 1.25$, and $\theta_2(0) = -0.8$, $\theta_{20}(0) = -2$, $\theta_3(0) = 0.8$, $\theta_4(0) = (3.45, 3.75, 1.35, 0.75)^T$, $\theta_5(0) = -1.5$. The control law (7.7) was developed in (6.6).

Our simulations indicate

1) if either a fixed or adaptive linear controller without a hysteresis inverse is applied to this plant, then the tracking error remains significant for large t ;

2) an inaccurate fixed hysteresis inverse can reduce the tracking error;

3) significant improvements of system tracking performance are achieved with the use of an adaptive hysteresis inverse either with a fixed linear controller, for $G(s)$ known, or with an adaptive linear controller, for $G(s)$ unknown.

Fig. 4. System responses: fixed controller without hysteresis inverse for $G(s)$ known.

Fig. 5. System responses: adaptive controller without hysteresis inverse for $G(s)$ unknown.

Some typical system responses for $r(t) = 12.7 \sin(2.3t)$ are shown in Figs. 4–8 for the above five controllers, respectively. It is clear that with an adaptive hysteresis inverse, the tracking error is significantly reduced with less control effort (the control signal is smoother and smaller).

VIII. CONCLUSIONS

Our construction of an adaptive hysteresis inverse, reparameterization of an adaptive linear controller, and choice of suitable error models have led to several adaptive control schemes applicable to plants with unknown hystereses. Simulation results indicate that these adaptive inverse schemes promise to significantly improve system performance.

APPENDIX A

PROOF OF THEOREM 5.1

From Lemma 5.1 and the condition 7), we have that $\theta_h(t) \in L_\infty$ and $\widehat{m}_t(t) \geq m_{t1} > 0$. Introducing $m = m_t = m_b$, $\widehat{m}_t(t) = \widehat{m}_b(t)$, and using $u(t) = H(v(t))$, $v(t) =$

(b)

Fig 8 System responses adaptive controller with adaptive hysteresis inverse for $G(s)$ unknown

(a)

(b)

Fig 7 System responses fixed controller with adaptive hysteresis inverse for $G(s)$ known

$\hat{H}(u_d(t))$ we express

$$u(t) = \frac{m}{m(t)} u_d(t) + d_2(t) \quad (\text{A } 1)$$

$$u(t) = mv(t) + \bar{d}_2(t) \quad (\text{A } 2)$$

for some bounded $d_2(t)$, $\bar{d}_2(t)$. We then define fictitious signals $z_0(t)$, $z_1(t)$ filters $K_1(s)$, $K(s)$ as

$$z_0(t) = \frac{1}{s + a_0} [u](t), \quad \bar{z}_1(t) = \frac{1}{s + a_0} [y](t), \quad a_0 > 0 \quad (\text{A } 3)$$

$$K_1(s) = 1 - K(s), \quad K(s) = \frac{a^n}{(s + a)^n} \quad a > 0 \quad (\text{A } 4)$$

and use (A.3), (A.4), and (2.1) to obtain

$$z_0(t) + a_0 K_1(s) [z_0](t) - K_1(s) [u](t) = K(s) G^{-1}(s) [z](t) \quad (\text{A } 5)$$

Using (A.1) and (A.3) in (5.1), we have

$$\begin{aligned} u(t) = & \frac{m}{m(t)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \frac{m(\cdot)}{m} (s + a_0) [z_0](t) + \\ & \frac{m}{m(t)} \theta_2^* I \frac{a(s)}{\Lambda(s)} (s + a_0) [z_1](t) \\ & + \frac{m}{m(t)} \theta_{20}^* (s + a_0) [z](t) + \frac{m}{m(t)} \theta_1^* I(t) \\ & + \left(1 - \frac{m}{m(t)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \frac{m(\cdot)}{m} \right) [d_2](t) \end{aligned} \quad (\text{A } 6)$$

Substituting this expression for $u(t)$ in (A.5), we see that $\bar{z}_1(t)$ and $z_0(t)$ are related by

$$\begin{aligned} & \left(1 + K_1(s) \left(a_0 - \frac{m}{m(\cdot)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \frac{m(\cdot)}{m} (s + a_0) \right) \right) [z_0](t) \\ & = \left(K(s) G^{-1}(s) + K_1(s) \frac{m}{m(\cdot)} \theta_2^* I \frac{a(s)}{\Lambda(s)} (s + a_0) \right. \\ & \quad + K_1(s) \frac{m}{m(\cdot)} \theta_{20}^* (s + a_0) [z](t) \\ & \quad + K_1(s) \left[\frac{m}{m(\cdot)} \theta_3^* I \right] (t) \\ & \quad \left. + K_1(s) \left(1 - \frac{m}{m(\cdot)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \frac{m(\cdot)}{m} \right) [d_2](t) \right) \end{aligned} \quad (\text{A } 7)$$

Consider a linear operator $T(s, t)$ with input $r(t)$. We define $T(s, t)$ as a stable and proper operator if $\|T(s, \cdot)[r](t)\| \leq \beta_1 \int_0^t e^{-\alpha(t-\tau)} \|r(\tau)\| d\tau + \beta_2 \|r(t)\|$ for some constants $\beta_1 \geq 0$, $\beta_2 \geq 0$, and $\alpha > 0$ all $t \geq 0$ and any $r(t)$. The operator $T(s, t)$ is stable and strictly proper if $\|T(s, \cdot)[r](t)\| \leq \beta_1 \int_0^t e^{-\alpha(t-\tau)} \|r(\tau)\| d\tau$ for some constants $\beta_1 \geq 0$ and $\alpha > 0$, all $t \geq 0$ and any $r(t)$. With this definition, the facts that $\hat{m}(t)$, $m(t) \in L_\infty$, $K_1(s)$ is strictly stable, and

$$\begin{aligned} & \frac{m}{m(t)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \frac{m(\cdot)}{m} (s + a_0) [z_0](t) \\ & = \frac{m}{m(t)} \theta_1^* I \frac{a(s)}{\Lambda(s)} \left[s \left[\frac{m}{m} z_0 \right] - s \left[\frac{\hat{m}}{m} \right] z_0 + a_0 \frac{m}{m} z_0 \right] (t) \end{aligned} \quad (\text{A } 8)$$

$$K_1(s) \frac{m}{m(\cdot)} \theta_{20}^*(s+a_0)[z](t) \\ = K_1(s) \left[s \left[\frac{m}{m(\cdot)} \theta_{20}^* z \right] - s \left[\frac{m}{m(\cdot)} \theta_{20}^* \right] z + a_0 \frac{m}{m(\cdot)} \theta_{20}^* z \right] (t) \quad (\text{A } 9)$$

imply that $(m/m(\cdot))\theta_1^{*T}(a(s)/\Lambda(s))(m(t)/m)(s+a_0)$ and $K_1(s)(m/m(\cdot))\theta_{20}^*(s+a_0)$ are stable and proper

By definition, the impulse response function $k_1(t)$ of $K_1(s)$ satisfies $\int_0^\infty |k_1(t)|dt = n^*/a$. Hence there exists $a^0 > 0$ such that for any finite $a > a^0$ the operator

$$T_0(s, t) \triangleq \left(1 + K_1(s) \left(a_0 - \frac{m}{m(\cdot)} \theta_1^{*T} \frac{a(s)}{\Lambda(s)} \frac{m(t)}{m} (s+a_0) \right) \right)^{-1}$$

is stable and proper. For a fixed $a > a^0$ (A 7) implies that

$$z_0(t) = I_1(s, t)[z](t) + d_1(t) \quad (\text{A } 10)$$

where $I_1(s, t)$ is a stable and proper operator, and $d_1(t)$ is a bounded signal due to $r(t)$, $d_2(t)$

As in the swapping lemma [12] we let (A_f, B_f, C_f) be a minimal realization of $I(s)$ define $W(s) = (C_f(sI - A_f))^{-1}$, $W_t(s) = (sI - A_f)^{-1}B_f$ and express $\xi_h(t)$ as

$$\xi_h(t) = W(s, t) \left[W_t(s)(s+a_0) \frac{1}{s+a_0} [\omega_h^T(t)] \theta_h \right] (t) \quad (\text{A } 11)$$

Using (4 13) and (4 31) we rewrite $\omega_h(t)$ as

$$\omega_h(t) = (-\dot{\chi}_t(t) + (\hat{\chi}_t(t) + \chi_t(t))\dot{\chi}_t(t) - \chi_t(t) - \hat{\chi}_t(t)) \\ \hat{\chi}_t(t)\dot{\chi}_t(t) - \hat{\chi}_t(t) - \chi_t(t)\dot{\chi}_t(t) - \hat{\chi}_t(t))^T \quad (\text{A } 12)$$

whose components except for $-\dot{\chi}_t(t)$ are all bounded. Using (A 2) and (A 3) we note

$$\frac{1}{s+a_0} [\omega_h](t) = \frac{1}{m} (v_0(t), 0, 0)^T + d_3(t) \quad (\text{A } 13)$$

where $d_3(t)$ is a bounded vector signal

Filtering both sides of (5 7) by $1/(s+a_0)$ and using (A 3) again, we obtain

$$z(t) = \frac{1}{s+a_0} [y_m](t) + \frac{1}{s+a_0} [e_h - \xi_h](t) \quad (\text{A } 14)$$

The inequality $|e_h(t)| < (|e_h(t)|/\sqrt{1+\zeta_h^T(t)\zeta_h(t)+\xi_h^2(t)}) (1+\|\zeta_h(t)\|+|\xi_h(t)|)$ and (A 9)–(A 14) imply

$$|z(t)| \leq v_0(t) + I_2(s, t)[v_1 I_3(s, t)[z]](t) \quad (\text{A } 15)$$

where $v_0(t) \in L_\infty$ and $v_1(t) \in L_\infty$ is such that

$$\int_{t_1}^t v_1^2(t) dt \leq \bar{k}_1 + \int_{t_1}^t \frac{\bar{k}_2}{1+\zeta_h^T(t)\zeta_h(t)+\xi_h^2(t)} dt \quad (\text{A } 16)$$

for some constants $\bar{k}_1 > 0$, $\bar{k}_2 > 0$ and any $t_2 \geq t_1 \geq 0$. The operator $T_2(s, t)$ is stable and strictly proper, while the operator $T_3(s, t)$ is stable and proper and has a nonnegative impulse response

If $\zeta_h(t)$, $\xi_h(t)$ are bounded, then from Lemma 5.1 and (5 7), we see that $e_h(t)$, $y(t)$ are bounded, from (A 3), (A 10) that $z(t)$, $z_0(t)$ are bounded, and from (A 6), (A 8), and (A 1) that $u(t)$ and $u_d(t)$ are bounded. Thus all closed-loop signals

are bounded. On the other hand, if $\zeta_h^T(t)\zeta_h(t)$ is unbounded, then the smallness of $v_1(t)$ in the second term results in the boundedness of $z(t)$ given by (A 15). This in turn implies that $z_0(t)$ in (A 10) is bounded so that (A 6), $u_d(t)$ in (A 1), $\omega_h(t)$ in (4 13), $\xi_h(t)$ in (5 6), in (5 7) are bounded. Hence we conclude that all closed-loop signals are bounded.

APPENDIX B PROOF OF THEOREM 6.1

A Proof for Adaptive Scheme I

Using (A 1), (A 3), (A 11), (A 12), and (6 3) we express

$$\theta_4^T(t)\omega_4(t) = \theta_a^T(t) \frac{a(s)}{\Lambda(s)} (s+a_0)[z_0](t) + d_5(t) \quad (\text{B } 1)$$

for some bounded $\theta_a(t) \in R^{n-1}$ for the controller I ($\theta_a(t) \in R^n$ for the controller II) of Section V and some bounded $d_5(t)$. Using $z_0(t)$, $K_1(s)$, $K(s)$ defined in (A 3)–(A 4) we obtain

$$z_0(t) + a_0 K_1(s)[z_0](t) - K_1(s)[u](t) \\ = K(s)G^{-1}(s) \frac{1}{s+a_0} [y](t) \quad (\text{B } 2)$$

Using (A 1)–(6 6)–(B 1), we obtain

$$u(t) = \frac{m}{m(t)} \theta_a^T(t) \frac{a(s)}{\Lambda(s)} (s+a_0)[z_0](t) \\ + \frac{m}{m(t)} \theta_2^T(t) \frac{a(s)}{\Lambda(s)} [y](t) + \frac{m}{m(t)} \theta_{20}^T(t) y(t) \\ + \frac{m}{m(t)} \theta_3(t) r(t) + \frac{m}{m(t)} d_5(t) + d_2(t) \quad (\text{B } 3)$$

From (B 2) and (B 3) it follows that

$$\left(1 + K_1(s) \left(a_0 - \frac{m}{m(\cdot)} \theta_a^T(s) \frac{a(s)}{\Lambda(s)} (s+a_0) \right) \right) [z_0](t) \\ = \left(K(s)G^{-1}(s) \frac{1}{s+a_0} + K_1(s) \frac{m}{m(\cdot)} \theta_2^T(s) \frac{a(s)}{\Lambda(s)} \right. \\ \left. + K_1(s) \frac{m}{m(\cdot)} \theta_{20}^T(s) \right) [y](t) + K_1(s) \left[\frac{m}{m} \theta_3 r \right] (t) \\ + K_1(s)[d_2](t) + K_1(s) \left[\frac{m}{m} d_5 \right] (t) \quad (\text{B } 4)$$

Similar to (A 9), we see from (B 4) with a sufficiently large $a > 0$ in $K(s)$, $K_1(s)$ that

$$z_0(t) = T_1(s, t)[y](t) + \bar{d}_3(t) \quad (\text{B } 5)$$

for some $T_1(s, t)$ stable and proper and some $\bar{d}_3(t)$ bounded

Similar to (A 10) with (A_f, B_f, C_f) being a minimal realization of $1/L(s)$ and $W(s) = C_f(sI - A_f)^{-1}$, $W_t(s) = (sI - A_f)^{-1}B_f$ we express $\xi(t)$ as

$$\xi(t) = W(s, t)[W_t(s)[\omega^T(t)]\theta](t) \quad (\text{B } 6)$$

Using (A 11), (6 3), (6 4), (5 2), (B 5), in (6 10), we see that

$$\omega(t) = \bar{T}_1(s, t)[y](t) + \bar{d}_4(t) \quad (\text{B } 7)$$

for some $\bar{T}_1(s, t)$ stable and proper, and some $\bar{d}_4(t)$ bounded

By rewriting (6.12), we get

$$y(t) = y_m(t) + e(t) - W_m(s)L(s) [\rho\xi - \alpha\xi(1 + \zeta^T\zeta + \xi^2) + \alpha e](t) \quad (B.8)$$

Similar to (A.15), (6.11), (B.6)–(B.8), and Lemma 6.1 imply

$$|y(t)| \leq r_0(t) + I_2(s)[r_1 T_3(s)[|y|]](t) \quad (B.9)$$

where $r_0(t) \in L_\infty$, and $r_1(t)$ is such that

$$\int_{t_1}^{t_2} r_1^2(t) dt \leq \bar{k}_3 + \int_{t_1}^{t_2} \frac{\bar{k}_4}{1 + \zeta^T(t)\zeta(t) + \xi^2(t)} dt \quad (B.10)$$

for some constants $\bar{k}_3 > 0$, $\bar{k}_4 > 0$ and any $t_2 \geq t_1 \geq 0$. The operator $T_2(s, t)$ is stable and strictly proper while the operator $T_3(s, t)$ is stable and proper and has a nonnegative impulse response. From here on, the closed-loop signal boundedness follows from a contradiction argument which is similar to that in the proof of Theorem 5.1.

B Proof for Adaptive Scheme II

Using (A.1), (6.6), (B.1), we obtain

$$\begin{aligned} u(t) = & \frac{m}{m(t)} \theta_a^T(t) \frac{a(s)}{\Lambda(s)} (s + a_0)[z_0](t) \\ & + \frac{m}{m(t)} \theta_2^T(t) \frac{a(s)}{\Lambda(s)} (s + a_0)[z](t) \\ & + \frac{m}{m(t)} \theta_{20}(t) (s + a_0)[\sim](t) \\ & + \frac{m}{m(t)} \theta_3(t) \tau(t) + \frac{m}{m(t)} d_5(t) + d_2(t) \end{aligned} \quad (B.11)$$

From (A.5) and (B.11) it follows that

$$\begin{aligned} & \left(1 + K_1(s) \left(a_0 - \frac{m}{m(t)} \theta_a^T(t) \frac{a(s)}{\Lambda(s)} (s + a_0) \right) \right) [z_0](t) \\ = & \left(K(s) G^{-1}(s) + K_1(s) \frac{m}{m(t)} \theta_2^T(t) \frac{a(s)}{\Lambda(s)} (s + a_0) \right. \\ & \left. + K_1(s) \frac{m}{m(t)} \theta_{20}(t) (s + a_0) \right) [z](t) \\ & + K_1(s) \left[\frac{m}{m(t)} \theta_3(t) \right] (t) + K_1(s) [d_2](t) \\ & + K_1(s) \left[\frac{m}{m(t)} d_5 \right] (t) \end{aligned} \quad (B.12)$$

where $K_1(s) \frac{m}{m(t)} \theta_{20}(t) (s + a_0)$ is stable and proper because

$$\begin{aligned} & K_1(s) \frac{m}{m(t)} \theta_{20}(t) (s + a_0) [z](t) \\ = & K_1(s) \left[s \left[\frac{m}{m(t)} \theta_{20}(t) \right] - s \left[\frac{m}{m(t)} \theta_{20}(t) \right] z + a_0 \frac{m}{m(t)} \theta_{20}(t) \right] (t) \end{aligned} \quad (B.13)$$

and $m(t)$, $\theta_a(t)$, $\theta_{20}(t)$, $\theta_3(t)$ are all bounded.

The remaining part of the proof is analogous to (A.9)–(A.14), followed by a contradiction argument similar to that used in the proof of Theorem 5.1.

ACKNOWLEDGMENT

We are thankful to J. Winkelman and D. Rhode of Ford Motor Company for stimulating this research, and to D. Recker of the University of Illinois for many helpful discussions.

Kokotovic (SM 74–F 80) has been active for more than 30 years as a control engineer, researcher, and educator, first in his native Yugoslavia, and then from 1966 through 1990 at the University of Illinois, where he held the endowed Grainger Chair. Since 1991, he has been Co-Director (with A. J. Laub) of the newly formed Center for Control Engineering and Computation at the University of California, Santa Barbara. He has coauthored eight books and numerous articles contributing to sensitivity analysis, singular perturbation methods,

and robust adaptive and nonlinear control. He is also active in industrial applications of control theory. As a consultant to Ford, he was involved in the development of the first series of automotive computer controls, and at General Electric, he participated in large-scale systems studies.

Dr. Kokotovic received the 1990 Quazza Medal, the 1983 and 1993 Outstanding IEEE Transactions Paper Awards, and presented the 1991 Bode Prize Lecture. He is the recipient of the 1995 IEEE Control Systems Award.

Robust Stability Under a Class of Nonlinear Parametric Perturbations

Minyue Fu, *Member, IEEE*, Soura Dasgupta, *Senior Member, IEEE*, and Vincent Blondel

Abstract—This paper considers the robust stability verification of linear time-invariant systems admitting a class of nonlinear parametric perturbations. The general setting is one of determining the closed-loop stability of systems whose open-loop transfer functions consist of powers, products, and ratios of polytopes of polynomials. Apart from this general setting, two special cases of independent interest are also considered. The first special case concerns uncertainties in the open-loop gain and real poles and zeros, while the second special case treats uncertainties in the open-loop gain and complex poles and zeros. In light of the zero exclusion principle, robust stability is equivalent to zero exclusion of the value sets of the system characteristic function (a value set consists of the values of the characteristic functions at a fixed frequency). The main results of this paper are as follows. 1) The value set of the characteristic function at each fixed frequency is determined by the edges and some frequency-dependent internal line segments. 2) Consequently, Hurwitz invariance verification simplifies to that of checking certain continuous scalar functions for avoidance of the negative real axis. 3) For the case of real zero-pole-gain variations, the critical lines are all frequency independent, and therefore, the determination of the robust stability is even simpler. 4) For the case of complex zero-pole-gain variations, the critical internal lines are shown to be either frequency independent or to be confined in certain (two-dimensional) planes or (three-dimensional) boxes.

1 INTRODUCTION

THE following problem is of interest in the robust stability verification of linear time-invariant control systems depicted in Fig. 1. Suppose we are given a stability region \mathcal{D} and a family of open-loop transfer functions parameterized by a real vector γ

$$T(\gamma) = \{t(s, \gamma) \mid \gamma \in \Gamma\} \quad (1.1)$$

where $t(s, \gamma)$ is the transfer function of the plant and controller, and Γ is a connected set in \mathbb{R}^N . Determine as simply

Fig. 1 Closed-loop uncertain system

as possible if all members of the family of the corresponding characteristic functions

$$H(\Gamma) = \{h(s, \gamma) = 1 + t(s, \gamma) \mid \gamma \in \Gamma\} \quad (1.2)$$

have all zeros contained entirely in \mathcal{D} (i.e., the family is \mathcal{D} -stable invariant). Generally, the transfer function coefficients depend nonlinearly on γ .

One approach to this problem is to treat it in its broadest generality, as is done in [1], [2] where a very broad class of $H(\Gamma)$ is considered. Alternatively, one can consider particular parameterizations reflecting specific forms of structural information supplied by the modeling process. This allows formulation of stability verification schemes which are computationally less demanding. Examples of this approach include [3], which considers a family of polynomials admitting independent variations in the coefficients, [4]–[6], which account for affinely dependent variations, and [7]–[9], which consider multilinear dependence (see [10], [11] for surveys). Each of [3]–[9], exploits the underlying structural information and demonstrates consequent simplifications.

This paper adopts the second approach by focusing on a special class of nonlinear parametric dependence. To keep the presentation simple, only Hurwitz invariance is investigated (i.e., \mathcal{D} is the open left-half plane), although the results do, in fact, generalize to more general stability regions. Specifically, the family of characteristic functions to be considered in this paper admits the following form

$$h(s, \gamma) = 1 + g_0(s) \frac{\prod_{i=1}^m (p_{i0}(s) + \gamma_i^T P_i(s))^\mu}{\prod_{i=m+1}^n (p_{i0}(s) + \gamma_i^T P_i(s))^\nu} \quad (1.3)$$

where $g_0(s)$ and the $p_{i0}(s)$ are real scalar rational functions and polynomials in s , respectively, $\gamma_i \in \Gamma_i \subset \mathbb{R}^N$ represent a partition of γ , i.e.,

$$\gamma = (\gamma_1^T, \gamma_2^T, \dots, \gamma_n^T)^T \quad (1.4)$$

and

$$\Gamma = \Gamma_1 \times \Gamma_2 \times \dots \times \Gamma_n \quad (1.5)$$

$P_i(s)$ are real vector polynomials with dimension N_i , and μ_i and ν_i are fixed positive exponents. The quantities $g_0(s)$, $p_{i0}(s)$, $P_i(s)$, n , N_i , μ_i , ν_i , and Γ are assumed known. The j th element of γ_i [respectively, $P_i(s)$] is denoted by γ_{ij} [respectively, $P_{ij}(s)$]. Since Γ is an axis parallel box, each γ_{ij} varies independently of the others within an interval

$$\gamma_{ij}^- \leq \gamma_{ij} \leq \gamma_{ij}^+. \quad (1.6)$$

Thus, each factor $(p_{i0}(s) + \gamma_i^T P_i(s))$ forms a polytope of polynomials as γ_i varies in Γ_i . Notice that a polytope can simplify to model an uncertain gain in the open-loop transfer function. Furthermore, in the case where the exponents μ_i and ν_i are restricted to be +1, the robust stability verification of (1.3) is equivalent to that of a subclass of the multilinear problem, i.e., the characteristic polynomial associated with (1.3) depends on γ_{ij} in a multilinear fashion. To simplify our notation, we rewrite (1.3) as follows:

$$h(s, \gamma) = 1 + g_0(s) \prod_{i=1}^n (p_{i0}(s) + \gamma_i^T P_i(s))^{k_i} \quad (1.7)$$

where k_i are allowed to be nonzero integers (either positive or negative).

There are several situations in which the setting of (1.7) becomes important. By way of background, we cite the results of [4], where the setting considered translates to one involving an uncertain plant having numerator and denominator polynomials lying in polytopic sets. Essentially, [4] asks the following question: Given a fixed controller $g_0(s)$, how can one determine if the uncertain closed loop is stable? Thus, the problem considered in [4] can be viewed as a subclass of (1.7), with $n = 2$, $k_1 = 1$, and $k_2 = -1$. In many applications involving process control, the overall plant is itself a cascade of several subplants, such that physical uncertain parameters of a given subplant enjoy physical independence from those of the other subplants. Now, if one models each uncertain subplant individually as lying in sets analogous to those in [4], one readily obtains a special case of the structure exhibited in (1.7).

To further illustrate the scope of (1.7), two more examples are considered. The first example is of a plant with independent real zero, pole and gain variations and is as follows

$$h(s, \gamma) = 1 + dg_0(s) \prod_{i=1}^{n-1} (s + \lambda_i)^{k_i} \quad (1.8)$$

where d and λ_i are uncertain real parameters lying in given bounds. In this case, $g_0(s)$ can be a given controller, d the gain, and λ_i the zeros and poles of the plant whenever the k_i are, respectively, positive or negative. The uncertainty assumes that the λ_i vary independently within given bounds. The objective is to verify if $g_0(s)$ stabilizes the plant for all possible parameter variations. Therefore, under the assumption of no zero-pole cancellation (which is trivial to check in this example), the closed-loop system associated with (1.8) is robustly stable if and only if the corresponding $H(\Gamma)$ is Hurwitz invariant. Note that the terms involving cases where $k_i \neq \pm 1$ reflect structural preservation of multiplicities.

To allow for complex zero and pole variations, one may include factors of the forms $(s^2 + a_i s + b_i)^{k_i}$, with a_i and b_i also varying independently in intervals. The version of (1.7) given in (1.9) below will be referred to as the complex zero-pole-gain variation problem:

$$h(s, \gamma) = 1 + dg_0(s) \prod_{i=1}^{\tau} (s + \lambda_i)^{k_i} \prod_{j=\tau+1}^{n-1} (s^2 + a_j s + b_j)^{k_j} \quad (1.9)$$

with

$$\gamma = (\lambda_1, \lambda_2, \dots, \lambda_{\tau}, a_{\tau+1}, b_{\tau+1}, \dots, a_{n-1}, b_{n-1}, d)^T. \quad (1.10)$$

Throughout this paper, we adopt the following assumptions on the function $h(s, \gamma)$ in (1.7).

Assumption 1.1: The function $h(s, \gamma)$ has no unstable zero-pole cancellation for any $\gamma \in \Gamma$.

Assumption 1.2: Continuous variations of γ result in continuous changes in the zeros of $h(s, \gamma)$.

Assumption 1.3: The function $h(s, \gamma)$ has no purely imaginary poles for any $\gamma \in \Gamma$.

We note that Assumption 1.1 is essential to assure the internal stability of the closed-loop system. However, violation of this assumption will not cause any difficulty for constructing the value set $H(j\omega, \Gamma)$. Further, in light of the recent results of [20], the verification of this assumption is a relatively simple matter.

Assumption 1.2, on the other hand, is a standard one that requires the leading coefficient of the overall numerator polynomial in (1.7) not to equal zero within the specified uncertainty bounds.

Finally, Assumption 1.3 can be simply tested through a series of straightforward algebraic [18] techniques.

A. Approach and Main Results

As in [8], [9], [12], [13], we follow the so-called value set approach to robust stability analysis. For the family of rational functions (1.2), the value set at a frequency ω is defined as

$$H(\omega, \Gamma) := \{h(j\omega, \gamma) : \gamma \in \Gamma\}, \quad (1.11)$$

and its boundary will be denoted by $\partial H(\omega, \Gamma)$.

Our approach exploits a slight variation of the zero exclusion principle (see, e.g., [9]). Under assumptions (1.1), (1.2), and the fact that the value set changes continuously with ω , this principle reduces to the following conditions as being necessary and sufficient for the Hurwitz invariance of $H(\Gamma)$:

- 1) at least one member of $H(\Gamma)$ is Hurwitz, and
- 2) $0 \notin \partial H(\omega, \Gamma)$, $\forall \omega \in \mathbb{R}$, where ∂ denotes "the boundary of."

There are several appealing qualities of the value set approach. First, it provides a unifying framework within which most of the currently known robust stability results can be understood. Second, it can be used to obtain simple and transparent proofs of these results (see, for example, [13], [14], [19] for proofs of [3], [4], [15]). Furthermore, while for certain special classes of uncertainties the robust stability of a family of polynomials reduces to that of some easily characterizable members of this family, the same does not hold for general

parameterizations. For example, when the uncertainty set is one of multiaffinely parameterized polynomials, in general there are no easily characterizable internal subsets of the parameter box Γ , whose Hurwitzness implies the Hurwitz invariance of the entire set [23]. In the same vein, it is shown in [16] that in considering the Hurwitz invariance of the characteristic polynomials of a polytope of $(n \times n)$ matrices, one has to check all $(2n - 4)$ -dimensional boundaries of the parameter space, a task which is computationally prohibitive even for matrices of reasonably small sizes. In such a case, the zero exclusion condition 2) above provides a relatively simple frequency sweeping procedure for verifying Hurwitz invariance. Such a graphical approach has been advocated through successful application in [9], [12], [13], and provides the conditions of [8], [9]. Recently, the so-called finite zero exclusion principle has been developed by Rantzer [21] to avoid frequency sweeping, and to thus permit fast computation. This approach too relies on the ready calculation of pertinent value sets. Besides their utility for robust stability analysis, value sets play an important role in the determination of the frequency response of a family of transfer functions; see, for example, [17]. Consequently, they can be used in designing robust controllers which meet performance considerations that go beyond mere closed-loop stabilization; see [22], for example.

Accordingly, in this paper, we consider both the determination of value sets as well as the Hurwitz invariance of (1.3). The principle contribution is to show that for the general family (1.7), at each fixed frequency ω , each member of $\partial H(\omega, \Gamma)$ has preimages in certain line segments in the parameter set Γ . These critical line segments are simply characterized, vary with frequency, are independent of the exponents k_i [see (1.7)], and consequently the Hurwitz invariance of the family of functions in (1.7) becomes equivalent to checking a finite number of continuous and piecewise differentiable scalar functions in ω for avoidance of the negative real axis.

For the case of (1.8), we show that the critical segments are, in fact, the edges of Γ plus certain simply constructable, frequency-independent, 45-degree line segments in the parameter space. Further, the Hurwitz invariance of $H(\Gamma)$ is guaranteed by that of these frequency-independent line segments (including the edges).

For the case of (1.9), we show that the critical lines determining the value set boundaries are either frequency independent or, as frequency varies, vary on certain (two-dimensional) planes and certain (three-dimensional) boxes in Γ . To check for robust Hurwitzness, it then suffices to check these frequency-independent lines, planes, and boxes.

It is instructive to compare this paper with the work of [24], which considers the set of uncertain polynomials

$$\sum \ddot{F}_i(s) \left(\prod \ddot{P}_{i,j}(s) \right) \quad (1.12)$$

where the $F_i(s)$ are fixed polynomials while the $P_{i,j}(s)$ vary in independent interval sets. Several points of difference are noteworthy. First, the set in (1.12) is broader than ours in the sense that it allows the sum of more than two factors. It is narrower than (1.7) in that the $P_{i,j}(s)$ vary in independent

intervals and have unity power, whereas in (1.7) arbitrary variations with arbitrary powers are allowed. However, the greatest difference lies in the approaches employed to obtain results derived in this paper and [24]. The latter employs a parameter space as opposed to the value set approach of Hurwitz invariance verification. Its result states that one has to check the Hurwitz invariance of internal manifolds to Γ of the dimension

$$\max \{n_i\}. \quad (1.13)$$

Thus, even for the cases of (1.8) and (1.9), [24] requires checking Hurwitz invariance over manifolds that have dimensions that increase with the number of factors in (1.8) and (1.9).

Section II considers the general case. The special cases of (1.8) and (1.9) are addressed in Sections III and IV, respectively. Section V is the conclusion.

II. VALUE SET BOUNDARIES

A major objective of this paper is to achieve the following. For a given frequency ω , identify a critical subset $\Gamma_c(\omega)$ of Γ having the property that for all

$$v \in \partial(H(\omega, \Gamma)) \quad (2.14)$$

there exists $\gamma \in \Gamma_c(\omega)$ such that

$$h(j\omega, \gamma) = v \quad (2.15)$$

i.e., every point on the boundary of the value set at this frequency has at least one preimage in $\Gamma_c(\omega)$. In characterizing such a $\Gamma_c(\omega)$, we will not attempt to extract the smallest possible such set, but will be content with one particular choice that enjoys the above properties, and at the same time has a relatively simple analytical description.

To this end, we adopt a somewhat indirect approach. Specifically, given ω , we give necessary conditions on a parameter vector γ such that

$$h(j\omega, \gamma) \in \partial(H(\omega, \Gamma)). \quad (2.16)$$

Clearly, parameter vectors satisfying these necessary conditions together suffice to define a $\Gamma_c(\omega)$ meeting the requirements specified above.

In the sequel, a k -side of the parameter box Γ will refer to a subset of Γ in which only k parameters vary and all others are fixed at their extreme values. By the same token, a point γ in the interior of a k -side has exactly k -elements that do not take extreme values. A point on the boundary of a k -side lies on this k -side, but not in its interior. If γ is in the interior of a k -side of Γ , then the elements of γ not fixed at extreme values will be called the variables on this k -side. We note, that every k -side of Γ is also a hyperrectangle, that all its l -sides, $l \leq k$ are also l -sides of Γ , and that corners and edges of Γ are its respective 0- and 1-sides. Further, the $\sum_{i=1}^n N_i$ -side of Γ (recall that this sum is the dimension of Γ) is Γ itself.

In characterizing $\Gamma_c(\omega)$, we will assume that all edges of Γ are automatically included in $\Gamma_c(\omega)$. Thereafter, for all

$$1 < k \leq \sum N_i \quad (2.17)$$

we will provide for each k -side of Γ necessary conditions for γ in its interior to obey (2.16).

The main results of this section can be summarized in the following way.

Result 1: Not all sides of Γ need contribute interior points to $\Gamma_c(\omega)$. In fact, certain sides are such that, irrespective of ω , their interior points need never be included in $\Gamma_c(\omega)$. In Section II-A, we give a result which characterizes what the sides that potentially contribute interior points to $\Gamma_c(\omega)$ are. A feature of this characterization is that, for each side which in Section II-A is identified as a potential interior point contributor, all the sides of this side are also similar contributors.

Result 2: Having eliminated a vast majority of sides by virtue of Result 1, we restrict attention to an arbitrary side Q of Γ whose interior points have been ascertained by Result 1 as being potential members of $\Gamma_c(\omega)$. For every such Q , at a given frequency ω , we associate a unique, possibly frequency-dependent affine line $L_a(Q)$ such that a γ in the interior of Q obeys (2.16) only if γ belongs to this line. Consequently, together with the edges of Γ , the union of the intersections of all $L_a(Q)$ with the interior of the corresponding contributing sides Q comprise $\Gamma_c(\omega)$. The affine line $L_a(Q)$ associated with a given contributing boundary Q is characterized in Section II-B.

The results to be presented will be illustrated through the following example.

$$h(j\omega, \gamma) = 1 + \frac{[(\omega^2 - 2)\gamma_{11} + (j\omega + 1)\gamma_{12}][\omega^2 + \gamma_{31} + \gamma_{32}]}{[(1 - \omega^2 + j\omega)\gamma_{21} + j\omega\gamma_{22}][0.5j\omega + \gamma_{41}]} \quad (2.18)$$

To proceed with the development, observe first that as far as the determination of $\Gamma_c(\omega)$ is concerned, one need only consider the transfer function

$$g(s, \gamma) = \prod_{i=1}^n (p_{i0}(s) + \gamma_i^T P_i(s))^{k_i} \quad (2.19)$$

For unless $g_0(j\omega)$ in (1.3) is zero, at any frequency ω , $g(j\omega, \gamma) \in \partial(G(\omega, \Gamma))$ (with $G(\omega, \Gamma)$, obviously defined), iff $h(j\omega, \gamma) \in \partial(H(\omega, \Gamma))$. Of course, if $g_0(j\omega) = 0$, then at this ω , $H(\omega, \Gamma)$ collapses to a single point, and any $\gamma \in \Gamma$, including any corner, describes $\partial(H(\omega, \Gamma))$. Thus, in this case, $\Gamma_c(\omega)$ can be trivially constituted by a solitary corner of Γ .

Thus, here onwards, attention will be restricted to the sets $g(j\omega, \gamma)$, $\partial(G(\omega, \Gamma))$ instead of $h(j\omega, \gamma)$, $\partial(H(\omega, \Gamma))$, respectively.

A. Result 1

We have the following theorem.

Theorem 2.1: For a given ω and every $v \in \partial(H(\omega, \Gamma))$, there exists a γ obeying (2.15), such that [see (1.4)], for each i , at most one γ_{i1} is a variable. Consequently, a boundary Q of Γ need contribute interior points to $\Gamma_c(\omega)$ only if, for each i , at most one γ_{i1} is a variable in the interior of Q .

Thus, for example, in (2.18), any side on which both γ_{11} , γ_{12} are variables is not included in $\Gamma_c(\omega)$. The proof of this theorem relies on the following lemma, proved in Appendix

A, which involves boundary determination of the power and the product of sets of complex numbers.

Lemma 2.1: Let $D_1, D_2, \dots, D_\sigma$ be bounded and closed sets of complex numbers. Define, for integers k_i ,

$$D_i^{(k_i)} := \{d_i^{k_i} : d_i \in D_i : i = 1, 2, \dots, \sigma\}, \quad (2.20)$$

and

$$\prod_{i=1}^{\sigma} D_i^{(k_i)} := \left\{ \prod_{i=1}^{\sigma} d_i^{k_i} : d_i \in D_i : i = 1, 2, \dots, \sigma \right\} \quad (2.21)$$

Then

$$\prod_{i=1}^{\sigma} (\partial D_i)^{(k_i)} \supset \partial \left(\prod_{i=1}^{\sigma} D_i^{(k_i)} \right) \quad (2.22)$$

We can now prove the theorem.

Proof of Theorem 2.1: In Lemma 2.1, identify

$$D_i := \{p_{i0}(j\omega) + \gamma_i^T P_i(s) : \gamma_i \in \Gamma_i\} \quad (2.23)$$

and $\sigma = n$. Then the result follows by noting that every element in $\partial(D_i)$ has at least one preimage in an edge of Γ_i [14].

B. Result 2

From here onwards, in determining contributions to $\Gamma_c(\omega)$ from the interior of a given side of Γ , attention need only be restricted to sides Q of Γ on which at most one element of each Γ_i is a variable.

Call such a prototype side Q . Lump the variables defining this side into the vector $q = [q_1, \dots, q_k]$, $k \leq n$. Suppose the coefficient polynomial of each q_i in (2.19) [i.e., the corresponding $P_{ij}(s)$], evaluated at $s = j\omega$, is nonzero. (If the coefficient polynomial is evaluated to be zero, then the corresponding q_i need not be included in q ; see discussion later.) Then, through a suitable extraction of the frequency-dependent coefficients of q_i in (2.19), at every ω , the image of the side Q under the mapping defined in (2.19), i.e., $G(\omega, Q)$, can be described by a set of complex numbers

$$f(Q) := \left\{ f(q) = f_0 \prod_{i=1}^k (q_i + \alpha_i + j\beta_i)^{k_i} : q \in Q \right\} \quad (2.24)$$

where f_0 is a complex constant, α_i and β_i , $i = 1, 2, \dots, k$ are real constants, and $k_i \neq 0$ for all $i = 1, 2, \dots, k$.

Fact 1: Notice that, as ω varies, f_0 , α_i , and β_i vary in a rational fashion with ω . Further, $f(Q)$ is bounded because of Assumption 1.3 and the fact that the coefficient polynomial of each q_i in (2.19) evaluated at $s = j\omega$ is nonzero.

Thus, for example, in (2.18), consider the interior of the 2-side defined by $\gamma_{12} = \gamma_{12}^+$, $\gamma_{32} = \gamma_{32}^-$, $\gamma_{21} = \gamma_{21}^+$, $\gamma_{41} = \gamma_{41}^+$, $\gamma_{22} = \gamma_{22}^-$. In this case, $q_1 = \gamma_{11}$, $q_2 = \gamma_{31}$:

$$Q := \{q = [q_1, q_2]^T : q_i^- \leq q_i \leq q_i^+, i = 1, 2\}. \quad (2.25)$$

Further

$$f(q) = \frac{(\omega^2 - 2)}{[(1 - \omega^2 + j\omega)\gamma_{21}^+ + j\omega\gamma_{22}^-][0.5j\omega + \gamma_{41}^+]} \cdot \left[q_1 + \frac{(j\omega + 1)\gamma_{12}^+}{(\omega^2 - 2)} \right] [q_2 + \omega^2 + \gamma_{32}^-]. \quad (2.26)$$

Observe that, at $\omega^2 = 2$, the coefficient of γ_{11} ($= q_1$) is zero. Consequently, the representation in (2.26) is infeasible. However, we argue now that at this ω , no interior point of Q under consideration need be included in $\Gamma_c(\omega)$. This is because, at this ω , $H(\omega, \Gamma)$ is independent of $\gamma_{11} = q_1$. Thus, if we select γ_{11} at an extreme value, without changing the variable $\gamma_{31} = q_2$, one does not alter the value of $h(j\omega, \gamma)$. Thus, corresponding to each point q in the interior of Q , there lies a point q^* on a boundary of Q having precisely the same image in the value set space as does q . Then, in determining contributors to $\Gamma_c(\omega)$, one need not consider any point in the interior of Q , as these points are covered by points on the boundary of Q . This observation leads to the following formal fact.

Fact 2: Suppose Q is a side of Γ that conforms to the requirements of Theorem 2.1. Further suppose, with q_i the variables on Q , at some frequency ω , and some j , the coefficient polynomial of q_j in (1.3) is zero. Then, $\Gamma_c(\omega)$ will not contain any points in the interior of Q . Also, if the coefficient polynomial of each q_i is nonzero, then f_0 in (2.24) is nonzero.

Finally, observe, from the foregoing that the basis for limiting the sides that contribute to $\Gamma_c(\omega)$ is that the edges of each individual factor by themselves cover the value set boundary of that factor. Although, in general, an N -dimensional polytope has $N2^{N-1}$ edges, at a given frequency, at most $2N$ of these edges need be considered for constructing the value set boundary of the polytope. These special $2N$ edges are easily characterized (see [18]). Thus, the number of contributing sides is even smaller than that specified in Theorem 2.1. However, to prevent notational encumbrances, henceforth we will adhere to the somewhat conservative characterization given in Theorem 2.1.

Provided in (2.24), $\beta_i \neq 0, \forall i \in \{1, \dots, k\}$, we will call the affine line in (2.27), below, the line associated with Q

$$L_a(Q) := \{(q_1 q_2 \dots q_k)^T = \rho(\beta_1 \beta_2 \dots \beta_k)^T : \rho(\alpha_1 \alpha_2 \dots \alpha_k)^T : -\infty < \rho < \infty\}. \quad (2.27)$$

The situation where one or more of the β_i equal zero will be dealt with later. Observe that the intersection of $L_a(Q)$ with the interior of Q is given by the segment

$$L(Q) = \{q = (q_1 \dots q_k)^T : q_i = \rho\beta_i - \alpha_i, \forall i \in \{1, \dots, k\}, \rho^-(Q) < \rho < \rho^+(Q), q \in Q\} \quad (2.28)$$

where

$$\rho^-(Q) = \max_{i \in \{1, \dots, k\}} \min \left\{ \frac{q_i^+ + \alpha_i}{\beta_i}, \frac{q_i^- + \alpha_i}{\beta_i} \right\} \quad (2.29)$$

and

$$\rho^+(Q) = \min_{i \in \{1, \dots, k\}} \max \left\{ \frac{q_i^+ + \alpha_i}{\beta_i}, \frac{q_i^- + \alpha_i}{\beta_i} \right\} \quad (2.30)$$

where q_i^+ and q_i^- are the extreme values of the variable q_i . Note the following important facts.

Fact 3: If $\rho^+(Q) \leq \rho^-(Q)$, then this set is empty, in which case, as will be shown soon, the interior of Q contributes nothing to $\Gamma_c(\omega)$.

Fact 4: As the α_i, β_i depend on ω (Fact 1), the line $L(Q)$. Equally, while at some frequencies, $L(Q)$ may be empty, at others, it may well be.

Fact 5: As noted earlier, whenever Q conforms to the requirements of Theorem 2.1, so do all its boundaries. It is easy to see from the foregoing definitions that the line associated with a boundary of Q is, in fact, a projection of the above line onto this boundary.

We now present the main result of this section, proved in Appendix B.

Theorem 2.2: Consider Q a boundary of Γ obeying the conditions of Theorem 2.1, with the various quantities as defined in the foregoing and $f_0 \neq 0$ (see Fact 2).

i) Suppose in (2.24) that, for some $i \in \{1, \dots, k\}, \beta_i = 0$. Then for every q in the interior of Q such that $f(q) \in \partial(f(Q))$, there exists a q^* on an edge of Q such that $f(q) = f(q^*)$. ii) Suppose $\beta_i \neq 0, \forall i \in \{1, \dots, k\}$, and there exists q in the interior of Q such that $f(q) \in \partial(f(Q))$. Then $q \in L(Q)$. iii) Suppose, in addition to the conditions set out in ii)

$$\sum_{i=1}^n k_i = 0. \quad (2.31)$$

Then there exists q^* on a boundary of Q such that for all $q \in L(Q)$

$$f(q) = f(q^*). \quad (2.32)$$

Before illustrating this theorem with the example of (2.18), we highlight some of its features. First of all, if any $\beta_i = 0$, then no point in the interior of Q is included in the formation of $\Gamma_c(\omega)$. For, given any γ in the interior of Q obeying (2.16), there is a parameter vector on an edge of Γ that has the same image in the value set space as does γ . Since $\Gamma_c(\omega)$ already includes the edges of Γ , the image of this γ stands covered from the outset.

Likewise, if (2.31) holds, then all interior points of Q mapping to the value set boundary have the same image on this boundary, an image also shared by another parameter vector lying in the interior of a boundary of Q . Thus, these points need not be included as they will be covered when one considers the boundaries of Q .

Further, in the event that i), iii) of the theorem do not hold, then the critical subset contributed by interior points of Q lies exclusively on the associated line segment. Thus, indeed, at every ω , $\Gamma_c(\omega)$ comprised exclusively of line segments, at most one for each side conforming to the requirements of Theorem 2.1. Of course, these segments in general vary with ω , and should their intersection with an associated Q be empty, then the interior of that Q fails to contribute elements to $\Gamma_c(\omega)$.

Finally, we note that the equations describing the internal line segments do not depend on the powers μ_i and ν_i .

We now illustrate these results by invoking the example of (2.18). In the example, assume $\omega = 2$, $\gamma_{1j}^- = 0$, and $\gamma_{1j}^+ = 1$.

Consider first any side on which γ_{31} or γ_{32} are variables [recall that if both were variables, then such a side will not contribute an interior point to $\Gamma_c(\omega)$]. Then i) of Theorem 2.2 holds, and no point in the interior of this boundary is included in $\Gamma_c(\omega)$.

Next, consider the 2-side defined by $\gamma_{31} = \gamma_{41} = 0$ and $\gamma_{32} = \gamma_{12} = \gamma_{22} = 1$. Then, on this boundary, with $q_1 = \gamma_{11}$ and $q_2 = \gamma_{21}$, (2.31) holds. Consequently, this side too contributes no interior points to $\Gamma_r(\omega)$.

Finally, consider the 3-side $\gamma_{12} = \gamma_{21} = 1$ and $\gamma_{31} = \gamma_{32} = 0$. Choose $q_1 = \gamma_{11}$, $q_2 = \gamma_{22}$, and $q_3 = \gamma_{41}$. Then, we have

$$f(q) = 4j \frac{q_1 + 0.5 + j}{[q_2 + 1 + 1.5j][q_3 + j]}. \quad (2.33)$$

Then the interior points of such a 3-side to be included in $\Gamma_r(\omega)$ are given by the segment

$$L(Q) = \{[q_1, q_2, q_3] = \rho[1, 1.5, 1] - [0.5, 1, 0] : 2/3 < \rho < 1\}. \quad (2.34)$$

C. Hurwitz Invariance

Having shown that $\partial(H(j\omega, \Gamma))$ is mapped from the critical line segments in Γ , we now turn to verifying the Hurwitz invariance of (1.7). Essentially, $\partial(H(j\omega, \Gamma))$ must be checked for zero exclusion.

In view of the definition of $\Gamma_r(\omega)$, the Hurwitz invariance of (1.7) is equivalent to the requirement that: i) at least one member of (1.7) is Hurwitz, and ii) that at every ω and all $\gamma \in \Gamma_r(\omega)$

$$h(j\omega, \gamma) \neq 0. \quad (2.35)$$

Since at every ω , $\Gamma_r(\omega)$ comprises the edges of Γ and certain ω -specific line segments, to check for Hurwitz invariance, it suffices to check that all transfer functions corresponding to the edges of (1.7) are Hurwitz, and that the image, in the value set space, of each aforementioned ω -specific line segment is zero exclusive. The principal contribution of this section is to demonstrate that the zero exclusivity of these segments can be verified by checking certain piecewise continuous and piecewise differentiable functions of ω for avoidance of the negative real axis.

To avoid notational complexities, we show this fact in a somewhat informal fashion. Consider a side Q of Γ , which meets the requirements implicit in Theorem 2.1. Recall that for each such Q , potentially there exists an internal line segment that contributes to $\Gamma_r(\omega)$.

For a prototype Q , the internal line segment is as given in (2.28)–(2.30), with the value set $G(\omega, \Gamma)$ as in (2.24). Observe that the various quantities in these equations depend on ω , and that at certain frequencies, this segment could be empty (Facts 3 and 4), or may not be a member of $\Gamma_r(\omega)$ (e.g., when i) and/or iii) of Theorem 2.2 holds, or when f_0 (see (2.24) and Fact 2) or $g_0(j\omega)$ is zero. Call the set of frequencies at which $L(Q)$ is a nonempty subset of $\Gamma_r(\omega)$, $\Omega(Q)$. Then we need to check that the image in the value set space of $L(Q)$ is zero exclusive at all $\omega \in \Omega(Q)$. Direct substitution of (2.28)–(2.30) into (2.24), together with the relation among $G(\omega, \Gamma)$, $H(\omega, \Gamma)$, and (2.24), shows that at all $\omega \in \Omega(Q)$, the image of $L(Q)$ is given by (2.36)–(2.38). In these equations, to avoid confusion, unlike (2.28)–(2.30) and (2.24) the various quantities have been expressed explicitly as functions of ω

and Q

$$h(j\omega, \gamma) = 1 + F(Q, \omega)(j + \rho)^{M(Q)}; \quad \rho^-(Q, \omega) < \rho < \rho^+(Q, \omega) \quad (2.36)$$

where

$$F(Q, \omega) = g_0(j\omega)f_0(Q, \omega) \prod_{i=1}^{k(Q)} \beta_i(Q, \omega)^{k_i(Q)} \quad (2.37)$$

and

$$M(Q) = \sum_{i=1}^{k(Q)} k_i(Q). \quad (2.38)$$

Recall that the choice of Q (see (2.31) and the discussion subsequent to Theorem 2.2) ensures that $M(Q) \neq 0$. Moreover, from the definition of $\Omega(Q)$,

$$F(Q, \omega) \neq 0, \quad \forall \omega \in \Omega(Q) \quad (2.39)$$

and

$$\rho^-(Q, \omega) < \rho^+(Q, \omega), \quad \forall \omega \in \Omega(Q). \quad (2.40)$$

We claim that the bounds $\rho^+(Q, \omega)$ and $\rho^-(Q, \omega)$ are continuous and piecewise differentiable in these frequency ranges. To see this, we note that $\alpha_i(Q, \omega)$ and $\beta_i(Q, \omega)$ [see (2.24)] are continuous and differentiable. The minmax functions in (2.29)–(2.30) preserve continuity, and the lack of differentiability occurs at the isolated frequencies where the minmax selections “change.”

Thus, from (2.36), one can see that (2.35) holds for all γ in the interior of this prototype Q and belonging to $\Gamma_r(\omega)$ iff

$$\mu(Q, \omega) := (-F(Q, \omega))^{-1/M(Q)} - j \notin (\rho^-(Q, \omega), \rho^+(Q, \omega)), \quad \forall \omega \in \Omega(Q). \quad (2.41)$$

In the above, if $M(Q) \neq \pm 1$, then all the roots of $(-F(Q, \omega))^{-1/M(Q)}$ should be considered. Define the functions

$$\xi(Q, \omega) = \begin{cases} \frac{\mu(Q, \omega) - \rho^-(Q, \omega)}{\mu(Q, \omega) - \rho^+(Q, \omega)} & \forall \omega \in \Omega(Q) \\ 1 & \text{otherwise.} \end{cases} \quad (2.42)$$

The functions $\xi(Q, \omega)$ defined above are piecewise continuous and differentiable. Moreover, $\forall \omega \in \{(-\infty, \infty) \cap \Omega(Q)\}$, $\xi(Q, \omega) = 1$. Recall that, at these frequencies, there are no contributions from the interior of Q to $\Gamma_r(\omega)$, and (2.41) need not be checked. Furthermore, the required zero exclusion of $h(j\omega, \gamma)$ for all γ in the interior of this prototype Q and belonging to $\Gamma_r(\omega)$ is equivalent to

$$\xi(Q, \omega) \notin (-\infty, 0). \quad (2.43)$$

We therefore have the following theorem.

Theorem 2.3: The family of transfer functions $H(\Gamma)$ described in (1.7) is Hurwitz invariant if and only if the following conditions hold:

a) $h(s, \gamma)$ is Hurwitz for all γ in the edges of Γ ; b) For each $\omega \in \mathbb{R}$, and all Q satisfying the requirements of Theorem 2.1, the piecewise continuous and differentiable functions $\xi(Q, \omega)$ defined in (2.42) avoid the negative real axis.

III. REAL ZERO-POLE-GAIN VARIATIONS

We now consider the special case of (1.2) where the certain parameters are real poles, zeros, and gains.

Consider the family of transfer function $H(\Gamma)$ described by (1.8) and (1.2). The parameters d and λ_i vary independently within given bounds, i.e.,

$$d^- \leq d \leq d^+; \lambda_i^- \leq \lambda_i \leq \lambda_i^+, \quad i = 1, 2, \dots, n-1 \quad (3.44)$$

and

$$\gamma \in \Gamma = [\lambda_1^-, \lambda_1^+] \times \dots \times [\lambda_{n-1}^-, \lambda_{n-1}^+] \times [d^-, d^+]. \quad (3.45)$$

Notice that Assumption 1.3 implies that if a given k_i is negative, the corresponding interval of λ_i cannot include zero.

Recall, from Section II, that apart from the edges of Γ , we need to consider an internal segment associated with each side of Γ , which conforms to the requirements of Theorem 2.1. Observe that every k -side Q of Γ , $k \geq 1$ conforms to this requirement. Consider, now, two possible cases of such k -sides Q .

Case I: The interior of Q has d as a variable.

Observe that, with $q_1 = d$ in (2.24), $\beta_1 = 0$. Thus, because of i) of Theorem 2.2, no parameter vector in the interior of such a Q is included in $\Gamma_c(\omega)$. Consequently, for each $\gamma \in \Gamma_c(\omega)$, d is at an extreme value.

Case II: The variables of Q exclude d

Assume the variables in Q are for some $S \subset \{1, \dots, n-1\}$, λ_i , $i \in S$. Observe, in (2.24), that each $\beta_i = \omega$ and $\alpha_i = 0$. From i) of Theorem 2.2, one concludes that at $\omega = 0$, $\Gamma_c(\omega)$ comprises only the edges of Γ . Also from Theorem 2.2, when $\omega \neq 0$, a parameter vector in the interior of Q is in $\Gamma_c(\omega)$ only if it obeys

$$\lambda_i = \rho\omega, \forall \rho^-(Q) < \rho < \rho^+(Q), \quad i \in S \quad (3.46)$$

where

$$\rho^-(Q) = \max_{i \in S} \lambda_i^- \quad (3.47)$$

and

$$\rho^+(Q) = \min_{i \in S} \lambda_i^+ \quad (3.48)$$

In addition [ii) of Theorem 2.2], we must have

$$\sum_{i \in S} k_i \neq 0. \quad (3.49)$$

Thus, we have the following theorem.

Theorem 3.1: Consider the parameter box Γ in \mathbb{R}^n given in (3.45). Then $\Gamma_c(\omega)$ is frequency invariant, and comprises the edges of Γ , and all line segments of the form in (3.51)–(3.53), for every $S \subset \{1, \dots, n-1\}$, obeying (3.49) and

$$\max_{i \in S} \lambda_i^- \leq \lambda_j \leq \min_{i \in S} \lambda_i^+, \quad \forall j \in S. \quad (3.50)$$

$$\lambda_i = \lambda_j, \quad \forall i, j \in S \quad (3.51)$$

$$\lambda_j \in \{\lambda_j^+, \lambda_j^-\}, \quad \forall j \notin S \quad (3.52)$$

$$d \in \{d^+, d^-\}.$$

Furthermore, the family of functions $H(\Gamma)$ is Hurwitz invariant if and only if $h(s, \gamma)$ is Hurwitz invariant on the 45-degree line segments and the edges of Γ .

A. A Special Case

Notice that if some of the λ_i vary in nonoverlapping intervals, then the number of critical segments reduces, as can be easily seen from (3.51). A case of special interest is when all the poles and zeros vary in intervals that do not overlap. In such an event, the projections mentioned above are empty, and edges suffice for value set boundary and Hurwitz invariance. One thus obtains the corollary below, itself a variation of the results (see Remark 3.3 for comparison) of [25], [26].

Corollary 3.1 (An Edge Theorem): Consider the parameter box Γ in (3.45) and the family of function $H(\Gamma)$ described by (1.8). Suppose $(\lambda_i^-, \lambda_i^+) \cap (\lambda_j^-, \lambda_j^+)$ are empty for all $1 \leq i < j < n$. Then the boundary of the value set $H(\omega, \Gamma)$ at any frequency ω is mapped from the edges of Γ . Furthermore, $H(\Gamma)$ is Hurwitz invariant if and only if all the edges of $H(\Gamma)$ are Hurwitz invariant.

Remark 3.1: For overlapping intervals of λ_i , however, the 45-degree line segments are indeed necessary. To show this, we provide the following simple example. Consider

$$h(s, \lambda_1, \lambda_2) = \frac{0.1(0.8s^2 + 0.8s + 4.5)(s + \lambda_1)(s + \lambda_2)}{s^4 + 10s^3 + 11.8s^2 + 11.8s + 0.2} \quad (3.54)$$

$$\lambda_1, \lambda_2 \in [-30, 0].$$

In this example, there are four edges with the associated transfer functions given by

$$h(s, 0, \lambda_2), \lambda_2 \in [-30, 0],$$

$$h(s, -30, \lambda_2), \lambda_2 \in [-30, 0],$$

$$h(s, \lambda_1, 0), \lambda_1 \in [-30, 0];$$

$$h(s, \lambda_1, -30), \lambda_1 \in [-30, 0].$$

There is only one 45-degree line segment given by

$$h(s, \lambda, \lambda), \lambda \in [-30, 0].$$

It is straightforward to verify that the transfer functions on all the edges are Hurwitz, but some on the 45-degree line segment are not. For example, at $\lambda = -15$, $h(s, \lambda, \lambda)$ has the unstable zeros $0.2424 \pm 1.8914j$.

Remark 3.2: In actual fact, the result in [26] is stronger. It requires that only $2n$ edges be considered. This fact is also recoverable from [27], which also employs the Jacobian rank deficiency approach underlying our development.

Remark 3.3: Neither [26] nor [25] deals with the overlapping root situation considered in Theorem 3.1 above; nor do [26] and [25] permit the structural preservation of pole-zero multiplicities.

IV. COMPLEX ZERO-POLE-GAIN VARIATIONS

In this section, the complex zero-pole-gain variations case of (1.9) is treated. As before, $\Gamma_c(\omega)$ comprise line segments.

We note that the case $\omega = 0$ is trivial. At this frequency, for every Q obeying Theorem 2.1, all the β_i in (2.24) are zero. Thus, from Theorem 2.2, $\Gamma_c(0)$ comprises the edges of Γ only, and $\omega \neq 0$ will be assumed in the sequel.

The characterization of the line segments follows as in Theorems 2.1 and 2.2. In this section, we will focus mainly on showing that these frequency-dependent line segments obey the confinement rules stated in the Introduction. To this end, we consider the various possible Q obeying Theorem 2.1, and consider how the associated line segments change with frequency. Observe, as in iii) of Theorem 2.2, that certain sides Q can be eliminated according to the combinations of powers of their defining factors. In the sequel, we will only consider Q on which (2.31) does not hold. Then the only restriction that Theorem 2.2 places on Q is that for no i can both a_i and b_i simultaneously be variables. Consider, now, the following possible cases of Q .

Case 1: d is a variable on Q . As in Section III, such a Q does not contribute interior points to $\Gamma_c(\omega)$.

Here onwards, we assume d is at an extreme value. In the sequel, without loss of generality, all nonvariables will be denoted with a superscript " \pm ," and the λ_i will always be considered as potential variables.

Case 2: No a_i nor any b_i is a variable. As in Section III, an interior point of Q is in $\Gamma_c(\omega)$ only if it is on a frequency-invariant 45-degree line segment similar to that in Section III. The set of all such segments will be called L_1 .

Case 3: No a_i is a variable, but some b_i are. Suppose, as before, that q_i are the variables. Then if $q_i = \lambda_i$, in the corresponding factor in (2.24), $\alpha_i = 0$ and

$$\beta_i = \omega. \quad (4.55)$$

Further, if $q_i = b_i$, then in the corresponding factor in (2.24)

$$\alpha_i = -\omega^2 \quad (4.56)$$

and

$$\beta_i = \omega a_i^\pm. \quad (4.57)$$

Thus, on the line segment associated with Q , the variable λ_i and b_i obey

$$\lambda_i = 0 + \rho\omega \quad (4.58)$$

$$b_i = -\omega^2 + \rho\omega a_i^\pm. \quad (4.59)$$

Defining $\rho_1 = \rho\omega$ and $\rho_2 = \omega^2$, one finds that all interior points of Q to be included in $\Gamma_c(\omega)$ lie on the two-dimensional plane,

$$\gamma = \rho_1 C_1 + \rho_2 C_2 \quad (4.60)$$

where $C_1, C_2 \in \mathbb{R}^N$ are frequency-independent constant vectors.

Case 4: No b_i is a variable. If $q_i = a_i$, then in the corresponding factor in (2.24)

$$\alpha_i = 0 \quad (4.61)$$

and

$$\beta_i = \omega - \omega^{-1} b_i^\pm \quad (4.62)$$

Then, as long as all the $\beta_i \neq 0$, on the line segment associated with Q , the variable λ_i obey (4.58) and a_i obey

$$a_i = 0 + \rho(\omega - \omega^{-1} b_i^\pm) \quad (4.63)$$

Thus, again, this segment is confined to a plane of the form of (4.60) with different C_1 and C_2 . The corresponding ρ_1 and ρ_2 in this case should be defined by $\rho_1 = \rho\omega$ and $\rho_2 = \rho\omega^{-1}$.

Case 5: For some i , a_i is a variable, for some others, b_i is a variable. As before, on the line segment associated with Q , the variable λ_i , b_i , and a_i , respectively, obey (4.58), (4.59), and (4.63). Then with $\rho_1 = \rho\omega$, $\rho_2 = \omega^2$, $\rho_3 = \rho\omega^{-1}$, and C_i , $i = 1, 2, 3$ frequency-independent constant vectors (C_1, C_2 different from those in Case 3), this segment can be seen to lie on a three-dimensional plane of following form

$$\gamma = \rho_1 C_1 + \rho_2 C_2 + \rho_3 C_3 \quad (4.64)$$

The set of two-dimensional planes covered by Cases 3 and 4 will be denoted L_2 , while the set of boxes in Case 5 will be called L_3 . The zero exclusion principle then immediately yields the following theorem.

Theorem 4.1: With L_1 , L_2 , and L_3 defined as above, the family of transfer functions $H(\Gamma)$ described by (1.9) is Hurwitz invariant if and only if all the edges, the internal segments in L_1 , the rectangles in L_2 , and the boxes in L_3 are Hurwitz invariant.

We note that the sets in L_1 , L_2 , and L_3 are easily characterized from the critical frequency-dependent segments they contain. As in Section III, many of these segments, rectangles, and boxes will be empty.

V. CONCLUSIONS

In this paper, we have considered robust stability verification of linear time-invariant systems characterized by the class of nonlinear parametric perturbations given in (1.7). In light of the zero exclusion principle, our focus has been on both the verification of Hurwitz invariance and the construction of value sets for the system characteristic function. The main result on construction of value sets shows that for the class of nonlinear parametric perturbations given in (1.7), the value set boundary of the characteristic function at each fixed frequency is determined by the edges and some frequency-dependent internal line segments in the parameter box. This result greatly simplifies the construction of the value sets, and considerably eases the task of robust stability verification. Indeed, a piecewise continuous and differentiable frequency sweeping function is found such that Hurwitz invariance of the set in question is equivalent to this function's avoidance of the negative real axis. For the special case of real zero-pole gain variations, the critical line segments are all frequency independent; hence, the determination of robust

stability is even simpler. For the case of complex zero-pole variations, the critical internal lines are either frequency dependent or vary in certain (two-dimensional) planes or (three-dimensional) boxes.

The key device used in our development concerns a Jacobian function which helps isolate certain critical subsets of the parameter box whose elements collectively determine the value set boundary. This Jacobian-based technique may provide an effective tool for the robust stability analysis of sets which are even more general than the ones considered here. Indeed, a similar device is featured in [7], [28], [27] in relation to the multilinear problem.

APPENDIX A

PROOF OF LEMMA 2.1

We prove this result in two parts. First, we show that for D a bounded and closed set of complex numbers,

$$(\partial D)^{(k)} \supset \partial(D^{(k)}). \quad (\text{A.65})$$

We then show that for $D_1, D_2, \dots, D_\sigma$ bounded and closed sets of complex numbers, with

$$\begin{aligned} \prod_{i=1}^{\sigma} D_i &:= \left\{ \prod_{i=1}^{\sigma} d_i : d_i \in D_i : i = 1, 2, \dots, \sigma \right\} \\ \prod_{i=1}^{\sigma} (\partial D_i) &\supset \partial \left(\prod_{i=1}^{\sigma} D_i \right). \end{aligned} \quad (\text{A.66})$$

Together, these two parts prove the result.

Proof of Part 1: Given any complex number $z \in \partial(D^{(k)})$, we need to show that $z \in (\partial D)^{(k)}$. By the boundedness of $D^{(k)}$ (from that of D), there exists a sequence of complex numbers $\{z_j\}$ outside $D^{(k)}$ such that $z_j \rightarrow z$ as $j \rightarrow \infty$. Since $D^{(k)}$ is closed (as D is closed), there exists some $d \in D$ such that $d^k = z$. Define $d_{1j}, d_{2j}, \dots, d_{kj}$ to be the k th roots of z_j . Then for all i, j , $d_{ij} \notin D$ because $z_j = (d_{ij})^k \notin D^{(k)}$. On the other hand, the sequence $\{d_{ij}\}$ has a subsequence converging to $d \in D$. It follows that $d \in \partial D$, or equivalently, $z = d^k \in (\partial D)^{(k)}$.

Proof of Part 2: Given any complex number $z \in \partial(\prod_{i=1}^{\sigma} D_i)$, we need to show $z \in \prod_{i=1}^{\sigma} (\partial D_i)$. This clearly holds if one of the D_i is just $\{0\}$. So, assume every D_i contains at least one nonzero element. This implies that every ∂D_i has at least one nonzero element. By the boundedness of $(\prod_{i=1}^{\sigma} D_i)$ (from that of D_i), there exists a sequence of complex numbers $\{z_j\}$ outside $(\prod_{i=1}^{\sigma} D_i)$ such that $z_j \rightarrow z$ as $j \rightarrow \infty$. Since $(\prod_{i=1}^{\sigma} D_i)$ is closed (as D_i is closed), there exist some $d_i \in D_i$, $i = 1, 2, \dots, \sigma$ such that $z = d_1 d_2 \cdots d_\sigma$. If z is zero, it follows that all d_i , except for one which is set to zero, can be chosen to be a nonzero boundary point of ∂D_i . In the sequel, we assume that at most one d_i is zero. We claim that $d_i \in \partial D_i$, $i = 1, 2, \dots, \sigma$. Without loss of generality, consider d_1 . From the foregoing, one can choose $d_1 \in \partial D_1$ if one of the other d_i is zero. On the other hand, if the remaining d_i are nonzero, we define

$$d_{1j} := d_2 \cdots d_\sigma \quad j = 1, 2, \dots \quad (\text{A.67})$$

Then, d_{1j} converge to d_1 as $j \rightarrow \infty$ because d_i are bounded. Yet $d_{1j} \notin D_1$ for all j because $z_j = d_1 d_2 \cdots d_\sigma \notin D$. Therefore, $d_1 \in \partial D_1$. Similarly, it can be shown that $d_i \in \partial D_i$ for all other i ; hence, the result holds.

APPENDIX B

PROOF OF THEOREM 2.2

To prove the theorem, we need three lemmas. The first of these is well known (see, e.g., [28], [27]), and hence its proof is omitted.

Lemma B.1: Consider the hyperrectangle

$$Q := \{q = (q_1 q_2 \cdots q_m)^T : q_i^- \leq q_i \leq q_i^+, i = 1, 2, \dots, m\} \subset \mathbb{R}^m \quad (\text{B.68})$$

and a differentiable complex valued function $f(\cdot) : Q \rightarrow \mathbb{C}$ with all its first derivatives continuous. In the sequel, we will denote

$$f(Q) := \{f(q) : q \in Q\}. \quad (\text{B.69})$$

Then a point q in the interior of Q obeys $f(q) \in \partial f(Q)$ only if the following Jacobian matrix, evaluated at q , has rank less than two

$$J_f(q) := \begin{bmatrix} \operatorname{Re} \left(\frac{\partial f(q)}{\partial q_1} \right) & \operatorname{Re} \left(\frac{\partial f(q)}{\partial q_2} \right) & \operatorname{Re} \left(\frac{\partial f(q)}{\partial q_m} \right) \\ \operatorname{Im} \left(\frac{\partial f(q)}{\partial q_1} \right) & \operatorname{Im} \left(\frac{\partial f(q)}{\partial q_2} \right) & \operatorname{Im} \left(\frac{\partial f(q)}{\partial q_m} \right) \end{bmatrix} \quad (\text{B.70})$$

It should be noted that the lemma above is of little value when $f(Q)$ degenerates to a real segment. For when $f(\cdot)$ is real, the second row of the matrix in (B.70) is identically zero, and hence rank deficiency occurs for all q . For such a case, we have the following result.

Lemma B.2. Consider the hyperrectangle Q in (B.68) and a real continuous function $f(\cdot) : Q \rightarrow \mathbb{R}$. Then $f(Q)$ can be mapped from the edges of Q if and only if the two extreme points (minimum and maximum) of $f(Q)$ can be mapped from the edges of Q .

Proof: Necessity is obvious. To prove sufficiency, suppose q^1 and q^2 are the edge points corresponding to the extreme points of $f(Q)$. Observe that q^1 and q^2 can be connected by a path entirely in the edges of Q . By continuity of $f(\cdot)$, the image of this path, which is a subset of the edges, covers the whole of $f(Q)$.

The final lemma needed is given below.

Lemma B.3: Consider the hyperrectangle Q and the bounded set $f(Q)$ in (2.24) with $\beta_i = 0, \forall i$. Then each point in $f(Q)$ has at least one preimage in the edges of Q .

Proof: Observe that the result will not be affected by the value of f_0 . So choose $f_0 = 1$. Using Lemma B.2, we simply need to show that both the minimum and the maximum of $f(Q)$ have preimages in the edges of Q . Take the minimum, for example, as the maximum can be dealt with in the same manner. Denote the minimum by f_m and consider the two cases: 1) $f_m = 0$; and 2) $f_m \neq 0$. Case 1) implies that some $q_i + \alpha_i$ is zero with $k_i > 0$. In this case, it is obvious that setting the other q_i at extreme values does not change f_m . In Case 2), we claim that all the q_i must take their extreme value. Indeed, if some q_i were not at its extreme, f_m would not be

minimum because we can decrease the value of the function by increasing or decreasing this q_i . Therefore, in both cases, f_m can be achieved at an edge point.

Proof of Theorem 2.2: Consider a point q in the interior of Q such that

$$f(q) \in \partial f(Q). \quad (\text{B.71})$$

Proof of i): Suppose first that $\beta_i = 0, \forall i$. Then, Lemma B.3 proves the conclusions of i). Next, suppose that at least one β , without loss of generality β_1 , is nonzero. Suppose also, that for some q in the interior of Q , $f(q) \in \partial f(Q)$. Then from Lemma B.1, $\forall i, j \in \{1, \dots, k\}$, there exist real scalars x and y , not both zero, such that

$$x \frac{\partial f(q)}{\partial q_i} = y \frac{\partial f(q)}{\partial q_j}. \quad (\text{B.72})$$

Thus, from (2.24), the above gives

$$\frac{k_i f(q)}{q_i + \alpha_i + j\beta_i} = \frac{k_j f(q)}{q_j + \alpha_j + j\beta_j} \quad (\text{B.73})$$

which simplifies to

$$(q_i + \alpha_i)\beta_j = (q_j + \alpha_j)\beta_i. \quad (\text{B.74})$$

Now, suppose that at least one $\beta_i, i \neq 1$, without loss of generality β_2 , equals zero. Then with $i = 1, j = 2$, one has from (B.74) that

$$q_2 + \alpha_2 = 0. \quad (\text{B.75})$$

Thus, $f(q) = 0$. Moreover, this holds no matter what value the $q_i, i \neq 2$ take. Setting these $q_i, i \neq 2$ to their respective extreme values, one proves i).

Proof of ii): Follows from (B.74).

Proof of iii): Direct substitution of (B.74) into (2.24) yields

$$f(q) = c(\rho + j)^M \quad (\text{B.76})$$

where c is a suitable complex constant and the integer M is given by

$$M = \sum_{i=1}^k k_i. \quad (\text{B.77})$$

Thus, when $M = 0$, $f(q)$ has the same value on the whole segment $L(Q)$. Thus, by continuity, the image of this entire segment is covered by any one of its endpoints which is on a boundary of Q .

Since 1992, Dr. Blondel has held research positions at the University of Oxford and at the Royal Institute of Technology, Stockholm, where he was the 1993-1994 Göran Gustafsson Research Fellow.

He is currently with INRIA Rocquencourt (the French National Research Institute in Computer Science and Applied Mathematics) near Paris. His current research interests include robust control, linear systems, analytic function theory, and computational complexity of control problems.

Discrete-Time Observers for Singularly Perturbed Continuous-Time Systems

Kenneth R. Shouse, *Member, IEEE*, and David G. Taylor, *Member, IEEE*

Abstract—The use of discrete-time observers for nonlinear singularly perturbed continuous-time systems is explored. The observer design approach is based on inversion of state-to-measurement maps. The two-time-scale nature of the system is exploited by constructing separate reduced-order observers for the approximate slow and fast subsystems, using multirate measurements and computation. The reduced-order observers are compared to a full-order observer designed for the same system. The comparison shows that although the reduced-order observers exhibit some approximation error, they also result in reduced computational requirements if the inversion is performed on-line, reduced memory requirements if the inversion is implemented by look-up table and reduced stiffness. The trade-off between accuracy and implementation requirements always favors the reduced-order approach for systems with significant separation of time scales. Numerical examples are provided, including a case-study of an observer-based control system for permanent-magnet synchronous motors.

I. INTRODUCTION

IN this paper, the problem of constructing state observers for nonlinear continuous-time singularly perturbed systems is investigated. One observer design concept that may be applied to such systems is based on inversion of the so-called state-to-measurement map (a set of algebraic equations) [4], [5]. Since this design concept is widely applicable, requiring only that standard observability assumptions be satisfied by the discrete-time representation of the system, this paper will adopt a map-inversion approach and will adhere to the basic principles outlined in [4], [5].

Unfortunately, when this full-order observer is applied to singularly perturbed systems, several difficulties are encountered. First, the discretization of the continuous-time system must be carried out at a sufficiently small sampling interval to accurately model the fast states, even though the states of primary interest may be the slow ones. This necessitates the use of faster sampling devices and faster processors than would otherwise be needed. Second, because of this separation in time scales, the equations which must be inverted to construct the observer are stiff. This means that accurate numerical solution is more difficult than if the system evolved in a single time scale.

Manuscript received June 12, 1992; revised May 20, 1993. Recommended by Past Associate Editor, A. Arapostathis. This work was supported in part by National Science Foundation Grants ECS-8909329, ECS-9007778, and ECS-9158037 and by Clifton Precision South, a division of Litton Systems, Inc.

IEEE Log Number 9407564.

The two-time-scale nature of the system can be exploited by decomposing the problem into one of designing separate reduced-order observers for the approximate slow and fast subsystems. This decomposition is quite straightforward for systems without inputs, but can also be applied when inputs are present with some technical modifications. The outputs of the two reduced-order observers can be used to estimate the state of the original system. Since the slow and fast observers are separate algorithms, they may be implemented using multirate measurements and computation. Consequently, the computational and/or memory requirements for state-to-measurement map inversion are significantly reduced from those of the full-order observer, and the numerical stiffness is relieved.

All the benefits of the reduced-order observers are achieved through a trade-off with accuracy. The reduced-order observers are only approximate, but each source of observation error vanishes as the singular perturbation parameter tends to zero. To demonstrate the practical value of reduced-order observers for feedback control, the paper concludes with a detailed case-study on velocity regulation of permanent-magnet synchronous motors with only stator current measurements.

II. FULL-ORDER ANALYSIS

In this section, the full-order observer for singularly perturbed autonomous systems is analyzed. This analysis is presented to provide a reference for comparison with the reduced-order observers that follow.

A The Full-Order Observer

We follow precisely the procedure recommended in [4], [5]. Consider the continuous-time nonlinear system

$$\dot{x} = f_1(x, z) \quad (2.1)$$

$$\dot{z} = f_2(x, z) \quad (2.2)$$

$$y = h(x, z) \quad (2.3)$$

where $x \in \mathcal{R}^N$, $z \in \mathcal{R}^M$, $y \in \mathcal{R}^Q$, $\epsilon > 0$ is a small parameter and the dot denotes differentiation with respect to time t . It is assumed that f_1 , f_2 and h are analytic, that unique solutions $x(t)$ and $z(t)$ exist, and that y is the only measured quantity. For notational convenience the representation

$$\dot{w} = f(w) := \begin{bmatrix} f_1(w_1, w_2) \\ \frac{1}{\epsilon} f_2(w_1, w_2) \end{bmatrix} \quad (2.4)$$

$$y = h(w) := h(w_1, w_2) \quad (2.5)$$

is used, where $w = [w_1' w_2']'$ with $w_1 := x$ and $w_2 := z$.

Discretizing this system at the instants $t = \ell\epsilon T$ where T is suitably chosen on the basis of the x dynamics, one obtains

$$w[\ell + 1] = F(w[\ell]) \quad (2.6)$$

$$y[\ell] = h(w[\ell]) \quad (2.7)$$

here $w[\ell] := w(\ell\epsilon T)$, $y[\ell] := y(\ell\epsilon T)$

$$F(w[\ell]) := \sum_{i=0}^{\infty} \frac{(\epsilon T)^i}{i!} [L_f^i w]_{w=u[\ell]} \quad (2.8)$$

and where the notation $L_f^i w$ denotes the Lie derivative operator L_f^i applied to each component of w [10].

Associated with the system (2.6)–(2.7) is the full-order state-to-measurement map

$$H(w) := \begin{bmatrix} h(w) \\ h \circ F(w) \\ \vdots \\ h \circ F^{N+M-1}(w) \end{bmatrix} \quad (2.9)$$

where F^i denotes F composed with itself i times. This state-to-measurement map satisfies

$$Y[\ell] = H(w[\ell - N - M + 1]) \quad (2.10)$$

where $Y[\ell]$ is the block of measurements

$$Y[\ell] := \begin{bmatrix} y[\ell - N - M + 1] \\ \vdots \\ y[\ell] \end{bmatrix} \quad (2.11)$$

Assumption 2.1 For some set $D_u \subseteq \mathcal{R}^{N+M}$, there exists a function $H^{-1}: \mathcal{R}^{(N+M)Q} \rightarrow \mathcal{R}^{N+M}$ such that $w \in D_u$ and $Y = H(w)$ imply $w = H^{-1}(Y)$.

Under Assumption 2.1, the full-order observer for the system (2.6)–(2.7) [and hence for the system (2.4)–(2.5)] is given by

$$\hat{w}[\ell] := F^{N+M-1} \circ H^{-1}(Y[\ell]) \quad (2.12)$$

This nonlinear observer is deadbeat on D_u , i.e., $w[\ell] = \hat{w}[\ell]$ for all $\ell \geq N + M - 1$ if $w[\ell - N - M + 1] \in D_u$.

To gain insight into the observer design given above and to aid in the analysis to follow, the specialization of this observer to the linear autonomous case is useful. Consider the system (2.4)–(2.5) defined by $f(w) = Aw$ and $h(w) = C'w$, where

$$A := \begin{bmatrix} A_{11} & A_{12} \\ \frac{1}{\epsilon}A_{21} & \frac{1}{\epsilon}A_{22} \end{bmatrix} \quad (2.13)$$

$$C' := [C'_1 \quad C'_2]. \quad (2.14)$$

Discretizing at the instants $t = \ell\epsilon T$ yields the model (2.6)–(2.7) with $F(w[\ell]) = \Phi w[\ell]$ and $h(w[\ell]) = C'w[\ell]$ where $\Phi := \exp(A\epsilon T)$. The specialization of Assumption 2.1 simply requires that the observability matrix

$$\mathcal{O} := \begin{bmatrix} C' \\ C'\Phi \\ \vdots \\ C'\Phi^{N+M-1} \end{bmatrix} \quad (2.15)$$

have full column rank. In this case, the full order observer

$$\hat{w}[\ell] := \Phi^{N+M-1}(\mathcal{O}'\mathcal{O})^{-1}\mathcal{O}'Y[\ell]$$

which has the deadbeat property $\hat{w}[\ell] = w[\ell]$ for $\ell \geq N + M - 1$.

B Full-Order Observer Stiffness

The full-order observer for a singularly perturbed system is inherently stiff. To see this, consider the linear system (2.13)–(2.14). To this system, apply the diagonalizing transformation [8]

$$\begin{bmatrix} \xi \\ \eta \end{bmatrix} := \begin{bmatrix} I_N - \epsilon L_2 L_1 & -\epsilon L_2 \\ L_1 & I_M \end{bmatrix} \begin{bmatrix} r \\ z \end{bmatrix} \quad (2.17)$$

where L_1 and L_2 solve

$$A_{21} - A_{22}L_1 + \epsilon L_1 A_{11} - \epsilon L_1 A_{12}L_1 = 0 \quad (2.18)$$

$$\epsilon(A_{11} - A_{12}L_1)L_2 - L_2(A_{22} + \epsilon L_1 A_{12}) + A_{12} = 0 \quad (2.19)$$

Note that L_1 and L_2 are guaranteed to exist provided that A_{22} is nonsingular (i.e., that the system is in “standard” form), and that ϵ is sufficiently small [8]. The result is

$$\begin{bmatrix} \dot{\xi} \\ \dot{\eta} \end{bmatrix} = \begin{bmatrix} A_\xi & 0 \\ 0 & A_\eta \end{bmatrix} \begin{bmatrix} \xi \\ \eta \end{bmatrix} \quad (2.20)$$

$$y = [C'_\xi \quad C'_\eta] \begin{bmatrix} \xi \\ \eta \end{bmatrix} \quad (2.21)$$

where $A_\xi := A_{11} - A_{12}L_1$, $A_\eta := A_{22} + \epsilon L_1 A_{12}$, $C'_\xi := C'_1 - C'_2 L_1$ and $C'_\eta := C'_2 - \epsilon(C'_1 L_2 - C'_2 L_1 L_2)$. Discretizing at the instants $t = \ell\epsilon T$ gives

$$\begin{bmatrix} \xi[\ell + 1] \\ \eta[\ell + 1] \end{bmatrix} = \begin{bmatrix} \Phi_\xi & 0 \\ 0 & \Phi_\eta \end{bmatrix} \begin{bmatrix} \xi[\ell] \\ \eta[\ell] \end{bmatrix} \quad (2.22)$$

$$y[\ell] = [C'_\xi \quad C'_\eta] \begin{bmatrix} \xi[\ell] \\ \eta[\ell] \end{bmatrix} \quad (2.23)$$

where $\Phi_\xi := \exp(A_\xi \epsilon T) = I_N + O(\epsilon)$ and $\Phi_\eta := \exp(A_\eta \epsilon T)$.

In these new coordinates, the observability matrix (2.15) is given by

$$\mathcal{O}_d := \begin{bmatrix} C'_\xi & C'_\eta \\ C'_\xi + O(\epsilon) & C'_\eta \Phi_\eta \\ \vdots & \vdots \\ C'_\xi + O(\epsilon) & C'_\eta \Phi_\eta^{N+M-1} \end{bmatrix}. \quad (2.24)$$

Since the first N columns of \mathcal{O}_d are nearly the same for small ϵ , it is very close to losing rank. The observability matrix (2.15) in original coordinates is

$$\mathcal{O} = \mathcal{O}_d \begin{bmatrix} I_N - \epsilon L_2 L_1 & -\epsilon L_2 \\ L_1 & I_M \end{bmatrix}. \quad (2.25)$$

Since the transformation matrix in (2.25) does not lose rank as $\epsilon \rightarrow 0$, \mathcal{O} is also ill-conditioned for small ϵ .

In the nonlinear case, ill-conditioning will be evident whenever $\partial H / \partial w$ is close to losing rank. Thus Jacobian clearly is the observability matrix of the classical linearization of the nonlinear discrete-time system (2.6)–(2.7). Since classical linearization and discretization are commutative [3], however,

this Jacobian is also the observability matrix of the discretization of some linearization of the system (2.1)–(2.3). Since any such observability matrix is inherently ill-conditioned, it follows that the nonlinear observer (2.12) is inherently stiff.

The stiffness of the full-order observer is a result of the inordinately fast sampling required. This fast sampling causes an ϵ dependence in $H(w)$, which leads to loss of rank as $\epsilon \rightarrow 0$. Since reduced-order observers may be operated in their natural time scales (in a multirate fashion), such stiffness is not an inherent feature of the approach considered in the following sections.

III. REDUCED-ORDER DESIGN

The problem of observer design for autonomous nonlinear singularly perturbed systems is now re-examined. The proposed reduced-order techniques can be applied to most singularly perturbed systems for which a full-order observer exists.

A. Time-Scale Decomposition

Appropriate design models are needed for the construction of reduced-order observers. These models will be determined by first obtaining continuous-time reduced-order models and by then computing the corresponding discrete-time reduced-order models. This is in contrast to [1], where full-order discretization is followed by discrete-time order-reduction. By performing the order reduction first, no tools from the (less developed) discrete-time singular perturbation theory are needed. By discretizing only models of reduced order, the resulting state-to-measurement maps (and their inverses) will be simpler.

Consider systems of the form (2.1)–(2.3), namely

$$\dot{x} = f_1(x, z), x(0) = x_0 \quad (3.1)$$

$$\epsilon \dot{z} = f_2(x, z), z(0) = z_0 \quad (3.2)$$

$$y = h(x, z) \quad (3.3)$$

where all notation and assumptions match those of (2.1)–(2.3). It is implicitly assumed that f_1 and f_2 have $O(1)$ magnitudes, so that the rate-of-change of z is about $1/\epsilon$ times larger than the rate-of-change of x . It will be convenient in the sequel to make use of the set notation $\mathcal{B}_r(\delta) := \{\chi \in \mathcal{R}^J : \|\chi\|_\infty < \delta\}$.

Assumption 3.1: For a fixed $t > 0$, there exist fixed positive scalars r_x and r_z such that $(x(t), z(t)) \in \mathcal{B}_N(r_x) \times \mathcal{B}_M(r_z)$ for all $t \in [0, t]$ and such that $0 = f_2(x, z)$ has the unique real solution $z = \phi(x)$ on $(x, z) \in \mathcal{B}_N(r_x) \times \mathcal{B}_M(r_z)$.

Following [8], the slow subsystem is defined by

$$\frac{dx_s}{dt} = f_1(x_s, \phi(x_s)) =: f_s(x_s), x_s(0) = x_0 \quad (3.4)$$

$$y_s = h(x_s, \phi(x_s)) =: h_s(x_s) \quad (3.5)$$

and the fast subsystem is defined by

$$\frac{dz_f}{d\tau} = f_2(x_0, \phi(x_0) + z_f) =: f_f(z_f), z_f(0) = z_0 - \phi(x_0) \quad (3.6)$$

$$y_f = h(x_0, \phi(x_0) + z_f) - h(x_0, \phi(x_0)) =: h_f(z_f) \quad (3.7)$$

where $\tau := t/\epsilon$. It is assumed that a unique solution $x_s(t)$ of the system (3.4)–(3.5) exists for all $t \in [0, t]$, and a unique solution $z_f(\tau)$ of the system (3.6)–(3.7) exists for all $\tau \in [0, t/\epsilon]$.

It is significant that $f_f(z_f)$ and $h_f(z_f)$ depend implicitly on the initial condition x_0 . This feature is inherent in the time-scale decomposition. It should also be emphasized that y_s and y_f are not signals available for observer design purposes.

Assumption 3.2: The fast states are asymptotically stable, i.e. $\text{Re}\left\{\lambda\left(\frac{\partial f_f}{\partial z}\right)\right\} \leq -\kappa < 0$ evaluated along $x = x_s$ and $z = \phi(x_s)$, for some fixed constant $\kappa > 0$. Furthermore, $x(0) = x_0$ and $z(0) = z_0$ are such that $z_f(0)$ belongs to the domain of attraction of the equilibrium $z_f = 0$ of the fast subsystem.

The following well-known theorem provides a method of approximating $x(t)$, $z(t)$ and $y(t)$ by solving the reduced-order subsystems (3.4)–(3.7) [7], [8].

Theorem 3.1 [Tikhonov]: If the system (3.1)–(3.3) satisfies Assumptions 3.1 and 3.2, then there exists an $\epsilon^* > 0$ such that for any $\epsilon \in (0, \epsilon^*)$

$$x(t) = x_s(t) + O(\epsilon) \quad (3.8)$$

$$z(t) = \phi(x_s(t)) + z_f(\tau) + O(\epsilon) \quad (3.9)$$

$$y(t) = y_s(t) + y_f(\tau) + O(\epsilon) \quad (3.10)$$

for all $t \in [0, t]$. Furthermore, for any $t^* \in (0, t]$ there exists an $\epsilon^{**} \in (0, \epsilon^*)$ such that for any $\epsilon \in (0, \epsilon^{**})$

$$z(t) = \phi(x_s(t)) + O(\epsilon) \quad (3.11)$$

for all $t \in [t^*, t]$

B. Synthesis of Reduced-Order Observers

Since the reduced-order models (3.4)–(3.5) and (3.6)–(3.7) are decoupled, they may be sampled at their natural rates. The slow subsystem is sampled at the instants $t = nT$ and the fast subsystem at the instants $\tau = mT/(k\epsilon)$, where $T \leq t/N$ is chosen on the basis of the x dynamics and where $k \geq M$ is an integer such that $T/k = O(\epsilon)$. Note that the fast sampling rate is precisely k times the slow sampling rate, and also that the separation in time scales is maintained in the discrete n and m indexes. Throughout this section, time-varying quantities will be written as functions of t (or n), or τ (or m), in a manner consistent with the notation of Theorem 3.1.

The discrete-time model of the slow subsystem is

$$x_s[n+1] = F_s(x_s[n]) \quad (3.12)$$

$$y_s[n] = h_s(x_s[n]) \quad (3.13)$$

where $x_s[n] := x_s(nT)$, $y_s[n] := y_s(nT)$, and

$$F_s(x_s[n]) := \sum_{i=0}^{T/\epsilon} \frac{T^i}{i!} [L_{f_s}^i x_s]_{x_s=x_s[n]}. \quad (3.14)$$

The discrete-time model of the fast subsystem is

$$z_f[m+1] = F_f(z_f[m]) \quad (3.15)$$

$$y_f[m] = h_f(z_f[m]) \quad (3.16)$$

where $z_f[m] := z_f(mT/(k\epsilon))$, $y_f[m] := y_f(mT/(k\epsilon))$, and

$$F_f(z_f[m]) := \sum_{i=0}^{\infty} \frac{1}{i!} \left(\frac{T}{k\epsilon} \right)^i \left[L_{f_f}^i z_f \right]_{z_f=z_f[m]} \quad (3.17)$$

It may seem that constructing observers for the reduced-order models (3.12)–(3.13) and (3.15)–(3.16) is simply a matter of repeating the full-order procedure for each of the subsystems. This is not possible, however, because only $y(t)$ is measured— $y_s[n]$ and $y_f[m]$ are not known. Intuitively, fast variations in the measured output may be attributed to the fast states. Consequently, any difference between $y(mT/k)$ and $y((m+1)T/k)$ will be approximately equal to the difference between $y_f[m]$ and $y_f[m+1]$. For this reason, the construction of the fast observer begins with the fast output function in incremental form

$$\Delta h_f(z_f) := h_f \circ F_f(z_f) - h_f(z_f). \quad (3.18)$$

Using (3.18), the incremental fast state-to-measurement map is defined as

$$\Delta H_f(z_f) := \begin{bmatrix} \Delta h_f(z_f) \\ \Delta h_f \circ F_f(z_f) \\ \vdots \\ \Delta h_f \circ F_f^{M-1}(z_f) \end{bmatrix} \quad (3.19)$$

which is implicitly parameterized by x_0 . Given the block of incremental fast subsystem outputs

$$\Delta Y_f[m] := \begin{bmatrix} y_f[m-M+1] - y_f[m-M] \\ \vdots \\ y_f[m] - y_f[m-1] \end{bmatrix} \quad (3.20)$$

this map satisfies the identity

$$\Delta Y_f[m] = \Delta H_f(z_f[m-M]). \quad (3.21)$$

Assumption 3.3: For some fixed positive scalars r_f and δ_f , there exists a function $\Delta H_f^{-1} : \mathcal{R}^{QM} \rightarrow \mathcal{R}^M$, parameterized by x_0 , such that:

- 1) $z_f \in \mathcal{B}_M(r_f)$ and $\Delta Y_f = \Delta H_f(z_f)$ imply $z_f = \Delta H_f^{-1}(\Delta Y_f)$.
- 2) $\Delta H_f^{-1}(\cdot)$ depends continuously on the parameter x_0 and is continuous on the set $\mathcal{B}_{QM}(r + \delta_f)$ where $r > 0$ is such that $\Delta H_f(\mathcal{B}_M(r_f)) \subseteq \mathcal{B}_{QM}(r)$.

Assumption 3.3–2 is required because of the approximation error introduced by order reduction. This requirement is not restrictive, since a similar assumption would be required in [4], [5] to handle measurement noise and/or parameter uncertainty. Invoking Assumption 3.3, whenever $z_f[m-M] \in \mathcal{B}_M(r_f)$ then

$$z_f[m] = F_f^M \circ \Delta H_f^{-1}(\Delta Y_f[m]) \quad (3.22)$$

which is computable for $m \geq M$.

Turning to the slow observer problem, consider the sum of blocks of slow and fast subsystem outputs

$$Y_{sf}[n] := \begin{bmatrix} y_s[n-N+1] \\ \vdots \\ y_s[n] \end{bmatrix} + \begin{bmatrix} y_f[k(n-N+1)] \\ \vdots \\ y_f[kn] \end{bmatrix}. \quad (3.23)$$

This quantity motivates the slow-plus-fast slow measurement map¹ definition

$$H_{sf}(x_s, Z_f[n]) := \begin{bmatrix} h_s(x_s) \\ h_s \circ F_s(x_s) \\ \vdots \\ h_s \circ F_s^{N-1}(x_s) \\ h_f(z_f[k(n-N+1)]) \\ h_f(z_f[k(n-N+2)]) \\ \vdots \\ h_f(z_f[kn]) \end{bmatrix} \quad (3.24)$$

which is parameterized implicitly by x_0 and explicitly by

$$Z_f[n] := \begin{bmatrix} z_f[k(n-N+1)] \\ \vdots \\ z_f[kn] \end{bmatrix}. \quad (3.25)$$

This map satisfies the identity

$$Y_{sf}[n] = H_{sf}(x_s[n-N+1], Z_f[n]). \quad (3.26)$$

Assumption 3.4: For the fixed positive scalar r_f and some fixed positive scalars r_s and δ_s , there exists a function $H_{sf}^{-1} : \mathcal{R}^{QN} \times \mathcal{R}^{MN} \rightarrow \mathcal{R}^N$ such that:

- 1) $x_s \in \mathcal{B}_N(r_s)$ and $Y_{sf} = H_{sf}(x_s, Z_f)$ imply $x_s = H_{sf}^{-1}(Y_{sf}, Z_f)$ for all $Z_f \in \mathcal{B}_{MN}(r_f)$.
- 2) $H_{sf}^{-1}(\cdot, \cdot)$ is continuous on the set $\mathcal{B}_{QN+MN}(r + \delta_s)$ where $r > 0$ is such that $H_{sf}(\mathcal{B}_N(r_s), \mathcal{B}_{MN}(r_f)) \times \mathcal{B}_{MN}(r_f) \subseteq \mathcal{B}_{QN+MN}(r)$.

Again, Assumption 3.4-2 is required to account for order reduction approximation error. Invoking Assumption 3.4, whenever $x_s[n-N+1] \in \mathcal{B}_N(r_s)$ and $Z_f[n] \in \mathcal{B}_{MN}(r_f)$, then

$$x_s[n] = F_s^{N-1} \circ H_{sf}^{-1}(Y_{sf}[n], Z_f[n]) \quad (3.27)$$

which is computable for $n \geq N-1$.

Of course, neither (3.22) nor (3.27) is computable using known signals. The fictitious signals ΔY_f and Y_{sf} may be approximated by

$$\Delta \hat{Y}_f[m] := \begin{bmatrix} y((m-M+1)T/k) - y((m-M)T/k) \\ \vdots \\ y(mT/k) - y((m-1)T/k) \end{bmatrix} \quad (3.28)$$

$$\hat{Y}_{sf}[n] := \begin{bmatrix} y((n-N+1)T) \\ \vdots \\ y(nT) \end{bmatrix} \quad (3.29)$$

and the unknown $Z_f[n]$ will be obtained from the fast observer defined below, according to

$$\hat{Z}_f[n] := \begin{bmatrix} \hat{z}_f[k(n-N+1)] \\ \vdots \\ \hat{z}_f[kn] \end{bmatrix}. \quad (3.30)$$

¹ Although in this section it is possible to formulate an implementable slow observer using a "slow" state-to-measurement map, this definition has been chosen to be consistent with a similar definition required in the next section.

TABLE I
 IMPLEMENTATION COSTS OF FULL- AND REDUCED-ORDER OBSERVERS

Observer	Numerical (flops)	Closed-Form (flops)	Look-Up Table (bytes)
Full-Order	$\frac{O((N+M)^3)}{T}$	$\frac{O((N+M)^2)}{T}$	$2^{b(N+M)+2}$
Theorem 3.2	$\frac{O(M^3)}{T} + \frac{O(N^3)}{T}$	$\frac{O(M^2)}{T} + \frac{O(N^2)}{T}$	$2^{bM+2} + 2^{bN+2}$
Corollary 3.1	$\frac{O(N^3)}{T}$	$\frac{O(N^2)}{T}$	2^{bN+2}

Note also that F_f , ΔH_f^{-1} and H_{sf}^{-1} all depend implicitly on x_0 . Hence, the following assumption is required.

Assumption 3.5: At least one of the following conditions is satisfied:

- 1) $\hat{x}_0 = x_0 + O(\epsilon)$ is known.
- 2) $f_2(x, z) = f_{2x}(x) + A_2 z$ and $h(x, z) = h_x(x) + C z$.

If Assumption 3.5-2 is true, then F_f , ΔH_f^{-1} , and H_{sf}^{-1} are independent of x_0 , since $f_f(z_f) = A_2 z_f$ and $h_f(z_f) = C z_f$. If Assumption 3.5-1 is true, then the unknown functions will be estimated by

$$\hat{F}_f(z_f) := F_f(z_f)|_{x_0=\hat{x}_0} \quad (3.31)$$

$$\Delta \hat{H}_f^{-1}(z_f) := \Delta H_f^{-1}(z_f)|_{x_0=\hat{x}_0} \quad (3.32)$$

$$\hat{H}_{sf}^{-1}(x_s, Z_f) := H_{sf}^{-1}(x_s, Z_f)|_{x_0=\hat{x}_0} \quad (3.33)$$

The implementable reduced-order observers are defined in the following theorem, and they are interconnected in the sense that $\hat{z}_f[m]$ drives $\hat{x}_s[n]$.

Theorem 3.2: Suppose $(x_s[n], z_f[m]) \in \mathcal{B}_N(r_s) \times \mathcal{B}_M(r_f)$ for $n = 0, \dots, \bar{n}$ and $m = 0, \dots, k\bar{n}$, where \bar{n} is the greatest integer such that $\bar{n}T \leq t$. If the system (3.1)–(3.3) satisfies Assumptions 3.1–3.5, then there exists an $\epsilon^* > 0$ such that for any $\epsilon \in (0, \epsilon^*)$

$$\hat{z}_f[m] := \hat{F}_f^M \circ \Delta \hat{H}_f^{-1}(\Delta \hat{Y}_f[m]) \quad (3.34)$$

$$= z_f(mT/(k\epsilon)) + O(\epsilon) \quad (3.35)$$

$$\hat{x}_s[n] := F_s^{N-1} \circ H_{sf}^{-1}(\hat{Y}_{sf}[n], \hat{Z}_f[n]) \quad (3.36)$$

$$= x_s(nT) + O(\epsilon) \quad (3.37)$$

for $n = N, \dots, n$ and $m = M, \dots, kn$.

Proof: Assumptions 3.1 and 3.2 imply that Theorem 3.1 holds for $n = 0, \dots, n$ (and $m = 0, \dots, k\bar{n}$). In light of (3.4) and the fact $T/k = O(\epsilon)$, it is evident that $r_s((m+1)T/k) = x_s(mT/k) + O(\epsilon)$. Since h_s is analytic, it is continuous and therefore $y_s((m+1)T/k) = y_s(mT/k) + O(\epsilon)$, which, along with (3.10), implies that

$$\Delta Y_f[m] = \Delta Y_f[m] + O(\epsilon). \quad (3.38)$$

This, together with Assumptions 3.3 and 3.5, the continuity of F_f and the hypothesis that $z_f[m] \in \mathcal{B}_M(r_f)$, implies (3.35). From (3.10), it follows that

$$\hat{Y}_{sf}[n] = Y_{sf}[n] + O(\epsilon). \quad (3.39)$$

Using (3.35), it follows that

$$\hat{Z}_f[n] = Z_f[n] + O(\epsilon). \quad (3.40)$$

Along with Assumption 3.4, the hypothesis that $x_s[n] \in \mathcal{B}_N(r_s)$ and the continuity of F_s , (3.39)–(3.40) imply (3.37). \square

Since the observers (3.34) and (3.36) are interconnected, it is helpful to describe their implementation further. The required sequence of calculations is as follows:

- 1) Using \hat{x}_0 if necessary, construct (3.31), (3.32) and (3.33).
- 2) Set $m = n = 0$.
- 3) While $n \leq \bar{n}$
 - a) Measure $y(mT/k)$.
 - b) If $m \geq M$, compute $\hat{z}_f[m]$ from (3.34) using $y((m-M)T/k), \dots, y(mT/k)$.
 - c) If $m = k(n+1)$ then
 - Set $n = n + 1$.
 - If $n \geq N$, compute $\hat{x}_s[n]$ from (3.36) using $y((n-N+1)T), \dots, y(nT)$ and $\hat{z}_f[k(n-N+1)], \dots, \hat{z}_f[kn]$.
 - d) Set $m = m + 1$.
- 4) Stop.

If the accuracy of the observer during the boundary layer is of no concern, then an estimate of $z_f[m]$ is not needed, and it is possible to obtain a simplified slow observer.

Corollary 3.1. Suppose that $x_s[n] \in \mathcal{B}_N(r_s)$ for $n = 0, \dots, n$. If the system (3.1)–(3.3) satisfies Assumptions 3.1, 3.2, and 3.4, then for any integer $n^* \in [N, \bar{n}]$ there exists an $\epsilon^{**} > 0$ such that for any $\epsilon \in (0, \epsilon^{**})$

$$\hat{x}_s[n] := F_s^{N-1} \circ H_{sf}^{-1}(\hat{Y}_{sf}[n], 0) \quad (3.41)$$

$$= x_s(nT) + O(\epsilon) \quad (3.42)$$

for all $n = n^*, \dots, n$.

Proof: Equation (3.11) implies that, under the hypothesis of the corollary, $z_f[m] = O(\epsilon)$ for $m \in [kt^*/T, kn]$. Taking n^* as the smallest integer such that $n^* \geq N - 1 + t^*/T$ leads to $Z_f[n] = O(\epsilon)$ for $n = n^*, \dots, n$. This, together with the fact that $\hat{H}_{sf}(\cdot, 0) \equiv H_{sf}(\cdot, 0)$ (which is evident from (3.24)) and (3.36), proves the result. \square

Corollary 3.1 reinforces the intuitive notion that if the parasitic states are fast enough, then their effects can be completely neglected. Note also that the observer (3.41) does not require either the invertibility of the incremental fast state-to-measurement map, knowledge of x_0 , or special structure of f_2 and h .

C. Reduced-Order Observer Advantages

Table I provides a comparison of the implementation requirements for both full-order and reduced-order observers, assuming $k = 1/\epsilon$. It is further assumed that numerical solution of j nonlinear equations requires $O(j^3)$ floating point operations, and that evaluation of a closed form solution to j nonlinear equations requires $O(j^2)$ floating point operations. If the inverse of a j -dimensional map is computed off-line and stored in a single precision floating point look-up table with b bit resolution, then 2^{bj+2} bytes of memory are assumed to be required. As a consequence of the conservative assumptions used, the values shown in Table I underestimate the advantages of the reduced-order approach.

To better illustrate these requirements, consider a fourth order system with two slow and two fast states ($N = M = 2$). The limiting ratio of on-line numerical inversion computational requirements is

$$\lim_{\epsilon \rightarrow 0} \frac{\text{full-order flops}}{\text{reduced-order flops}} = \begin{cases} 8, & \text{Theorem 3.2} \\ \infty, & \text{Corollary 3.1} \end{cases}$$

The 8-bit look-up table memory requirements for the full- and reduced-order implementations for this system are given by

$$\text{memory size} = \begin{cases} 16 \text{ Gbyte,} & \text{full-order} \\ 512 \text{ Kbyte,} & \text{Theorem 3.2} \\ 256 \text{ Kbyte,} & \text{Corollary 3.1.} \end{cases}$$

Clearly, a look-up table full-order observer is not practical for this system, whereas both of the reduced-order schemes require only moderately sized look-up tables.

As for the stiffness, there is no assurance that the reduced-order inversions will be well-conditioned, since poor observability will not be improved by singular perturbation approximations. On the other hand, as previously shown, the full-order inversions are always ill-conditioned for small enough ϵ .

D. Autonomous Example

Consider the linear system

$$\dot{x} = \begin{bmatrix} 30.9265 & -24.9047 \\ 35.3095 & -27.4703 \end{bmatrix} x + \begin{bmatrix} -13.9306 & 23.3253 \\ -16.8008 & 25.4823 \end{bmatrix} z \quad (3.43)$$

$$\epsilon \dot{z} = \begin{bmatrix} 24.5739 & -18.8923 \\ 9.4471 & -6.1202 \end{bmatrix} x + \begin{bmatrix} -12.2427 & 19.0368 \\ -5.9734 & 6.2865 \end{bmatrix} z \quad (3.44)$$

$$y = [1.5630 \quad 1.6125]x + [1.7635 \quad 2.7318]z \quad (3.45)$$

where $x_1(0) = 1$, $x_2(0) = 2$, $z_1(0) = -2$, $z_2(0) = 1$, $T = 0.05$, and k is the greatest integer less than or equal to $1/\epsilon$. This system satisfies the requirements of Assumptions 3.1–3.5. According to Theorem 3.2, when $1/\epsilon$ is an integer, the fast observer is given by

$$\hat{z}_f[m] = \begin{bmatrix} 2.5922 & -3.4629 \\ 1.7732 & -2.0408 \end{bmatrix} \begin{bmatrix} y[m-1] - y[m-2] \\ y[m] - y[m-1] \end{bmatrix} \quad (3.46)$$

and, otherwise, the numerical matrix in this expression will be a perturbation of that shown. The slow observer is given by

$$\hat{x}_s[n] = \begin{bmatrix} -1.7104 & 1.9170 \\ 0.1755 & 0.0236 \end{bmatrix} \begin{bmatrix} y[n-1] - [1.7635 \quad 2.7318]\hat{z}_f[k(n-1)] \\ y[n] - [1.7635 \quad 2.7318]\hat{z}_f[kn] \end{bmatrix} \quad (3.47)$$

Fig. 1 shows the actual and reduced-order estimated responses for the case $\epsilon = 0.04$. The reduced-order observers do an excellent job of reconstructing the slow and fast states for this value of ϵ . The behavior of the observers as ϵ varies from 0.01 to 0.1 is shown in Fig. 2. In Fig. 2(a), the averages (over the time indexes) of the absolute values of the observer errors are shown. For small values of ϵ the estimates are good, but for large enough ϵ , the estimates degrade as expected.

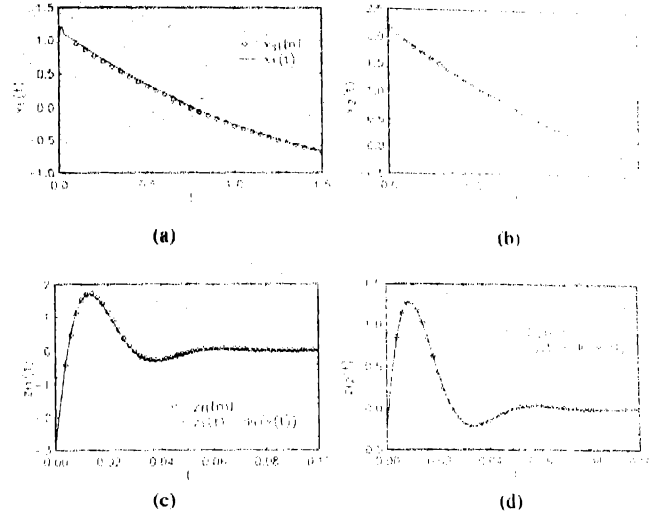

Fig. 1. Actual and estimated state responses for the case $\epsilon = 0.04$. (a) $x_1(t)$ and $\hat{x}_{s1}[n]$, (b) $x_2(t)$ and $\hat{x}_{s2}[n]$, (c) $z_1(t) - \phi_1(x(t))$ and $\hat{z}_{f1}[m]$ and (d) $z_2(t) - \phi_2(x(t))$ and $\hat{z}_{f2}[m]$.

Fig. 2(b) compares the matrix 2-norm condition numbers of the full-order observability matrix, the slow observability matrix, and the incremental fast observability matrix. The full-order observer for this system is ill-conditioned—particularly for small ϵ , whereas the reduced-order observers are not. Fig. 2(c) shows the ratio of the full-order to reduced-order flop count. The reduced-order observers require only about 40% of the calculations required by the full-order observer, assuming that the matrix inversions are computed off-line. Based on the earlier analysis, it is expected that this flops ratio will approach four as $\epsilon \rightarrow 0$.

IV. REDUCED-ORDER DESIGN WITH INPUTS

In this section, the design of reduced-order observers is extended to a class of nonlinear singularly perturbed systems with piecewise-constant inputs. The section concludes with a practical application of the theory: velocity regulation of permanent-magnet synchronous motors, using only stator current measurements.

A. Decomposition with Piecewise-Constant Inputs

Nonlinear singularly perturbed systems exhibiting linearity in the fast states and the control inputs admit reduced-order models that are easy to discretize. Moreover, this class of systems also models the dynamics of some important electromechanical devices. Hence, we consider systems of the form

$$\dot{x} = a_1(x) + A_1(x)z + B_1(x)u, x(0) = x_0 \quad (4.1)$$

$$\epsilon \dot{z} = a_2(x) + A_2(x)z + B_2(x)u, z(0) = z_0 \quad (4.2)$$

$$y = c(x) + C(x)z \quad (4.3)$$

where $x \in \mathcal{R}^N$, $z \in \mathcal{R}^M$, $u \in \mathcal{R}^P$, $y \in \mathcal{R}^Q$, $\epsilon > 0$ is a small parameter, and the dot denotes differentiation with respect to t . It is assumed that $a_1, a_2, A_1, A_2, B_1, B_2, c$ and C are analytic functions, that unique solutions $x(t)$ and $z(t)$ exist, and that y is the only measurement available. Furthermore,

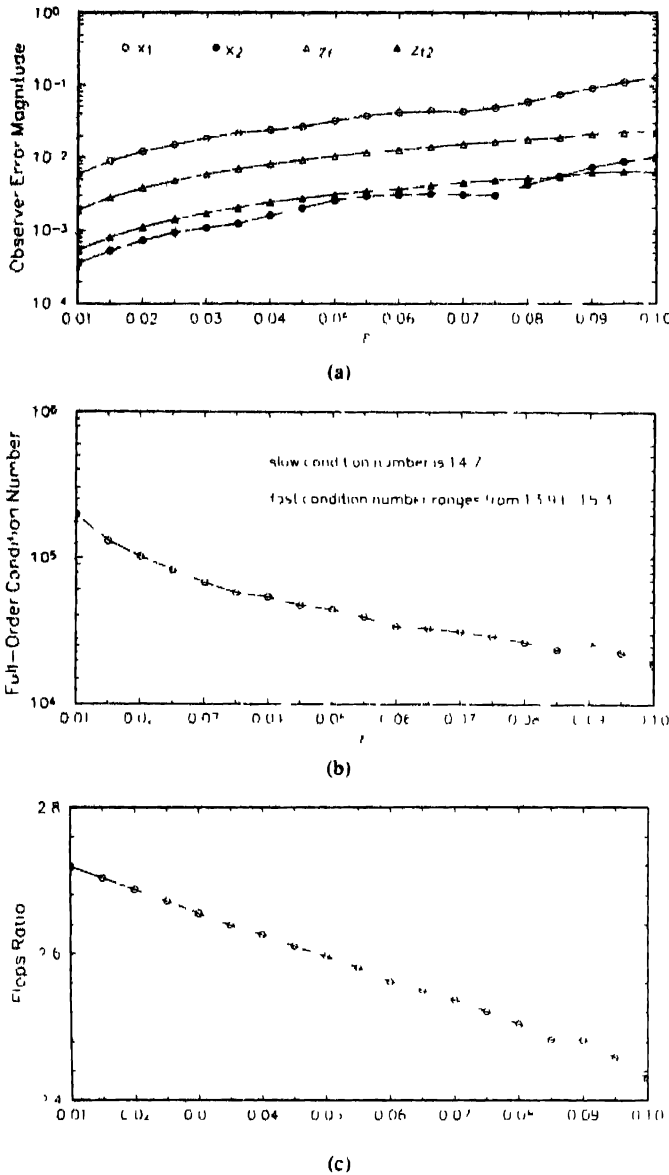

Fig. 2 Observer performance as a function of ϵ (a) Average absolute observer error, (b) Observability matrix condition numbers, and (c) Full-order to reduced-order flops ratio

$u(t)$ is assumed to be piecewise-constant

$$u(t) = u(nT) =: u[n], \forall t \in [nT, (n+1)T) \quad (4.4)$$

where T is consistent with the speed of the x dynamics. The need to accommodate piecewise-constant inputs rules out any straightforward use of Theorem 3.1. Hence, a systematic approach to time-scale decomposition for the system (4.1)–(4.4) must be developed.

As pointed out in [2], each step in the input will excite the fast dynamics. For this reason, a family of slow manifolds will be considered, each of interest over one control interval.

Assumption 4.1: For a fixed $n \geq N$, there exist fixed positive scalars r_x , r_z and r_u such that $u(t) \in \mathcal{B}_M(r_u)$ and $(x(t), z(t)) \in \mathcal{B}_N(r_x) \times \mathcal{B}_M(r_z)$ for all $t \in [0, nT]$, and such that $A_2(x)$ is nonsingular for all $x \in \mathcal{B}_N(r_x)$.

The family of slow manifolds is determined by setting $\epsilon = 0$ in (4.2), leading to

$$\phi_n(x_s(t), u[n]) := -A_2^{-1}(x_s(t))(a_2(x_s(t)) + B_2(x_s(t))u[n]). \quad (4.5)$$

The slow subsystem, which models the system assuming that $z(t) = \phi_n(x_s(t), u[n])$, is defined by

$$\frac{dx_s}{dt} = a_s(x_s(t)) + B_s(x_s(t))u[n], x_s(0) = x_0 \quad (4.6)$$

$$y_s(t) = c_s(x_s(t)) + D_s(x_s(t))u[n] \quad (4.7)$$

where

$$a_s(x_s) := a_1(x_s) - A_1(x_s)A_2^{-1}(x_s)a_2(x_s) \quad (4.8)$$

$$B_s(x_s) := B_1(x_s) - A_1(x_s)A_2^{-1}(x_s)B_2(x_s) \quad (4.9)$$

$$c_s(x_s) := c(x_s) - C(x_s)A_2^{-1}(x_s)a_2(x_s) \quad (4.10)$$

$$D_s(x_s) := -C(x_s)A_2^{-1}(x_s)B_2(x_s). \quad (4.11)$$

A unique solution $x_s(t)$ of the system (4.6)–(4.7) is assumed to exist for all $t \in [0, nT]$.

The family of fast subsystems, which models the deviation of z from its quasi-steady-state $\phi_n(x_s(nT), u[n])$, is defined by

$$\frac{dz_{f(n)}}{d\tau_n} = A_2(x_s(nT))z_{f(n)}(\tau_n) \quad (4.12)$$

$$y_{f(n)}(\tau_n) = C'(x_s(nT))z_{f(n)}(\tau_n) \quad (4.13)$$

in the fast time-scale

$$\tau_n := \frac{t - nT}{\epsilon}. \quad (4.14)$$

Each member could be initialized with $z(nT) = \phi_n(x(nT), u[n])$, but this approach will be taken only for $n = 0$. For $n \geq 1$, we substitute $x_s(nT)$ for $x(nT)$ and use the continuity of z at $t = nT$ to justify substitution of $z_{f(n-1)}(T/\epsilon) + \phi_{n-1}(x_s(nT), u[n-1])$ for $z(nT)$. Hence, the family of initial conditions is defined by

$$z_{f(n)}(0) = \begin{cases} z_0 - \phi_0(x_0, u[0]), n = 0 \\ z_{f(n-1)}(T/\epsilon) + \phi_{n-1}(x_s(nT), u[n-1]) \\ - \phi_n(x_s(nT), u[n]), n \geq 1. \end{cases} \quad (4.15)$$

Note that (4.12)–(4.15) are evaluated in a sequential nature, with the n th member of the family depending on the terminal value of the $(n-1)$ st member and on $x_s(nT)$. This formulation was motivated by (and encompasses) the resetting condition given in [9]. It is significant that (4.12)–(4.15), in general, depend on $x_s(nT)$.

The validity of the reduced-order subsystems as asymptotic approximations requires a stability assumption on (4.1)–(4.4).

Assumption 4.2: The fast states are asymptotically stable, i.e. $\text{Re}\{\lambda(A_2(x))\} \leq -\kappa < 0$ evaluated on $x = x_s$, for some fixed constant $\kappa > 0$.

The following theorem provides a method of approximating $x(t)$, $z(t)$ and $y(t)$ by solving the reduced-order subsystems (4.6)–(4.15).

Theorem 4.1: If the system (4.1)–(4.4) satisfies Assumptions 4.1 and 4.2, then there exists an $\epsilon^* > 0$ such that for any $\epsilon \in (0, \epsilon^*)$

$$x(t) = x_s(t) + O(\epsilon) \quad (4.16)$$

$$z(t) = \phi_n(x_s(t), u[n]) + z_{f(n)}(\tau_n) + O(\epsilon) \quad (4.17)$$

$$y(t) = y_s(t) + y_{f(n)}(\tau_n) + O(\epsilon) \quad (4.18)$$

for all $t \in [nT, (n+1)T)$, and $n = 0, \dots, \bar{n}$. Moreover, given any $T > 0$, there exists an $\epsilon^{**} \in (0, \epsilon^*)$ such that for any $\epsilon \in (0, \epsilon^{**})$

$$z_{f(n)}(T/\epsilon) = O(\epsilon) \quad (4.19)$$

for all $n = 0, \dots, \bar{n}$.

Proof: Over each interval $t \in [nT, (n+1)T)$, the system (4.1)–(4.4) can be viewed as a special case of system (3.1)–(3.3) parameterized by $u[n]$. From this point of view, Assumptions 4.1 and 4.2 imply Assumptions 3.1 and 3.2. Furthermore, note that (4.6)–(4.7) are equivalent to (3.4)–(3.5) except for the initial conditions taken at $t = nT$, and note that (4.12)–(4.13) are equivalent to (3.6)–(3.7) except for the parameterizing values of x and the initial conditions taken at $t = nT$. For $n = 0$, Theorem 3.1 may be directly applied (there are no exceptions for this index), proving the validity of (4.16)–(4.18) over $t \in [0, T)$. For $n \geq 1$, the exceptions can be summarized by noting that initial conditions (and parameterizing values of x) are assigned according to

$$x_s(nT) = \begin{cases} x(nT), \S 3.1 \\ x_s(nT), \S 4.1 \end{cases} \quad (4.20)$$

$$z_{f(n)}(0) = \begin{cases} z(nT) - \phi_n(x(nT), u[n]), \S 3.1 \\ z_{f(n-1)}\left(\frac{T}{\epsilon}\right) + \phi_{n-1}(x_s(nT), u[n-1]), \S 4.1 \\ -\phi_n(x_s(nT), u[n]), \S 4.1. \end{cases} \quad (4.21)$$

Now suppose that (4.16)–(4.18) hold for some $n' \geq 0$. Since x and z are continuous, $x((n'+1)T) = x_s((n'+1)T) + O(\epsilon)$ and $z((n'+1)T) = \phi_{n'}(x_s((n'+1)T), u[n']) + z_{f(n')}(T/\epsilon) + O(\epsilon)$. Hence, the discrepancies between the assignments indicated by (4.20)–(4.21) at $n = n' + 1$ are $O(\epsilon)$. Since all the differential equations involved admit solutions which depend continuously on their initial conditions (and parameterizing values of x), we see that (4.16)–(4.18) hold for $n' + 1$. By induction, (4.16)–(4.18) are proven for all $n = 0, \dots, \bar{n}$. The last claim, (4.19), is an easy consequence of Assumption 4.2. \square

B. Synthesis of Reduced-Order Observers with Inputs

In order to design reduced-order observers, discrete-time representations of the subsystem models are needed. The slow subsystem is sampled at the instants $t = nT$ to obtain

$$x_s[n+1] = F_s(x_s[n], u[n]) \quad (4.22)$$

$$y_s[n] = h_s(x_s[n], u[n]) \quad (4.23)$$

where $x_s[n] := x_s(nT)$, $y_s[n] := y_s(nT)$ and

$$h_s(x_s[n], u[n]) := c_s(x_s[n]) + D_s(x_s[n])u[n]. \quad (4.24)$$

The function F_s is given by [10]

$$F_s(x_s[n], u[n]) := \sum_{i=0}^{\infty} \frac{T^i}{i!} \left[\left(L_{a_s} + \sum_{j=1}^P u_j[n] L_{b_{s,j}} \right)^i x_s \right]_{x_s = x_s[n]} \quad (4.25)$$

where $b_{s,j}$ is the j th column of B_s , and u_j is the j th element of u . The family of fast subsystems is sampled at the instants $\tau_n = mT/(k\epsilon)$, where k is an integer ($k \geq M$) such that $T/k = O(\epsilon)$, to obtain

$$z_{f(n)}[m+1] = \Phi_{f(n)} z_{f(n)}[m] \quad (4.26)$$

$$y_{f(n)}[m] = C_{f(n)} z_{f(n)}[m] \quad (4.27)$$

where $z_{f(n)}[m] := z_{f(n)}(mT/(k\epsilon))$, $y_{f(n)}[m] := y_{f(n)}(mT/(k\epsilon))$ and

$$\Phi_{f(n)} := \exp \left(A_2(x_s[n]) \frac{T}{k\epsilon} \right) \quad (4.28)$$

$$C_{f(n)} := C(x_s[n]). \quad (4.29)$$

Note that the fast index m is implicitly associated with a slow index n . For simplicity, this dependence is suppressed in the notation. Note also that throughout this section, time-varying quantities are written in a manner consistent with the notation of Theorem 4.1.

The reduced-order observers are constructed by formulating the appropriate state-to-measurement maps. For each n , the incremental fast state-to-measurement map

$$\Delta H_{f(n)}(z_{f(n)}) := \begin{bmatrix} C_{f(n)}(\Phi_{f(n)} - I_M)z_{f(n)} \\ C_{f(n)}\Phi_{f(n)}(\Phi_{f(n)} - I_M)z_{f(n)} \\ \vdots \\ C_{f(n)}\Phi_{f(n)}^{M-1}(\Phi_{f(n)} - I_M)z_{f(n)} \end{bmatrix} \quad (4.30)$$

is implicitly parameterized by $x_s[n]$, and satisfies the identity

$$\Delta Y_{f(n)}[m] = \Delta H_{f(n)}(z_{f(n)}[m-M]) \quad (4.31)$$

where $\Delta Y_{f(n)}[m]$ is the block of incremental fast subsystem outputs

$$\Delta Y_{f(n)}[m] := \begin{bmatrix} y_{f(n)}[m-M+1] - y_{f(n)}[m-M] \\ \vdots \\ y_{f(n)}[m] - y_{f(n)}[m-1] \end{bmatrix}. \quad (4.32)$$

Assumption 4.3: For some positive scalars r_s and δ_f , there exist functions $\Delta H_{f(n)}^{-1} : \mathcal{R}^{QM} \rightarrow \mathcal{R}^M$ for $n = 0, \dots, \bar{n}$, parameterized by $x_s[n]$, such that

- 1) $\Delta Y_{f(n)} = \Delta H_{f(n)}(z_{f(n)})$ implies $z_{f(n)} = \Delta H_{f(n)}^{-1}(\Delta Y_{f(n)})$ for all $x_s[n] \in \mathcal{B}_N(r_s)$.
- 2) $\Delta H_{f(n)}^{-1}$ are continuous in the parameterizing $x_s[n]$ over the set $\mathcal{B}_N(r_s + \delta_f)$.

From (4.30), $\Delta H_{f(n)}^{-1}$ is a matrix pseudo-inverse. However, since $\Delta H_{f(n)}$ depends on x_s , the inversion may not in general be done off-line. Using Assumption 4.3, if $x_s[n] \in \mathcal{B}_N(r_s)$, then

$$z_{f(n)}[m] = \Phi_{f(n)}^M \Delta H_{f(n)}^{-1} (\Delta Y_{f(n)}[m]) \quad (4.33)$$

which is computable for $m = M, \dots, k$ and $n = 0, \dots, n$.

In constructing the slow observer, it will be convenient to use the notation $h_s^u(x_s) := h_s(x_s, u)$ and $F_s^u(x_s) := F_s(x_s, u)$. Summing slow and fast subsystem output blocks yields the identity

$$Y_{sf}[n] = \begin{bmatrix} h_s^{u[n-N+1]}(x_s[n-N+1]) \\ h_s^{u[n-N+2]} \circ F_s^{u[n-N+1]}(x_s[n-N+1]) \\ \vdots \\ h_s^{u[n]} \circ F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]}(x_s[n-N+1]) \end{bmatrix} + \begin{bmatrix} C(x_s[n-N+1])z_{f(n-N+1)}[0] \\ C \circ F_s^{u[n-N+1]}(x_s[n-N+1])z_{f(n-N+2)}[0] \\ \vdots \\ C \circ F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]}(x_s[n-N+1])z_{f(n)}[0] \end{bmatrix} \quad (4.34)$$

where

$$Y_{sf}[n] := \begin{bmatrix} y_s[n-N+1] \\ \vdots \\ y_s[n] \end{bmatrix} + \begin{bmatrix} y_{f(n-N+1)}[0] \\ \vdots \\ y_{f(n)}[0] \end{bmatrix}. \quad (4.35)$$

The slow-plus-fast state-to-measurement map² is defined as

$$H_{sf}(x_s, Z_f[n-1], U[n-1]) := \begin{bmatrix} h_s^{u[n-N]}(x_s) \\ h_s^{u[n-N+1]} \circ F_s^{u[n-N+1]}(x_s) \\ \vdots \\ h_s^{u[n-1]} \circ F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]}(x_s) \end{bmatrix} + \begin{bmatrix} C(x_s)z_{f(n-N)}[k] \\ C \circ F_s^{u[n-N+1]}(x_s)z_{f(n-N+1)}[k] \\ \vdots \\ C \circ F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]}(x_s)z_{f(n-1)}[k] \end{bmatrix} \quad (4.36)$$

which is parameterized by the vectors

$$Z_f[n-1] := \begin{bmatrix} z_{f(n-N)}[k] \\ \vdots \\ z_{f(n-1)}[k] \end{bmatrix} \quad (4.37)$$

$$U[n-1] := \begin{bmatrix} u[n-N] \\ \vdots \\ u[n-1] \end{bmatrix}. \quad (4.38)$$

Note that the right-hand side of (4.34) is not the same as the right-hand side of (4.36). However, substitution of the initial

²Since the fast output block in (4.34) depends on x_s , an implementable slow observer cannot be formulated using a "slow" state-to-measurement map, in contrast to the previous section.

conditions (4.15) (along with the definition (4.24)) into (4.34) proves that this map satisfies

$$H_{sf}(x_s[n-N+1], Z_f[n-1], U[n-1]) = Y_{sf}[n]. \quad (4.39)$$

Assumption 4.4. For the fixed positive scalar r_s and some positive scalars r_f and δ_s , there exists a function $H_{sf}^{-1} : \mathcal{R}^{QN} \times \mathcal{R}^{MN} \times \mathcal{R}^{PN} \rightarrow \mathcal{R}^N$ such that

- 1) $x_s \in \mathcal{B}_N(r_s)$ and $Y_{sf} = H_{sf}(x_s, Z_f, U)$ imply $x_s = H_{sf}^{-1}(Y_{sf}, Z_f, U)$ for all $(Z_f, U) \in \mathcal{B}_{MN}(r_f) \times \mathcal{B}_{PN}(r_u)$.
- 2) $H_{sf}^{-1}(\cdot, \cdot, U)$ is continuous on the set $\mathcal{B}_{QN+MN}(r + \delta_s)$ where $r > 0$ is such that $H_{sf}(\mathcal{B}_N(r_s), \mathcal{B}_{MN}(r_f), \mathcal{B}_{PN}(r_u)) \times \mathcal{B}_{MN}(r_f) \subseteq \mathcal{B}_{QN+MN}(r)$.

Using Assumption 4.4, if $x_s[n-N+1] \in \mathcal{B}_N(r_s)$ and $Z_f[n] \in \mathcal{B}_{MN}(r_f)$ then

$$x_s[n] = F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]} \circ H_{sf}^{-1}(Y_{sf}[n], Z_f[n-1], U[n-1]) \quad (4.40)$$

which is computable for $n = N, \dots, n$.

Neither (4.33) nor (4.40) is implementable. The unknown signals are estimated by

$$\Delta \hat{Y}_{f(n)}[m] := \begin{bmatrix} y(nT' + (m-M+1)T/k) - y(nT' + (m-M)T/k) \\ \vdots \\ y(nT' + mT/k) - y(nT' + (m-1)T/k) \end{bmatrix} \quad (4.41)$$

$$Y_{sf}[n] := \begin{bmatrix} y((n-N+1)T) \\ \vdots \\ y(nT) \end{bmatrix} \quad (4.42)$$

$$Z_f[n-1] := \begin{bmatrix} z_{f(n-N)}[k] \\ \vdots \\ z_{f(n-1)}[k] \end{bmatrix} \quad (4.43)$$

where $\hat{z}_{f(n)}[m]$ will be supplied by the fast observer. Also, $\Phi_{f(n)}$ and $\Delta H_{f(n)}^{-1}$ require knowledge of $x_s[n]$, motivating the following assumption.

Assumption 4.5. At least one of the following conditions is satisfied:

- 1) $\hat{x}_0 = x_0 + O(\epsilon)$ is known.
- 2) The matrices $A_2(x) = A_2$ and $C(x) = C$ are constant.

If Assumption 4.5-2 is true, then both $\Phi_{f(n)}$ and $\Delta H_{f(n)}^{-1}$ are independent of $x_s[n]$. If Assumption 4.5-1 is true, then $\Phi_{f(n)}$ and $\Delta H_{f(n)}^{-1}$ are estimated according to

$$\hat{\Phi}_{f(n)} := \Phi_{f(n)}|_{x_s[n] = \hat{x}_s[n]} \quad (4.44)$$

$$\Delta \hat{H}_{f(n)}^{-1}(z_{f(n)}) := \Delta H_{f(n)}^{-1}(z_{f(n)})|_{x_s[n] = \hat{x}_s[n]} \quad (4.45)$$

where

$$\hat{x}_s[n] := \begin{cases} \hat{x}_0, n=0 \\ F_s^{u[n-1]} \circ \dots \circ F_s^{u[0]}(\hat{x}_0), n=1, \dots, N-1 \end{cases} \quad (4.46)$$

and where $\hat{x}_s[n]$ will be supplied by the slow observer for $n = N, \dots, \bar{n}$.

The implementable reduced-order observers are defined in the following theorem, and they are interconnected in the sense that $\hat{x}_s[n]$ is used to compute $\hat{z}_{f(n)}[k]$, which in turn is used to compute $\hat{x}_s[n+1]$, and so on.

Theorem 4.2: Suppose $(x_s[n], z_{f(n)}[m]) \in \mathcal{B}_N(r_s) \times \mathcal{B}_M(r_f)$ for $n = 0, \dots, \bar{n}$ and $m = 0, \dots, k$. If the system (4.1)–(4.4) satisfies Assumptions 4.1–4.5, then there exists an $\epsilon^* > 0$ such that for any $\epsilon \in (0, \epsilon^*)$

$$\hat{z}_{f(i)}[m] := \hat{\Phi}_{f(i)}^M \Delta \hat{H}_{f(i)}^{-1} (\Delta \hat{Y}_{f(i)}[m]) \quad (4.47)$$

$$= z_{f(i)}(mT/(k\epsilon)) + O(\epsilon) \quad (4.48)$$

$$\hat{x}_s[n] := F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]} \circ H_{sf}^{-1} (\hat{Y}_{sf}[n], \hat{Z}_f[n-1], U[n-1]) \quad (4.49)$$

$$= x_s(nT) + O(\epsilon) \quad (4.50)$$

for all $i = 0, \dots, \bar{n}$, $n = N, \dots, \bar{n}$, and $m = M, \dots, k$.

Proof: By (4.6) and the fact that $T/k = O(\epsilon)$, it is evident that $x_s(iT + mT/k) = x_s(iT + (m+1)T/k) + O(\epsilon)$. The continuity of h_s , along with (4.18) implies that

$$\Delta \hat{Y}_{f(i)}[m] = \Delta Y_{f(i)}[m] + O(\epsilon). \quad (4.51)$$

This fact, along with Assumptions 4.3 and 4.5 and (4.46), implies (4.48) for $i = 0, \dots, N-1$. We now proceed inductively in n . The above analysis proves that

$$\hat{Z}_f[n'-1] = Z_f[n'-1] + O(\epsilon) \quad (4.52)$$

for $n' = N$. Also, (4.18) implies that

$$\hat{Y}_{sf}[n'] = Y_{sf}[n'] + O(\epsilon) \quad (4.53)$$

for $n' = N$. These two facts, along with Assumption 4.4, the continuity of F_s and the hypothesis that $(x_s[n'], Z_f[n'-1]) \in \mathcal{B}_N(r_s) \times \mathcal{B}_{MN}(r_f)$ imply (4.50) for $n = n' = N$. But $\hat{x}_s[n'] = x_s[n'] + O(\epsilon)$ in turn implies (as argued above) that $\hat{z}_{f(n')}[m] = z_{f(n')}[m] + O(\epsilon)$ for $m = M, \dots, k$. Thus, repetition of this argument at an arbitrary n' inductively proves the result. Note finally that since this induction stops when $n' = n$, any cumulative errors are guaranteed to be $O(\epsilon)$. \square

Since the observers (4.47) and (4.49) are quite complex, it is helpful to enumerate the sequence of operations that implements the algorithm. The observers are evaluated by:

- 1) Using $\hat{x}_s[0] = \hat{x}_0$ if necessary, construct (4.44) and (4.45) for $n = 0$.
- 2) Set $m = n = 0$.
- 3) While $n \leq \bar{n}$
 - a) Measure $y(nT + mT/k)$.
 - b) If $m \geq M$, compute $\hat{z}_{f(n)}[m]$ from (4.47) using $y(nT + (m-M)T/k), \dots, y(nT + mT/k)$.
 - c) If $m = k$, then
 - Set $n = n + 1$ and $m = 0$.
 - If $n \geq N$, compute $\hat{x}_s[n]$ from (4.49) using $y((n-N+1)T), \dots, y(nT)$, $\hat{z}_{f(n-N)}[k], \dots, \hat{z}_{f(n-1)}[k]$ and $u[n-N], \dots, u[n-1]$. Else, set $\hat{x}_s[n]$ according to (4.46).

- Using $\hat{x}_s[n]$ if necessary, construct (4.44) and (4.45).

d) Set $m = m + 1$.

4) Stop.

Under certain conditions, it is possible to construct a slow observer which is independent of the fast observer. This is possible because if $z_{f(n)}$ is fast enough relative to T , then its contribution to the slow observer may be neglected.

Corollary 4.1: Suppose $x_s[n] \in \mathcal{B}_N(r_s)$ for $n = 0, \dots, \bar{n}$. If the system (4.1)–(4.4) satisfies Assumptions 4.1, 4.2, and 4.4, then there exists an $\epsilon^{**} > 0$ such that for any $\epsilon \in (0, \epsilon^{**})$

$$\tilde{x}_s[n] := F_s^{u[n-1]} \circ \dots \circ F_s^{u[n-N+1]} \circ H_{sf}^{-1} (\hat{Y}_{sf}[n], 0, U[n-1]) \quad (4.54)$$

$$= x_s(nT) + O(\epsilon) \quad (4.55)$$

for $n = N, \dots, \bar{n}$.

Proof: In light of (4.19), there exists an ϵ^{**} so that (for the given T) $z_{f(n)}[k] = O(\epsilon)$ for all $n = 0, \dots, \bar{n}$. Utilizing this fact in (4.49) yields (4.55). \square

Corollary 4.1 is different from Corollary 3.1 in that (4.54) produces estimates over the same range of n as (4.49) does. This is because ϵ is assumed to be small enough so that the boundary layers are over in one slow sampling interval. Note that it is not possible to simply “wait long enough” for the boundary layer to be over, because it is excited by each step in the slow input. Finally, the observer (4.54) does not require either fast subsystem observability, knowledge of x_0 , or special structure of A_2 and C .

C. Electromechanical System Example

An important practical application considered now is velocity control of two-phase permanent-magnet synchronous motors using only phase current measurements. In [6], a recursive nonlinear observer similar to an Extended Kalman Filter is constructed to estimate the rotor motion from stator current measurements. The disadvantages of the scheme in [6], in comparison with the methods introduced in this paper, include: sampling and computation necessarily occur in the electrical time-scale; the innovation gains must be selected for a specific and limited range of rotor velocities to avoid poor estimation error convergence.

The two-phase permanent-magnet synchronous motor can indeed be modeled as a singularly perturbed nonlinear system in the form (4.1)–(4.4) under standard assumptions. Assuming that magnetic saturation effects are negligible, that the air gap is smooth, that the distribution of windings eliminates harmonic effects, and that the load is a constant inertia, the continuous-time dynamic model is

$$\frac{d\theta}{dt} = \omega \quad (4.56)$$

$$\frac{d\omega}{dt} = \frac{1}{J} (K_m (i_1 \sin(N_p \theta) + i_2 \cos(N_p \theta)) - B\omega) \quad (4.57)$$

$$L \frac{di_1}{dt} = v_1 - Ri_1 - K_m \omega \sin(N_p \theta) \quad (4.58)$$

$$L \frac{di_2}{dt} = v_2 - Ri_2 - K_m \omega \cos(N_p \theta) \quad (4.59)$$

Fig. 3. Motor response under output feedback control using only the slow observer of Corollary 4.1 for $L = L_{nom}$ and $L = 10L_{nom}$. (a) Actual rotor velocity $\omega(t)$ and (b) Phase 1 current $i_1(t)$ and slow manifolds $\phi_n(x_s(t), u[n])$ for $n = 0, \dots, 4$ at $L = L_{nom}$.

where θ and ω are the angular position and velocity of the rotor, i_1 and i_2 are the currents in the stator phases, v_1 and v_2 are the voltages applied to the stator phases, K_m is the magnet constant, N_p is the number of magnet pole pairs on the rotor, J is the total rotor inertia, B is the total rotor viscous damping coefficient, L is the inductance of the stator phases, and R is the resistance of the stator phases. Typically, L can be taken as a small parameter so that, in the notation of (4.1)–(4.3), $\epsilon = L$, $x = [\theta \ \omega]'$, $z = [i_1 \ i_2]'$, $u = [v_1 \ v_2]'$, and $y = [i_1 \ i_2]'$.

The reduced-order observers are formulated according to Theorem 4.2. The fast observer is decoupled from the slow observer and is defined for all $1 \leq m \leq k$ and each fixed n by

$$\hat{i}_{f(n)1}[m] = \frac{\phi_f}{\phi_f - 1} (i_{n1}[m] - i_{n1}[m-1]) \quad (4.60)$$

$$\hat{i}_{f(n)2}[m] = \frac{\phi_f}{\phi_f - 1} (i_{n2}[m] - i_{n2}[m-1]) \quad (4.61)$$

where $i_n[m] := i(nT + mT/k)$ and $\phi_f := \exp(-RT/Lk)$. The slow observer can be constructed using only the slow subsystem output equations. Thus, discretization of the slow subsystem is not necessary, and the slow observer is implicitly defined for $n \geq 1$ as a solution $(\hat{\theta}_s[n], \hat{\omega}_s[n])$ of the system of nonlinear algebraic equations

$$\begin{aligned} \psi_1 &:= \frac{1}{K_m} (v_1[n-1] - R(i_1[n] - \hat{i}_{f(n-1)1}[k])) \\ &= \hat{\omega}_s[n] \sin(N_p \hat{\theta}_s[n]) \end{aligned} \quad (4.62)$$

$$\begin{aligned} \psi_2 &:= \frac{1}{K_m} (v_2[n-1] - R(i_2[n] - \hat{i}_{f(n-1)2}[k])) \\ &= \hat{\omega}_s[n] \cos(N_p \hat{\theta}_s[n]) \end{aligned} \quad (4.63)$$

where $i[n] := i(nT)$, and where ψ_1 and ψ_2 are computed from known quantities. The observer of Corollary 4.1 is recovered by setting $\hat{i}_{f(n-1)}[k] = 0$ in (4.62)–(4.63).

A few comments are in order concerning the inversion of the slow observer equations. Whenever $\psi_1 \neq 0$ or $\psi_2 \neq 0$, (4.62)–(4.63) can be solved for $\hat{\theta}_s[n]$ and $\hat{\omega}_s[n]$. There are, however, multiple solutions. If (θ^0, ω^0) is a solution, then so are $(\theta^0 \pm \frac{2\pi}{N_p}j, \omega^0)$ and $(\theta^0 \pm \frac{\pi}{N_p}(2j-1), -\omega^0)$, for any integer j . In the previous section, this type of difficulty was avoided by insisting that $x_s[n] \in \mathcal{B}_N(r_s)$. In this example, such an approach would require $\theta_s[n] \in \mathcal{B}_1(\pi/2N_p - \delta_\theta)$ for some $\delta_\theta \in (0, \pi/2N_p)$. Since limiting the rotor motion is not practical, heuristic rules will be used to decide which solution of (4.62)–(4.63) is the correct one. Assuming that T is sufficiently small so that θ does not vary more than $\pm\pi/(2N_p)$ from one slow sampling instant to the next, it is reasonable to choose the solution closest to the previous estimate. If the motor starts from rest and $\theta(0)$ is known to $\pm\pi/(2N_p)$, then this scheme will provide the correct solution. If $\psi_1 = \psi_2 = 0$, then $\hat{\omega}_s[n] = 0$ and thus (4.62)–(4.63) cannot be inverted, so the estimate $\hat{\theta}_s[n] = \hat{\theta}_s[n-1]$ will be used in this case.

The observer-based feedback will be designed from the slow subsystem. The simplest such feedback, one that emulates a continuous-time linearizing slow controller, is given by

$$\begin{aligned} \begin{bmatrix} v_1[n] \\ v_2[n] \end{bmatrix} &= \begin{bmatrix} \sin(N_p \hat{\theta}_s[n]) \\ \cos(N_p \hat{\theta}_s[n]) \end{bmatrix} \\ &\times \left(\frac{K_m^2 + BR - JRK_\omega}{K_m} \omega_s[n] + \frac{JRK_\omega}{K_m} \omega^d \right) \end{aligned} \quad (4.64)$$

where ω^d is the desired velocity and $K_\omega > 0$ is a design parameter. The continuous-time version of (4.64) acting on the slow subsystem (under the assumptions that $L = 0$, $\theta_s = \theta$, and $\hat{\omega}_s = \omega_s$) results in closed-loop dynamics $\dot{\theta}_s = \omega_s$, $\dot{\omega}_s = K_\omega(\omega^d - \omega_s)$. Since (4.64) emulates a continuous-time control, T needs to be relatively small.

Simulations were run with parameters from a commercially available motor: $N_p = 2$ pole pairs, $R = 0.418\Omega$, $L = 0.131$ mH, $K_m = 29.4$ mN·m/A, $J = 0.0205$ g·m²/rad, $B = 0.013$ g·m²/rad·sec, $T = 0.001$ sec and $k = 10$. Note that the value given above for L (i.e. ϵ) will be used as a “nominal” value. In all cases, the motor, starting from rest with $\hat{\theta}_s[0] = 0$ and $\theta(0) = 0.2$, was commanded to regulate to $\omega^d = 40$ rad/sec for $t \in [0, 2.5]$ sec, and to $\omega^d = -40$ rad/sec for $t \in [2.5, 5.0]$ sec, with $K_\omega = 13$.

The first case considered corresponds to output feedback control using the slow observer of Corollary 4.1. Fig. 3(a) shows $\omega(t)$ for $L = L_{nom}$ and $L = 10L_{nom}$. At $L = L_{nom}$, the controller does an excellent job of providing the desired linear response. At $L = 10L_{nom}$, however, the controller has trouble at startup, and the heuristics for choosing the correct sign of the velocity fail. In Fig. 3(b), $i_1(t)$ and the corresponding first five slow manifolds are shown for $L = L_{nom}$. In this case, T is just large enough for $i_1(t)$ to settle to its quasi-steady-state value. For $L = 10L_{nom}$, this property no longer holds and, hence, the observer fails severely.

Fig. 4 Motor response under output feedback control using both the slow and fast observers of Theorem 4.2 for $L = 10I_{nom}$ and $L = 500I_{nom}$. (a) Actual rotor velocity $\omega(t)$ and (b) Phase 1 current $i_1(t)$ and slow manifolds $u[n]$ for $n = 0, \dots, 1$ at $L = 10I$.

The second case considered corresponds to output feedback control using the slow and fast observers of Theorem 4.2. Fig. 4(a) shows $\omega(t)$ for $L = 10I_{nom}$ and $L = 500I_{nom}$. At $L = 10I_{nom}$ the controller performs very well although a perceptible steady-state error occurs. Although not evident from the plot the steady state error is not a consequence of observation error but instead is due to the failure of the emulating controller. At $L = 500I_{nom}$ the controller yields substantially degraded performance. In Fig. 4(b), $i_1(t)$ and the corresponding first five slow manifolds are shown for $L = 10I_{nom}$. Even though $i_1(t)$ doesn't settle to its quasi-steady-state value, use of the fast observer has accounted for this feature, resulting in good performance.

V CONCLUSIONS

In this paper, the observer design problem for nonlinear singularly perturbed systems has been formulated as one of designing separate observers for the approximate slow and fast subsystem models. Not only are the resulting observers of reduced-order, they are also implemented in a multirate fashion. Both of these features result in significant savings in computational and/or memory requirements. Furthermore, the stiffness inherent in a full-order implementation is eliminated by this approach.

It has been proven that this reduced-order observer design methodology guarantees $O(\epsilon)$ observation errors. Hence for sufficiently small ϵ , these errors will be acceptable for all practical purposes. Although the development of stabilizing observer-based control algorithms has not been attempted, the use of observer-based feedback has been considered in a case-

study. For the application to so-called sensorless control of permanent-magnet synchronous motor, the performance has been demonstrated using our reduced-order observer designs.

From 1986-1988, Dr. Shouse worked as a Project Engineer for Viste Chemical Co. in Lake Charles, LA. He is currently a Research Engineer in the Engine and Vehicle Research Division of the Southwest Research Institute, San Antonio, TX. His research interests include discrete time nonlinear control theory and its application to internal combustion engines and electromechanical systems.

David G. Taylor (S'80, M'88) was born in Oak Ridge, Tennessee, on August 7, 1961. He received the B.S. degree from the University of Tennessee, Knoxville, in 1983 and the M.S. and Ph.D. degrees from the University of Illinois, Urbana-Champaign, in 1985 and 1988, respectively, all in electrical engineering.

During the summers from 1981 to 1983, he was employed by Oak Ridge National Laboratory, Oak Ridge, Tennessee, and IBM Corporation, Charlotte, North Carolina. From 1983 to 1988, he held various fellowships and assistantships at the University of Illinois, Urbana-Champaign. Since 1988, he has been with the School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, where he is now an Associate Professor.

Dr. Taylor's research interests include nonlinear control theory and its applications to electromechanical systems. He received the NSF Presidential Young Investigator Award in 1991.

Adaptive Back-Pressure Congestion Control Based on Local Information

Leandros Tassiulas, *Member, IEEE*

Abstract—The problem of distributed congestion control as it arises in communication networks as well as in manufacturing systems is studied in this paper. In particular, a multistage queueing system that models virtual circuit and datagram communication networks and a class of manufacturing systems are considered. The topology may be arbitrary, there are multiple traffic classes, and the routing can be class dependent, with routes that may form direct or indirect loops. The model incorporates the functions of transmission scheduling, flow control, and routing, through which congestion control is performed in the network. A policy is given that performs these functions jointly. According to the policy, heavily loaded queues are given higher priority in service. A congested node may reduce the flow from upstream nodes through a flow control mechanism. Whenever routing is required, it is performed in such a manner that the lightly loaded queues receive most of the traffic. For arrival processes with bounded burstiness, the policy guarantees bounded backlogs in the network, as long as the load of each server is less than one. The actions of each server are based on the state of its own queues and of the queues one hop away. Therefore, they are implementable in a distributed fashion. An adaptive version of the policy is also provided which makes it independent of the arrival rates.

I. INTRODUCTION

DYNAMIC control achieves a better utilization of the transmission and switching resources of a communication network over static schemes. Dynamic schemes have been adopted for packet routing, for sharing the transmission capacity of a link among several competing information streams, or for controlling the flow of traffic in a packet switching network. In large networks though, where the control functions are distributed, dynamic control policies are prone to misbehavior, and the network may enter intriguing instability modes. The same phenomenon has been observed in manufacturing systems with distributed scheduling [10], [6]. In this work, we present a new distributed dynamic control policy in a multistage queueing system that models virtual circuit and datagram communication networks, as well as a class of manufacturing systems. The policy, which we call the adaptive back-pressure (ABP) congestion control policy, schedules the servers, routes the served traffic, and controls the flow based on local information, and therefore is amenable to distributed implementation. Each server is allocated dynamically based on the state of the queues that it serves, as well as on the state

of downstream queues, which are one hop away. When there are routing options, the decision is taken again in a similar distributed fashion. It is shown that under the ABP policy, the backlog in the network remains bounded as long as the utilization of each server is less than one.

A central problem in the design of virtual circuit (VC) communication networks is the sharing of the transmission capacity of a link among the virtual circuits that go through it. Several schemes have been proposed, including round robin, weighted round robin, golden ratio scheduling, virtual clock, and processor sharing [4], [9], [14], [8], [5]. In some of the above schemes [4], [5], the link transmission scheduling is combined with window flow control. One of the main problems arising in this context is how to evaluate the throughput of a virtual circuit network, that is, the session rates that can be sustained by the network for certain transmission control policies, without experiencing instabilities. Cruz [2], [3] has considered this problem in virtual circuit networks by employing several different link transmission disciplines including FIFO, LIFO, and strict priority. He obtained bounds for the backlog in the nodes of the network. These bounds depend on the session arrival rates and burstiness characteristics, and guarantee stable operation of the system for the traffic parameters for which they remain finite. In certain cases though, in networks with virtual circuits that may form cycles, these bounds explode for arrival rates which give utilization strictly less than one at all network links. In this case, no conclusion can be drawn for the stability of the network. Chang [1] extended these results, obtaining backlog bounds in multiclass networks with routing. The stability problem yet remained open for certain cases in networks with cycles. Yaron and Sidi [13] addressed the same question with processes satisfying constraints on the tails of the backlog distribution. Hahne [4] has shown that with round robin scheduling in each link and hop-by-hop window flow control, there exist window sizes to stabilize the network as long as the link utilization is less than one. The selection of the window sizes depends on the arrival rates. By the ABP policy, stabilization of the network is achieved as long as the utilization of every link is less than one, and no knowledge of the arrival rates is required for its implementation. When the routes of the packets are not prespecified but only their final destinations are given, as is the case with datagram communication networks, then the ABP policy combines routing with the scheduling mechanisms described in the VC case to preserve bounded queue lengths.

A problem of stability, similar to the one discussed above, arises in manufacturing systems operated under distributed

scheduling policies. Perkins and Kumar [10] and Kumar and Seidman [6] have studied the problem of stability in a flexible manufacturing system with distributed scheduling. While simple distributed policies are shown to stabilize acyclic manufacturing networks in [10], a simple two-stage queueing network is presented in [6]. In this model instabilities occur in situations in which all servers of the system are strictly underloaded and the system is operated under a work-conserving policy. This example demonstrates how instabilities may occur in multistage manufacturing systems due to the phenomena of starvation and overloading. The queueing network that corresponds to the manufacturing system considered falls within the scope of the networks presented in our study. The ABP policy stabilizes the manufacturing system as long as the utilization of each machine is less than one. The scheduling of each machine i is determined by the size of the backlog of the different part types in i , as well as the size of the backlogs of those part types in downstream machines one hop away from i . Occasionally, the machines are forced to idle again, depending on the local state. The queueing system presented here extends the above manufacturing systems model to include the case where a part type may have the option of several alternative manufacturing scenarios and routing decisions are made. In Section II-C, this is discussed in more detail. The ABP policy in that case combines scheduling and routing decisions to achieve the same goal. In [11], a single-class network was considered, and a routing policy of the same nature was studied for Poisson arrivals.

For the arrival process, we assume that the burstiness is bounded by a deterministic bound [2], [3]. This traffic assumption has been used widely lately since the outputs of the traffic regulators that shape the traffic before it enters a high-speed network satisfy this type of constraint. Lu and Kumar [7] have used a similar type of traffic in the context of a manufacturing system.

The rest of the paper is organized as follows. In Section II, the queueing network is presented, and the correspondence with virtual circuit and datagrams networks as well as manufacturing systems is demonstrated. In Section III, the issue of stability is discussed, and the sufficient stability condition is shown. In Section IV, a parametric class of policies is specified, and their stability is studied. In Section V, the ABP policy is specified and investigated. Finally, in Section VI, the results are discussed and some open problems are presented.

II. THE NETWORK MODEL

We consider a network consisting of N servers and B buffers (Fig. 1). Each server i can serve any buffer from the set of buffers B_i , $i = 1, \dots, N$ —it is allocated to the buffers according to some scheduling discipline. The sets B_i may be overlapping, that is, a buffer may be served by more than one server simultaneously. The served traffic from buffer j can be directed to any buffer of the set \mathcal{R}_j . A routing policy determines to which buffer in \mathcal{R}_j the traffic from j is routed. From certain buffers, the traffic can be directed out of the system; this is indicated by including a 0 in the set \mathcal{R}_j . We make the natural assumption that, from every buffer, the work

can be forwarded out of the system if it is routed through an appropriate sequence of buffers. We consider a fluid model for the work coming into the system. The time is continuous and the instantaneous rate with which work comes to buffer i from outside is $a_i(t)$. For simplicity, we assume that the arrival stream can contain no impulses, that is, the arrival rate $a_i(t)$ for all buffers i is bounded uniformly over time by a bound λ . In the time interval (t_1, t_2) , an amount of work equal to

$$\int_{t_1}^{t_2} a_i(t) dt$$

enters buffer i from outside. We assume that the arrival streams satisfy some burstiness constraints; that is, there are nonnegative numbers a_i, b_i , $i = 1, \dots, B$ such that, for all $0 \leq t_1 < t_2$, we have

$$\int_{t_1}^{t_2} a_i(t) dt \leq a_i(t_2 - t_1) + b_i. \quad (2.1)$$

We will assume that the long-run average rate with which work enters the system in buffer i exists

$$\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t a_i(s) ds = a_i, \quad i = 1, \dots, B$$

and a_i will be referred to as the arrival rate to buffer i . The latter assumption is not needed for the validity of the results. It is introduced only because it is conceptually simpler to think of the a_i as being the arrival rate to buffer i . When server i provides service to buffer $j \in B_i$ which is nonempty, work leaves the buffer with a constant rate μ_{ij} , the service rate of server i at buffer j . If server i is assigned to buffer j continuously for an amount of time T and the traffic is directed to buffer l in \mathcal{R}_j , then an amount of work $T\mu_{ij}$ is transferred from j to l . The selection of buffer $j \in B_i$ served by i and of buffer $l \in \mathcal{R}_j$ to where the traffic is directed is done by the control policy. This work is routed to some buffer in \mathcal{R}_j . We allow more than one server to serve the same buffer; in that case, the service rate is assumed to be equal to the sum of the rates of the servers that serve the buffer. When server i that serves buffer j and directs the traffic to buffer k switches to buffers l and m , respectively, a switchover time δ_{iklm}^s is involved during which the server idles. The results in the paper hold for arbitrary and distinct switchover times. For notational simplification but no loss of generality, however, we will assume that the switchover time denoted by δ and be the same for all servers and buffers. In the following, we discuss how certain networks fall within the scope of the above model.

A. Virtual Circuit Networks

A VC network is characterized by its topology graph $G = (V, E)$, the transmission rates of the links and the established VC's. The topology graph contains one node for every network node and one directed link $e = (v, w)$ for every communication link from node v to node w . The transmission rate of link e is denoted by μ_e . A virtual circuit i is specified by the sequence of links e_1^i, \dots, e_N^i that traverses as it goes through the network. The traffic of VC i enters the network at the origin node of e_1^i and leaves it at the destination node

Fig. 1. An example of the network specified in Section II is depicted. There are three servers 1, 2, 3 (not depicted) which serve the queues in the sets B_1 , B_2 , and B_3 , respectively. The traffic from each queue i may be routed to any queue j to which there is an arrow from i .

of link e_N^i . A scheduling policy schedules for each link the transmissions of the virtual circuits going through it. Also, at certain times, the link may be forced to idle due to flow control actions.

A virtual circuit network is modeled by the above queueing system as follows (Fig. 2). Each link corresponds to a server with transmission capacity equal to its service rate. Clearly, in this case, the service rate of server (link) j is the same for all buffers in B_j . There is one buffer for every VC i and every link e_k^i is traversed by i . The buffers of virtual circuit i contain traffic of that VC waiting to be transmitted through the corresponding link. When a link is allocated to any of the buffers of the VC's going through it, that buffer empties with rate equal to the link transmission rate. The traffic from the buffer of virtual circuit i at link e_j^i is routed to the buffer of the same virtual circuit at link e_{j+1}^i , except if e_j^i is the last link traversed by VC i ; in the latter case, the traffic leaves the system. Hence, the set \mathcal{R}_j contains a single element for each j and no routing is needed. The traffic in the VC's consists of streams of packets, and clearly, the link cannot switch from VC to VC in a time period smaller than a packet transmission time. In the assumptions we made, though, in the previous section, the traffic is considered as a continuous flow. For the results that we obtain here, it is not important whether the traffic is continuous or in terms of packets since the policies we propose can be easily modified to work with packetized traffic.

B. Datagram Networks

In datagram networks, the traffic of a communication session does not have to follow a specific route, but can be routed arbitrarily, and different packets may follow different paths to the destination. The packets are differentiated only by their destination nodes. When a packet arrives at a node which is not its final destination, a decision is made as to which outgoing link the packet will follow next; then the packet is placed at the outgoing buffer of that link. There are no constraints on

Fig. 2. A virtual circuit network

which outgoing link the packets of each specific destination will follow; this is determined by the routing policy. Packets of several different destinations are waiting in the buffer of each outgoing link to be transmitted. The link scheduling discipline determines which is the packet to be transmitted next. In the corresponding queueing model, the buffers are in one-to-one correspondence with the links. For each server i , there is one buffer in B_i for each destination node. The traffic with destination node k , which is transmitted through link i , is stored in the corresponding buffer of B_i . These buffers do not necessarily correspond to physical buffers in the origin node of link i . Their introduction enables the differentiation of the traffic, based on the destination and the link the traffic will go through. If, from the topology of the network or from other constraints, it turns out that the traffic of a specific destination never transverses link i , then the corresponding buffer in B_i will be permanently empty.

C. Manufacturing Systems

In manufacturing systems, several different types of parts are fabricated. A part type, in order to be manufactured, needs to be processed by a number of machines in some prespecified order. In flexible manufacturing systems, a machine can process more than one type of part. In this case, the machine has to switch from one part type to another at certain times since the different parts are not processed simultaneously. The switching of the machine involves a period during which the machine idles. The switching should be done rarely enough such that the fraction of time that the machine is utilized is higher than the loading.

Perkins and Kumar [10] have obtained a distributed scheduling policy that stabilizes any acyclic network of manufacturing machines. When cycles are formed by the routes of the parts in the manufacturing system, then the behavior of the system is more difficult to characterize. The intrinsic complexity of the problem was demonstrated by a counterintuitive example of instability in a simple manufacturing system in [6]. The queueing network considered here is readily interpreted into a manufacturing system model. The servers correspond to the machines, the arrival streams to the different part types, and the buffers of each machine store the part types at intermediate processing stages. If a part type needs to be processed by a machine more than once in its manufacturing cycle, then it

waits in a different buffer each time. When the part types have unique routes through the manufacturing system, then the sets \mathcal{R}_j have a unique element, the next buffer that the parts will join when they leave from j . Kumar and Seidman in [6] propose a scheduling policy with a supervisor mechanism that stabilizes the manufacturing system as long as the load of each machine is less than one. The supervisory mechanism, though, relies on knowledge of the arrival rates. The ABP policy stabilizes the system without the arrival rate information. The model considered here extends the one considered in [10], [6] to include cases where a part type has the option to follow different routes at certain points of its processing, in which case routing is performed.

III. NECESSARY AND SUFFICIENT STABILIZABILITY CONDITIONS

We are interested in the average rate with which work can be served. We consider that certain throughput rates can be achieved if there exists a policy under which the network is stable when the long-run average arrival rates are equal to the desired throughputs. Denote by $X_j(t)$ the amount of work in buffer j at the time t .

Definition. The system is stable under a policy π if

$$\limsup_{t \rightarrow \infty} \sum_{j \in \mathcal{B}_i} X_j(t) < D$$

where D may depend only on the arrival rates $\mathbf{a} = (a_1, \dots, a_N)$, the burstiness coefficients $\mathbf{b} = (b_1, \dots, b_N)$, and the service rates $\mu = (\mu_{ij} : i = 1, \dots, N, j \in \mathcal{B}_i)$, but not on the initial condition.

The following condition on the arrival and service rates is necessary and sufficient for the existence of a policy under which the network is stable.

C1. There exist nonnegative numbers f_{jk} , $j = 1, \dots, B$, $k \in \mathcal{R}_j$ that satisfy the flow conservation equations

$$a_i + \sum_{k \in \mathcal{R}_i} f_{ki} = \sum_{k \in \mathcal{R}_i} f_{jk}, \quad i = 1, \dots, B. \quad (3.1)$$

Also, there exist nonnegative numbers u'_j , $i = 1, \dots, N$, $j = 1, \dots, B$ such that

$$\sum_{j \in \mathcal{B}_i} u'_j < 1, \quad i = 1, \dots, N, \quad (3.2a)$$

$$\sum_{i \in \mathcal{R}_j} f_{ji} \leq \sum_{i \in \mathcal{B}_i} u'_i \mu_{ij}, \quad j = 1, \dots, B. \quad (3.2b)$$

More specifically, it is shown that C1 is sufficient for stability if the burstiness condition (2.1) holds, while C1 is necessary for stability when the arrival process satisfies a "bounded idleness" condition, to be specified later. No existence of the arrival rate is needed. An intuitive justification of C1 follows. The number f_{jk} in the condition C1 represents the long-run average rate with which work is transferred from buffer j to buffer k . Hence, (3.1) is indeed a flow conservation equation. A collection of nonnegative numbers f_{jk} , $j = 1, \dots, B$, $k \in \mathcal{R}_j$ which satisfy (3.1) will be referred

Fig. 3. A network with routing control.

to as flow in the following. The number u'_j represents the fraction of time that server i spends serving buffer j . Inequality (3.2b) expresses the fact that the rate with which work leaves buffer j [the sum on the left side of (3.2b)] cannot be greater than the server capacity [the sum on the right of (3.2b)] that is allocated to that buffer.

In the case of a virtual circuit network, condition C1 is equivalent to the condition that, for every link, the sum of the average rates of all virtual circuits that go through the link is strictly less than its transmission capacity. This can be easily seen by observing the following. Since there is no routing involved, \mathcal{R}_j contains a single element for all j 's and f_{jk} is equal to the arrival rate of the virtual circuit that buffer j corresponds to (recall that in the VC network case, each buffer corresponds to one virtual circuit). Each buffer can be served by one server (link) only; therefore, the sums at the second inequality in (3.2) are reduced to single terms; these inequalities are equivalent to the fact that the traffic load of every link is less than one. The proof of the necessity of C1 for stabilizability follows, while the sufficiency will be proved in Section IV where the parametric back-pressure policy, the predecessor of the ABP, will be specified.

A. Necessity

When the long-run average rate with which work goes from buffer j to k as well as the long-run average fraction of time spent by server i serving buffer j exist, the intuitive interpretation of C1 given earlier turns readily into a proof of the necessity of C1. These long-run averages, though, do not exist for every policy, even if the system is stable, as illustrated in the following counterexample; therefore, a different approach should be taken to show the necessity of C1.

Counterexample: Consider the system in Fig. 3 that consists of three buffers. Buffer 1 receives work with constant rate 0.8, and is served by a server of higher service rate; therefore, it leaves the buffer instantaneously. The served work is routed either to buffer 2 or to 3, from where it leaves the system instantaneously. The switchover time is equal to 0. Clearly, as long as the server does not idle, the system will be stable. The routing is specified by the variable $\tau(t)$ which represents the buffer that is fed from buffer 1 at time t . Let

$$\tau(t) = \begin{cases} 2, & 3^{2k} \leq t \leq 3^{2k+1}, \quad k = 0, 1, \dots \\ 3, & 3^{2k+1} \leq t \leq 3^{2k+2}, \quad k = 0, 1, \dots \end{cases}$$

If f_{12}^i is the average flow from buffer 1 to buffer 2 at the i th routing transition, then we can see that f_{12}^i fluctuates between values which are greater than $\frac{8}{15}$ and less than $\frac{1}{15}$; therefore, it cannot converge, and the long-run average flow does not exist. \diamond

Next, we show the necessity of condition C1. The necessity follows when the arrival streams satisfy the following condition.

S1: There exist nonnegative numbers \hat{b}_i , $i = 1, \dots, B$ such that

$$\int_{t_1}^{t_2} a_i(\tau) d\tau \geq a_i(t_2 - t_1) - \hat{b}_i.$$

Condition S1 can be viewed as a constraint on the idling of the arrival streams.

Theorem 3.1: If the system is stable and condition S1 holds, then condition C1 holds as well.

The proof of the theorem will follow after a lemma. The following definition is needed. A collection of nonnegative numbers f_{jk} , $j = 1, \dots, B$, $k \in \mathcal{R}_j$ is called a *superflow* if

$$a_j + \sum_{k \in \mathcal{R}_k} f_{kj} \leq \sum_{k \in \mathcal{R}_j} f_{jk}, \quad j = 1, \dots, B \quad (3.3)$$

and a *strict superflow* if the inequality in (3.3) is strict whenever $\sum_{k \in \mathcal{R}_j} f_{jk} > 0$. The notions of superflow and strict superflow do not correspond to any physical quantities in the system, and they are introduced only to be used in the proofs.

Lemma 3.1: If $\mathbf{f}' = (f'_{jk}, j = 1, \dots, B, k \in \mathcal{R}_j)$ is a superflow, then there exists a flow $\mathbf{f} = (f_{jk}, j = 1, \dots, B, k \in \mathcal{R}_j)$ such that

$$\mathbf{f} \leq \mathbf{f}' \quad (3.4)$$

where the inequality (3.4) holds componentwise. If \mathbf{f}' is a strict superflow, then there exists a flow \mathbf{f} such that (3.4) holds with strict inequality, for the nonzero elements of \mathbf{f} and \mathbf{f}' .

Proof. Consider the transformation T defined by $\mathbf{f}^{i+1} = T(\mathbf{f}^i)$ where

$$f_{jk}^{i+1} = \begin{cases} \frac{a_j + \sum_{l \in \mathcal{R}_l} f_{lj}^i}{\sum_{l \in \mathcal{R}_j} f_{jl}^i} f_{jk}^i & \text{if } \sum_{l \in \mathcal{R}_j} f_{jl}^i > 0 \\ f_{jk}^i & \text{otherwise.} \end{cases}$$

It is claimed that if \mathbf{f}' is a superflow, then \mathbf{f}^{i+1} is a superflow as well and

$$\mathbf{f}^{i+1} \leq \mathbf{f}' \quad (3.5)$$

while if \mathbf{f}' is a strict superflow, then \mathbf{f}^{i+1} is a strict superflow as well, and (3.5) holds with strict inequality. Notice that (3.5) follows readily since the fact that \mathbf{f}' is a superflow (strict superflow) implies readily that

$$\frac{a_j + \sum_{l \in \mathcal{R}_l} f_{lj}^i}{\sum_{l \in \mathcal{R}_j} f_{jl}^i}$$

is less (strictly less) than one. From the definition of $T(\cdot)$, we have

$$\sum_{k \in \mathcal{R}_j} f_{jk}^{i+1} = a_j + \sum_{l \in \mathcal{R}_l} f_{jl}^i. \quad (3.5a)$$

From (3.5) and (3.5a), it follows that

$$\sum_{k \in \mathcal{R}_j} f_{jk}^{i+1} \geq a_j + \sum_{l \in \mathcal{R}_l} f_{jl}^{i+1} \quad (3.5b)$$

if \mathbf{f}' is a superflow, while (3.5b) holds with strict inequality if \mathbf{f}' is a strict superflow. Relation (3.5b) shows that \mathbf{f}^{i+1} is a superflow and (3.5b), with strict inequality, that it is a strict superflow.

Obviously, if \mathbf{f}' is a flow, then $\mathbf{f}^{i+1} = \mathbf{f}'$. Consider the sequence of superflows \mathbf{f}^i , $i = 0, 1, \dots$ defined as $\mathbf{f}^0 = \mathbf{f}'$, $\mathbf{f}^{i+1} = T(\mathbf{f}^i)$, $i = 0, 1, \dots$. This sequence is nonincreasing, and as a consequence, it converges to a fixed point of $T(\cdot)$ denoted by \mathbf{f}^∞ . Note, though, that all fixed points of T are flows; hence, \mathbf{f}^∞ is a flow which is less than or equal to \mathbf{f}' in general, and strictly less than \mathbf{f}' if \mathbf{f}' is a strict superflow. \diamond

Remark: If \mathbf{f}' in the above lemma contains no cycles, that is, there is no sequence of buffers l_1, l_2, \dots, l_k such that $l_1 = l_k$, $l_{j+1} \in \mathcal{R}_{l_j}$, $j = 1, \dots, k-1$, $f_{l_j l_{j+1}} > 0$, $j = 1, \dots, k-1$, then the sequence of the superflows \mathbf{f}^i , $i = 0, 1, \dots$ in the proof of Lemma 3.1 will converge after a finite number of steps. If there is a cycle in \mathbf{f}' , then the convergence takes an infinite number of steps.

Now, we can proceed to the proof of the theorem.

Proof of Theorem 3.1. Assume that the system is stable. From the definition of stability, there exists D such that for every $\mathbf{X}(0)$, there exists T , which may depend on $\mathbf{X}(0)$, for which

$$\sum X_j(t) \leq D, \quad t \geq T. \quad (3.6)$$

Assume that initially each buffer has a backlog equal to $2D$, and T is such that (3.6) holds for this initial condition. Let Q_{jk} be the total amount of work that has been transferred from buffer j to buffer $k \in \mathcal{R}_j$ in the time interval $(0, T')$, where $T' > T$ is a time to be selected appropriately, as we will see in the following. Clearly, $X_j(T') \leq D$, $j = 1, \dots, B$ and

$$X_j(T') = 2D + \sum_{k \in \mathcal{R}_k} Q_{kj} - \sum_{k \in \mathcal{R}_j} Q_{jk} + \int_0^{T'} a_j(t) dt \leq D, \quad j = 1, \dots, B. \quad (3.6a)$$

Consider the nonnegative vector $\mathbf{f} = (f_{jk} : j = 1, \dots, B, k \in \mathcal{R}_j)$ where $f_{jk} = Q_{jk}/T'$. If we divide (3.6a) by T' , and using S1, we get

$$\begin{aligned} a_j + \sum_{k \in \mathcal{R}_k} f_{kj} &\leq \sum_{k \in \mathcal{R}_j} f_{jk} + a_j - \frac{1}{T'} \int_0^{T'} a_j(t) dt - \frac{D}{T'}, \quad j = 1, \dots, B \\ &\leq \sum_{k \in \mathcal{R}_j} f_{jk} + \frac{\hat{b}_j}{T'} - \frac{D}{T'}. \end{aligned} \quad (3.7)$$

If we select $D > \max_{j=1, \dots, B} \hat{b}_j$, and condition S1 holds, then (3.7) implies that \mathbf{f} is a strict superflow. Let T'_{jk} be the amount of time that server i serves buffer j and directs the traffic to buffer k during the time period from 0 to T' . Define

$$\hat{w}_j = \frac{\sum_{k \in \mathcal{R}_j} T'_{jk}}{T'}.$$

Since each server may serve at most one buffer at a time, we have

$$\sum_{j \in \mathcal{B}_i} \hat{u}_j^i \leq 1 \quad (3.8)$$

We also have

$$Q_{jk} = \sum_{i \in \mathcal{B}} T'_{jk} \mu_{ij} \quad k \in \mathcal{R}_j,$$

which yields

$$\sum_{k \in \mathcal{R}_j} Q_{jk} = \sum_{k \in \mathcal{R}} \sum_{j \in \mathcal{B}} I'_{jk} \mu_{ij} \quad k \in \mathcal{R}_j$$

and therefore

$$\sum_{k \in \mathcal{R}} f_{jk} = \sum_{i \in \mathcal{B}} u_j^i \mu_{ij} \quad k \in \mathcal{R}_j \quad (3.9)$$

From Lemma 3.1, since f is a strict superflow, there exists a flow f' such that $f'_{jk} < f_{jk}$ if $f_{jk} > 0$. Let

$$\epsilon = \max \left\{ \frac{f'_{jk}}{f_{jk}} : j = 1, \dots, B, k \in \mathcal{R}_j, f_{jk} > 0 \right\}$$

Clearly $\epsilon < 1$. Define

$$u_j^i = \epsilon u_j^i \quad i = 1, \dots, n, j \in \mathcal{B}_i$$

It holds that

$$\sum_{j \in \mathcal{B}} u_j^i < 1$$

By multiplying each part of (3.9) by ϵ and given the fact that $f'_{jk} \leq \epsilon f_{jk}$, it follows that

$$\sum_{k \in \mathcal{R}} f'_{jk} \leq \sum_{i \in \mathcal{B}} u_j^i \mu_{ij} \quad j = 1, 2, \dots, B \quad (3.10)$$

◇

The necessity of strict inequality in relation (3.2a) of condition C1 is due to the definition of stability that we have and more specifically to the requirement that the asymptotic bound of the backlog is independent of the initial conditions. It is possible that bounded backlog is guaranteed without strict inequality in (3.2a). This bound, though, cannot be independent of the initial condition. This is illustrated in the following counterexample. Consider the case of a single-server queue with constant instantaneous arrival rate equal to a and service rate μ . Condition C1, with strict inequality in (3.2a), boils down to the condition $a < \mu$. If equality is allowed in (3.2a), we may have $a = \mu$. In the latter case, and if the instantaneous arrival rate is constant and equal to the service rate μ , then the backlog at all times will be equal to the backlog at the time instant 0. Therefore, the network will be unstable according to the definition of stability considered in the paper, since there is no asymptotic bound in the backlog independent of the initial condition.

IV. THE PARAMETRIC BACK PRESSURE POLICY

In this section we will present and study the parametric back-pressure policy $PBP(\alpha)$. This policy determines whether a server idles or not, and if it does not idle, which queue is served and where the traffic is directed. The frequency at which a server is switched from queue to queue depends on the parameter $\alpha > 1$. We include α as an argument in the name of the policy to emphasize that dependence.

PBP(α) While the server i serves a buffer j and directs the traffic to a buffer k , it is constantly monitoring the quantity

$$A_i(t) = \max_{l \in \mathcal{B}} \left\{ \mu_{il} \max_{n \in \mathcal{R}_l} \{ \lambda_l(t) - \lambda_n(t) \} \right\} \quad (4.1)$$

If

$$\alpha \mu_{ij} (\lambda_k(t) - \lambda_j(t)) > 0$$

and

$$A_i(t) \geq \alpha \mu_{ij} (\lambda_k(t) - \lambda_j(t))$$

then the server is rescheduled to serve the queue $l \in \mathcal{B}$ and the traffic is directed to queue $n \in \mathcal{R}_l$ which together realize the maximum in (4.1), with ties broken arbitrarily. Service is reassumed after the switchover time δ .

If

$$A_i(t) \leq 0$$

then the server idles for a time period δ . If at the end of the idling period it is still $A_i(t) \leq 0$, then the server restarts an idling period of the same duration. Otherwise, server i is rescheduled to serve the queue $l \in \mathcal{B}_i$ and the traffic is directed to queue $n \in \mathcal{R}_l$ which together realize the maximum in (4.1).

Some clarifications on the operation of $PBP(\alpha)$ follow. According to $PBP(\alpha)$, the served traffic of buffer l is routed to buffer n which achieves the maximum in

$$\max_{n \in \mathcal{R}_l} \{ \lambda_l(t) - \lambda_n(t) \} \quad (4.1a)$$

whenever buffer l is served. Server i selects which buffer $l \in \mathcal{B}_i$ to serve based on the terms

$$\mu_{il} \max_{n \in \mathcal{R}_l} \{ \lambda_l(t) - \lambda_n(t) \} \quad l \in \mathcal{B}_i$$

It selects the one which achieves the maximum in (4.1). The policy is illustrated in Fig. 4. In order to avoid server i switching from queue to queue too often, the policy reschedules the server only if the quantity (4.1a) for the queue l under service becomes considerably smaller than $A_i(t)$. How much smaller it should become is determined by α which regulates how often the server switches. This feature is reminiscent of the clear a fraction policy considered in [10]. If the backlog in all the downstream queues is larger than the backlog in the queues of \mathcal{B}_i , that is the quantity $A_i(t)$ is negative, then the server i idles.

Note that the scheduling of server i relies on information about the queue lengths of the buffers in \mathcal{B}_i and in $\mathcal{R}_j, j \in \mathcal{B}_i$. This is local information for server i in several practical

Fig. 4. Server 1 is allocated to one of the queues 1, 2, 3. When the backlogs are as illustrated in the picture, then queue 2 will be selected for service and the traffic will be directed to buffer 4.

systems. For example, in the case of the VC network, the buffers in B_i and in R_j , $j \in B_i$, reside in the origin and destination node of the server/link j ; therefore, policy PBP(α) can be implemented in a distributed fashion.

The stabilizability properties of PBP(α) are stated in the following.

Theorem 4.1: If the arrival and service rates satisfy condition C1, then there exists an $\alpha > 1$ such that the system is stable under PBP(α).

Note that the policy PBP(α) needs only the service rates for its application. Furthermore, the stability holds for any value of the parameter δ in the definition of the policy. The proof of the theorem relies on the following lemma, which is a drift-type condition on the sum of the squared backlogs in the system.

Lemma 4.1: If the arrival and service rates satisfy condition C1, then there exists an α which depends only on the arrival and service rates and the burstiness coefficients such that when policy PBP(α) is employed, the following holds. There exist numbers D_0 , T , and ϵ such that

$$\sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) < -\epsilon \quad \text{if} \quad \sum_{j=1}^B X_j^2(t) \geq D_0.$$

Proof: The proof of the lemma is lengthy, and relies on some intermediate results. It is given in Appendix A. \diamond

Proof of Theorem 4.1: We show that there exists a \hat{T} , which may depend on $X(0)$, α , μ , and δ , and a D' , which may depend on α , μ , and δ , such that

$$\sup_{t \geq \hat{T}} \sum_{j=1}^B X_j(t) \leq D'. \quad (4.1b)$$

Let T and ϵ be such that

$$\sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) < -\epsilon \quad \text{if} \quad \sum_{j=1}^B X_j^2(t) \geq D_0. \quad (4.1c)$$

From Lemma 4.1, T and ϵ as above exist. Let \hat{k} be the smallest integer k such that

$$\sum_{j=1}^B X_j^2(kT) \leq D_0.$$

Fig. 5. The link from node 1 to node 2 that carries 4 VC's and the buffers in the origin and destination nodes of the link are illustrated. When the backlogs are as they appear in the picture, the link will transmit VC2.

From (4.1c), clearly such a \hat{k} exists. Define $\hat{T} = \hat{k}T$ and

$$\hat{D} = \left(\sqrt{D_0} + \sum_{j=1}^B (a_j T + b_j) \right)$$

We show by induction that we have

$$\sum_{j=1}^B X_j^2(lT) \leq B\hat{D}, \quad l \geq \hat{k}. \quad (4.1d)$$

The induction step is as follows. If $\sum_{j=1}^B X_j^2(lT) \leq D_0$, then, clearly, $\sum_{j=1}^B X_j^2((l+1)T) \leq B\hat{D}$. If $D_0 \leq \sum_{j=1}^B X_j^2(lT) \leq B\hat{D}$, then $\sum_{j=1}^B X_j^2((l+1)T) \leq \sum_{j=1}^B X_j^2(lT) - \epsilon$, and therefore, $\sum_{j=1}^B X_j^2((l+1)T) \leq \hat{D}$. \diamond

The actions taken by policy PBP(α) in the general network correspond to scheduling the server, routing of the traffic, and idling of the server. If routing is not involved, then the policy is simplified considerably. This is the case in a virtual circuit network where PBP(α) acts as follows. Every link is allocated to the virtual circuits that go through it based on the backlogs of the buffers of these VC's in its origin node and in its destination node. For each VC, the differences of the backlog of the buffer in the origin node of the link minus that of the buffer in the destination node of the link are formed (Fig. 5). If all differences are negative, then the link idles. Otherwise, the quantity

$$A_i(t) = \max_{l \in B_i} \{X(t) - X_l(t)\} \quad (4.1e)$$

is computed where l and \hat{l} are the buffers that correspond to the same virtual circuit in the origin and destination node, respectively, of link i . If

$$A_i(t) > \alpha \mu_{i,j} (X_j(t) - X_{\hat{j}}(t))$$

where j, \hat{j} are the buffers that correspond to the VC currently transmitted, then the server switches to the VC that achieves the maximum in (4.1e).

Note that in the model, it is possible that work goes through the same buffer more than once. It appears that this possibility may lead to instabilities under a distributed policy. The following is an intuitive explanation of why this is not happening with PBP(α). The goal of the policy is to push all the traffic out of the network. It is possible that work may

it a buffer more than once, following a cycle of buffers with small backlogs, instead of following a route out of the network, when the buffers that lead out of the network are congested. Eventually, though, the latter buffers will empty, and the work will find its way out of the network by selecting the route with the low-backlog buffers.

The PBP(α) policy achieves a bounded backlog in the network under the necessary and sufficient stabilizability condition C1, and is indeed distributed since the decisions at each node rely on the one hop away state information. Nevertheless, the arrival and service rates and the topology of the network need to be known in order to select the appropriate α . In the next section, the ABP policy (an adaptive version of the PBP) is obtained, which does not rely on knowledge of the arrival and service rates.

V. THE ADAPTIVE BACK-PRESSURE POLICY

The adaptive back-pressure policy is identical to PBP(α), except that α is not preselected, but is computed at each node based on the local (one hop away) state. Each server i computes a parameter $\alpha_i(t)$ based on the lengths of the queues that it may serve and the queues that it may direct the traffic to, as follows. Consider a function $g: \mathbb{R}^+ \rightarrow \mathbb{R}^+$ which is nonincreasing, strictly greater than 1, and such that

$$\lim_{x \rightarrow \infty} g(x) = 1$$

$$\lim_{x \rightarrow \infty} x(g(x) - 1) = \infty. \quad (5.1)$$

The function $g(x) = 1 + x^{-a}$ satisfies (5.1) for all $0 < a < 1$. Define $\alpha_i(t)$ as

$$\alpha_i(t) = g\left(\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\}\right).$$

The policy ABP is as follows

ABP: Each server acts as in the PBP(α) policy with the difference that server i uses the locally computed $\alpha_i(t)$ instead of α .

The following holds for ABP.

Theorem 5.1: The network is stable under ABP if condition C1 holds.

The proof of Theorem 5.1 is the same as that of Theorem 4.1, given the drift condition stated in the following lemma.

Lemma 5.1: If the arrival and service rates satisfy condition C1 and the network is operated under ABP, then there exist numbers D_0 , T , and ϵ such that

$$\sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) < -\epsilon \quad \text{if } \sum_{j=1}^B X_j^2(t) \geq D_0.$$

Proof: The proof is given in Appendix B. \diamond

Note that there is no parameter estimation taking place in the policy. In fact, the average arrival rates might not even exist. The logic of the adaptive policy is that it adjusts α such that it goes closer to 1 with a certain rate as the backlog increases. In

this manner, it is achieved that the servers switch to the queues that have the heavier backlog difference frequently enough.

VI. CONCLUSIONS AND DISCUSSION

In the ABP policy, each server is scheduled based on the lengths of the queues that it serves and of the queues one hop away, which were assumed to be instantaneously available to the server in our study. This is not always the case, though. For example, in the virtual circuit network, the link scheduling was based on the queue lengths at the origin and the destination nodes of the link. Clearly, the queue lengths in the destination node could not be made available at the origin node without a delay greater than or equal to the propagation delay of the link. In high-speed networks, the link propagation time is enough for the state of the queues to change considerably. Therefore, there will be a discrepancy between the actual queue lengths and those available to the server. Nevertheless, as long as the difference between the actual queue lengths and those available to the server is bounded independently of the queue length values, then the results obtained in the paper remain unaffected. That is, the ABP policy stabilizes the network with delayed information about the queue lengths as well.

According to the ABP policy, server i idles if the quantity $A_i(t)$ becomes less than or equal to 0 or, in other words, if for every queue $l \in \mathcal{B}_i$ the backlog of all queues in \mathcal{R}_l is greater than or equal to that of queue l . The results remain unaffected when $A_i(t)$ is compared with an arbitrary negative number instead of 0 in the definition of ABP. That is, the server idles only if the backlog in the downstream queues becomes greater than that of the upstream queues by a certain amount.

The delay through the network is an issue left open for further research. Bounded backlogs imply bounded delay; therefore, under the ABP policy, the delay will be finite when the stability condition C1 holds. There are several questions which are left open, though. How does the delay vary when the function g that estimates the parameter α in each node changes? Which is a good choice of g as far as the delay is concerned? As we said earlier, the backlog in the network remains bounded even if the server i idles whenever $A_i(t) < h$ for an arbitrary h , and not necessarily for $h = 0$. What is a good choice of h for small delays? Also, what will be the effect of the delayed information about the state of the one hop away queues on the delays through the network, and how will the latter be affected from the propagation delay? The investigation of these questions might lead to refinements of ABP with improved performance with respect to delay.

APPENDIX A

Lemma 4.1 is proved here. Two lemmas precede its proof. The first quantifies the property of policy PBP(α) that the switching of the server becomes less frequent as the queue lengths increase and more frequent as α approaches 1. Note that the maximum rate with which the difference of two queues may vary (increase or decrease) is less than or equal to

$$B\lambda + \sum_{i=1}^N \sum_{j \in \mathcal{B}_i} \mu_{ij} = M.$$

Lemma A.1: If for a server i we have

$$\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \geq \frac{4\alpha}{\alpha - 1} MT \quad (\text{A.1})$$

then i will switch at most once in the time interval $(t, t + T)$ and

$$\begin{aligned} & \sum_{j \in \mathcal{B}_i, l \in \mathcal{R}_j} Q_{ji}^i(X_j(t) - X_l(t)) \\ & \geq \frac{1}{\alpha} (T - \delta) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ & \quad - 4M(T + \delta)^2 \end{aligned} \quad (\text{A.2})$$

where Q_{ji}^i is the amount of work served by server i and transferred from buffer j to buffer l during the time interval $(t, t + T)$.

Proof: At time t , server i serves queue j_1 and directs the traffic to queue l_1 . We distinguish two cases. Assume first that

$$\mu_{ij_1}(X_{j_1}(t) - X_{l_1}(t)) = \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \quad (\text{A.3})$$

Since the maximum rate with which any difference $\mu_{ij_1}(X_{j_1}(t) - X_{l_1}(t))$ may vary is M , we have

$$\begin{aligned} & \alpha \mu_{ij_1}(X_{j_1}(t') - X_{l_1}(t')) \\ & \geq \alpha \left(\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} - 2MT \right), \\ & \quad t \in (t, t + T). \end{aligned} \quad (\text{A.4})$$

Also, for any pair of queues $j \in \mathcal{B}_i, l \in \mathcal{R}_j$

$$\begin{aligned} & \mu_{ij}(X_j(t') - X_l(t')) \\ & \geq \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} + 2MT, \\ & \quad t' \in (t, t + T). \end{aligned} \quad (\text{A.5})$$

From (A.4), (A.5) we can see that if (A.1) holds, then

$$\alpha \mu_{ij_1}(X_{j_1}(t') - X_{l_1}(t')) \geq \mu_{ij_1}(X_{j_1}(t') - X_{l_1}(t')), \quad j \in \mathcal{B}_i, j \neq j_1, l \in \mathcal{R}_j, t' \in (t, t + T) \quad (\text{A.5a})$$

and the server will not switch in the time interval $(t, t + T)$. Then, clearly

$$\begin{aligned} & \sum_{j \in \mathcal{B}_i, l \in \mathcal{R}_j} Q_{ji}^i(X_j(t) - X_l(t)) \\ & = Q_{j_1 l_1}^i(X_{j_1}(t) - X_{l_1}(t)) \\ & = T \mu_{ij_1}(X_{j_1}(t) - X_{l_1}(t)) \\ & = T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \end{aligned} \quad (\text{A.6})$$

and (A.2) follows. Note that (A.6) assumes that the server is always busy during $(t, t + T)$, which is a valid assumption based on (A.1).

Assume now that (A.3) does not hold. From the definition of the policy at time t , we have

$$\alpha \mu_{ij_1}(X_{j_1}(t) - X_{l_1}(t)) \geq \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\}. \quad (\text{A.7})$$

If server i will not switch queues during the interval $(t, t + T)$, then from (A.7), relation (A.2) follows easily. If the server will switch, then let t_1 be the first time after t at which the server switches. Let j_2 be the queue that is served after the switching, and l_2 the queue to which the traffic is routed. At time $t_1 + \delta$, we have

$$\begin{aligned} & \mu_{ij_2}(X_{j_2}(t_1 + \delta) - X_{l_2}(t_1 + \delta)) \\ & = \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t_1 + \delta) - X_l(t_1 + \delta)\} \right\} \\ & \geq \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} - 2M(t_1 - t + \delta) \end{aligned} \quad (\text{A.8})$$

and arguing similarly as above

$$\begin{aligned} & \mu_{ij_2}(X_{j_2}(t') - X_{l_2}(t')) \\ & \geq \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} - 2MT \end{aligned} \quad (\text{A.8a})$$

Equation (A.8a) together with (A.5) imply that if (A.1) holds, then the server will not switch again in the time interval $(t_1 + \delta, t + T)$. Let Q_{ji}^i be the amount of work served by server i and transferred from buffer j to buffer l during the time interval (t, t_1) , let \hat{Q}_{ji}^i be the same quantity for the time interval $(t_1 + \delta, t + T)$. Then, clearly, $Q_{ji}^i = \hat{Q}_{ji}^i + \tilde{Q}_{ji}^i$ and

$$\begin{aligned} & \sum_{j \in \mathcal{B}_i, l \in \mathcal{R}_j} Q_{ji}^i(X_j(t) - X_l(t)) \\ & = (t_1 - t) \mu_{ij_1}(X_{j_1}(t) - X_{l_1}(t)) \\ & \geq \frac{1}{\alpha} (t_1 - t) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \end{aligned} \quad (\text{A.9})$$

while

$$\begin{aligned} & \sum_{j \in \mathcal{B}_i, l \in \mathcal{R}_j} \tilde{Q}_{ji}^i(X_j(t) - X_l(t)) \\ & = Q_{j_2 l_2}^i(X_{j_2}(t) - X_{l_2}(t)) \\ & = (T + t - t_1 - \delta) \mu_{ij_2}(X_{j_2}(t) - X_{l_2}(t)). \end{aligned} \quad (\text{A.10})$$

Notice that

$$\mu_{ij_2}(X_{j_2}(t) - X_{l_2}(t)) \geq \mu_{ij_2}(X_{j_2}(t_1 + \delta) - X_{l_2}(t_1 + \delta)) - 4M(t_1 - t + \delta) \quad (\text{A.11})$$

From (A.8), (A.10), and (A.11), we get

$$\begin{aligned} & \sum_{j \in \mathcal{B}_i, l \in \mathcal{R}_j} \tilde{Q}_{ji}^i(X_j(t) - X_l(t)) \\ & \geq (T + t - t_1 - \delta) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ & \quad - 4TM(t_1 - t + \delta). \end{aligned} \quad (\text{A.12})$$

from (A 9) and (A 12), we have

$$\begin{aligned}
 & \sum_{j \in B, l \in \mathcal{R}_j} Q'_{jl}(X_j(t) - X_l(t)) \\
 & \geq \frac{1}{\alpha}(t_1 - t) \max_{j \in B} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\
 & \quad + (T + t - t_1 - \delta) \max_{j \in B} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\
 & \quad - 4TM(t_1 - t + \delta) \\
 & \geq \frac{1}{\alpha}(I - \delta) \max_{j \in B} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\
 & \quad - 4M(I + \delta)^2 \quad (\text{A 12a})
 \end{aligned}$$

In the following we show that one of the differences $X_j(t) - X_l(t)$, $j = 1, \dots, B$, $l \in \mathcal{R}_j$, is on the order of $\sqrt{\sum_{j=1}^B X_j^2(t)}$. A result similar to the following lemma has been shown in [11]. The lemma is included here for completeness. Notice that it holds independently of the policy and is a characteristic of the network.

Lemma A 2 There is a constant $\epsilon > 0$ that depends only on the topology of the network so that

$$\max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \geq \epsilon \sqrt{\sum_{j=1}^B X_j^2(t)}$$

Proof Consider the queue j_0 with the maximum length. Clearly

$$X_{j_0}(t) \geq \sqrt{\sum_{j=1}^B X_j^2(t)/B}$$

There exists a sequence of queues through which the work can be routed out of the network, that is, there exist a sequence i_1, \dots, i_n such that $n \leq B$, $i_1 = j_0$, $0 \in \mathcal{R}_{i_1}$, $i_{k+1} \in \mathcal{R}_{i_k}$, $k = 1, \dots, n-1$. Then we have

$$\begin{aligned}
 & \sum_{k=1}^{n-1} (X_{i_k}(t) - X_{i_{k+1}}(t)) = X_{i_1}(t) - X_{i_n}(t) \\
 & \Rightarrow \max_{k=1, \dots, n-1} (X_{i_k} - X_{i_{k+1}}) \geq \frac{X_{i_1}(t)}{B} \geq \sqrt{\frac{\sum_{j=1}^B X_j^2(t)}{B^3}}
 \end{aligned}$$

Proof of Lemma 4.1 With simple calculations we get for every l

$$\begin{aligned}
 & \sum_{j=1}^B X_j^2(t+I) - \sum_{j=1}^B X_j^2(t) \\
 & = 2 \sum_{j=1}^B (X_j(t+I) - X_j(t)) X_j(t) \\
 & \quad + \sum_{j=1}^B (X_j(t+I) - X_j(t))^2 \quad (\text{A 13})
 \end{aligned}$$

Notice that

$$(X_j(t+I) - X_j(t))^2 \leq M^2 I^2 \quad j = 1, \dots, B$$

where M is the maximum rate with which any X_j vary, and it has been defined before Lemma A 1

$$\sum_{j=1}^B (X_j(t+I) - X_j(t))^2 \leq BM^2 I^2$$

In the following we proceed to bound the first term on the right hand side of (A 13). Let Q'_{jl} be the amount of work served by server j and transferred from buffer j to l during the time interval $(t, t+I)$. Let Q_j be the amount of work transferred to buffer j from outside, and Q_{j0} the amount of work served by server j and transferred from buffer j to outside during $(t, t+I)$. Clearly,

$$X_j(t+I) - X_j(t) + Q_j + \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q'_{il} - \sum_{l \in \mathcal{P}_j} \sum_{i=1}^N Q_{il}$$

Hence for the first term on the right side of (A 13) we have

$$\begin{aligned}
 & \sum_{j=1}^B (X_j(t+I) - X_j(t)) X_j(t) \\
 & = \sum_{j=1}^B Q_j X_j(t) + \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q_{il} X_j(t) \\
 & \quad - \sum_{j=1}^B \sum_{l \in \mathcal{P}_j} \sum_{i=1}^N Q'_{il} X_j(t) \\
 & = \sum_{j=1}^B Q_j X_j(t) + \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q'_{jl} (X_j(t) - X_l(t)) \quad (\text{A 15})
 \end{aligned}$$

From the burstiness constraints on the arrival streams we have

$$Q_j \leq a_j I + b_j \quad j = 1, \dots, B$$

which together with condition C1 gives

$$\begin{aligned}
 & \sum_{j=1}^B Q_j X_j(t) \leq I \sum_{j=1}^B a_j X_j(t) + \sum_{j=1}^B b_j X_j(t) \\
 & = I \sum_{j=1}^B \left(\sum_{l \in \mathcal{R}_j} f_{jl} + \sum_{l \in \mathcal{P}_j} f_{lj} \right) X_j(t) \\
 & \quad + \sum_{j=1}^B b_j X_j(t) \\
 & = I \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} f_{jl} (X_j(t) - X_l(t)) + \sum_{j=1}^B b_j X_j(t) \\
 & \leq I \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} f_{jl} \max_{k \in \mathcal{R}_j} (X_j(t) - X_k(t)) \\
 & \quad + \sum_{j=1}^B b_j X_j(t) \quad (\text{A 16})
 \end{aligned}$$

In the following, we upper bound the second term on the right side of (A 15). Note that

$$Q'_{il} (X_j(t) - X_l(t)) \geq -M^2 I^2 \quad i = 1, \dots, N, \quad j, l = 1, \dots, B \quad (\text{A 17})$$

This is so because, first

$$0 \leq Q_{jl}^i \leq MT, \quad i = 1, \dots, N, \quad j, l = 1, \dots, B$$

and, second, if $X_j(t) - X_l(t) < -MT$, then $X_j(t') - X_l(t') \leq 0$ for all $t' \in (t, t+T)$, and Q_{jl}^i will be equal to 0 since no server will serve queue j in the time interval $(t, t+T)$. By interchanging the order of the summation, we have

$$\begin{aligned} \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q_{jl}^i (X_l(t) - X_j(t)) \\ = - \sum_{i=1}^N \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} Q_{jl}^i (X_j(t) - X_l(t)) \quad (\text{A.18}) \end{aligned}$$

Define $\hat{D} = \sum_{j=1}^B X_j^2(t)$. From Lemma A.2, we get that for some i , say $i = i_0$, we have

$$\begin{aligned} \max_{j \in \mathcal{B}_{i_0}} \left\{ \mu_{i_0 j} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ = \max_{i=1, \dots, N} \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq \min_{j \in \mathcal{B}, i=1, \dots, N} \{ \mu_{ij} \} \max_{j \in \mathcal{B}, l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \geq \epsilon \sqrt{D}. \end{aligned}$$

Hence, for \hat{D} large enough, inequality (A.1) is satisfied for at least one server. Let \mathcal{F} be the set of servers for which (A.1) holds. Replacing in (A.18) from (A.2) and (A.17), we get

$$\begin{aligned} \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q_{jl}^i (X_l(t) - X_j(t)) \\ \leq - \sum_{i \in \mathcal{F}} \frac{1}{\alpha} (T - \delta) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + 4M(T + \delta)^2 + NB^2 M^2 T^2 \\ \leq - \sum_{i \in \mathcal{F}} \left(1 - \sum_{j \in \mathcal{B}_i} u_j^i \right) \frac{1}{\alpha} T \max_{j \in \mathcal{B}_i} \\ \cdot \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + 4M(T + \delta)^2 + NB^2 M^2 T^2 \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u_j^i \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + \sum_{i \in \mathcal{F}} \frac{\delta}{\alpha} \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u_j^i \right) T \left(\frac{1}{\alpha} - 1 \right) \max_{j \in \mathcal{B}_i} \\ \cdot \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \quad (\text{A.19}) \end{aligned}$$

Define

$$u = \min_{i=1, \dots, N} \left\{ 1 - \sum_{j \in \mathcal{B}_i} u_j^i \right\}, \quad m = \min_{i=1, \dots, N} \min_{j \in \mathcal{B}_i} \mu_{ij}. \quad (\text{A.19a})$$

Then, we can easily check that

$$\begin{aligned} \sum_{i \in \mathcal{F}} \left(1 - \sum_{j \in \mathcal{B}_i} u_j^i \right) \frac{1}{\alpha} T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq u \frac{1}{\alpha} T m \max_{j=1, \dots, B, l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\}. \quad (\text{A.20}) \end{aligned}$$

Clearly

$$\sqrt{\hat{D}} \geq \max_{j=1, \dots, B, l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \quad (\text{A.21})$$

Let $\mu = \max_{i=1, \dots, N} \max_{j \in \mathcal{B}_i} \mu_{ij}$. Then, from (A.21)

$$\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \leq \mu \sqrt{\hat{D}}, \quad i = 1, \dots, N$$

and

$$\sum_{i \in \mathcal{F}} \frac{\delta}{\alpha} \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \leq N \frac{\delta}{\alpha} \mu \sqrt{\hat{D}} \quad (\text{A.22})$$

From (A.21), and since $1/\alpha < 1$, we have

$$\begin{aligned} \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u_j^i \right) T \left(\frac{1}{\alpha} - 1 \right) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq \sum_{i \in \mathcal{F}} T \left(\frac{1}{\alpha} - 1 \right) 2\mu \sqrt{\hat{D}} \\ \geq 2NT \left(\frac{1}{\alpha} - 1 \right) \mu \sqrt{\hat{D}} \quad (\text{A.23}) \end{aligned}$$

From (A.19), (A.20), (A.22), and (A.23), we have

$$\begin{aligned} \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q_{jl}^i (X_l(t) - X_j(t)) \\ \leq -u \frac{1}{\alpha} T m \epsilon \sqrt{\hat{D}} + 4M(T + \delta)^2 + NB^2 M^2 T^2 \\ + N \frac{\delta}{\alpha} \mu \sqrt{\hat{D}} - 2NT \left(\frac{1}{\alpha} - 1 \right) \mu \sqrt{\hat{D}} \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u_j^i \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \quad (\text{A.24}) \end{aligned}$$

Let $\hat{\mathcal{F}}$ be the set of all queues j for which

$$\min_{l \in \mathcal{R}_j} (X_j(t) - X_l(t)) > \frac{4\alpha}{(\alpha - 1)} MT \quad (\text{A.24a})$$

Then, from (A.16), we have

$$\begin{aligned} \sum_{j=1}^B Q_j X_j(t) \\ \leq \sum_{j=1}^B X_j(t) b_j + T \sum_{j \in \hat{\mathcal{F}}} \max_{k \in \mathcal{R}_j} \{X_j(t) - X_k(t)\} \sum_{l \in \mathcal{R}_j} f_{jl} \\ + B \sum_{i=1}^B a_i \frac{4\alpha}{\alpha - 1} MT. \quad (\text{A.25}) \end{aligned}$$

ote that from (A.24a), if $j \in \hat{\mathcal{F}}$, then all i 's such that $j \in \mathcal{B}_i$ long to \mathcal{F} . Based on this fact, in the following, we verify that

$$\sum_{i \in \mathcal{F}} \max_{k \in \mathcal{R}_i} \{X_j(t) - X_k(t)\} \sum_{l \in \mathcal{R}_i} f_{jl} \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \right\}. \quad (\text{A.26})$$

Note first that

$$\sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \right\} \geq T \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{B}_i} u'_j \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \quad (\text{A.27})$$

and from the fact that if $j \in \hat{\mathcal{F}}$, then all i 's such that $j \in \mathcal{B}_i$ belong to \mathcal{F} , we have

$$I \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{B}_i} u'_j \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \geq T \sum_{i \in \mathcal{F}} \sum_{j \in \mathcal{B}_i} u'_j \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\}. \quad (\text{A.28})$$

From (A.27), (A.28), and (3.2), the relation (A.26) follows. By adding the inequalities (A.24)–(A.26) and (A.15), and after the simplifications, we get

$$\begin{aligned} & \sum_{j=1}^B (X_j(t+T) - X_j(t)) X_j(t) \\ & \leq -u \frac{1}{\alpha} T \mu \sqrt{D} + 4M(I + \delta)^2 + NB^2 M^2 T^2 \\ & \quad + N \frac{\delta}{\alpha} \mu \sqrt{D} - 2NT \left(\frac{1}{\alpha} - 1 \right) \mu \sqrt{D} \\ & \quad + \sqrt{D} \sum_{j=1}^B b_j + B \sum_{i=1}^B a_i \frac{\alpha \alpha}{\alpha - 1} MT \end{aligned} \quad (\text{A.28a})$$

By replacing in (A.13) from (A.14) and (A.28a), we get

$$\begin{aligned} & \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) \\ & \leq c_1 T^2 - c_2 \frac{1}{\alpha} T \sqrt{\hat{D}} + c_3 \sqrt{D} \\ & \quad + c_4 T \sqrt{\hat{D}} \left(1 - \frac{1}{\alpha} \right) \\ & \quad + c_5 \frac{4\alpha}{\alpha - 1} T \end{aligned} \quad (\text{A.29})$$

where c_1, \dots, c_5 are positive constants which depend only on the system topology and the arrival and service parameters. Select $\alpha > 1$ such that $c_4 - (c_2 + c_4/\alpha) = -\zeta < 0$, and let $T = (\hat{D})^{1/4}$. Then (A.29) becomes

$$\begin{aligned} & \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) \\ & \leq c_1 (\hat{D})^{1/2} - \zeta (\hat{D})^{3/4} + c_3 \sqrt{D} \\ & \quad + c_5 \frac{4\alpha}{\alpha - 1} (\hat{D})^{1/4} \end{aligned}$$

It is clear that if \hat{D} is large enough, the right side of (A.29) becomes strictly negative and the lemma follows.

APPENDIX B

The proof of Lemma 5.1 is given in this Appendix after some intermediate results. Define

$$\alpha_i^T = q \left(\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \right\} + 2MI \right)$$

Lemma B.1 If for a server i , we have

$$\max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \right\} > \frac{4\alpha_i^T}{(\alpha_i^T - 1)} MT \quad (\text{B.1})$$

then i will switch at most once in the time interval $(t, t+T)$ and

$$\begin{aligned} & \sum_{j \in \mathcal{B}} \sum_{l \in \mathcal{R}_i} Q'_{jl} (X_j(t) - X_l(t)) \\ & \geq \frac{1}{\alpha_i(t)} (T - \delta) \max_{j \in \mathcal{B}} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_i} \{X_j(t) - X_l(t)\} \right\} \\ & \quad - 4M(T + \delta)^2 \end{aligned} \quad (\text{B.2})$$

where Q'_{jl} is the amount of work served by server i and transferred from buffer j to buffer l during the time interval $(t, t+T)$.

Proof The proof follows the same steps as with Lemma A.1, except for the following differences. Inequality (A.4) holds with α replaced by $\alpha_i(t)$ on the left side and with α_i^T on the right side. Inequalities (A.5a), (A.7), (A.9), and (A.12a) hold with α replaced by $\alpha_i(t)$. \diamond

Proof of Lemma 5.1 From (A.13)–(A.15), we get

$$\begin{aligned} & \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) \\ & = \sum_{j=1}^B Q_j X_j(t) \\ & \quad + \sum_{j=1}^B \sum_{l \in \mathcal{R}_i} \sum_{i=1}^N Q'_{jl} (X_l(t) - X_j(t)) \\ & \quad + BM^2 T^2. \end{aligned} \quad (\text{B.3})$$

Also

$$\begin{aligned} & \sum_{j=1}^B Q_j X_j(t) \leq T \sum_{j=1}^B \sum_{l \in \mathcal{R}_i} f_{jl} \max_{k \in \mathcal{R}_i} (X_j(t) - X_k(t)) \\ & \quad + \sum_{j=1}^B X_j(t) b_j. \end{aligned} \quad (\text{B.4})$$

In the following, we upper bound the second term on the right side of (B.3). Note first that

$$Q'_{jl}(X_j(t) - X_l(t)) \geq -M^2 T^2, \quad i = 1, \dots, N, \\ j, l = 1, \dots, B. \quad (\text{B.5})$$

By interchanging the order of the summation, we have

$$\sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q'_{il}(X_i(t) - X_j(t)) \\ = - \sum_{i=1}^N \sum_{j=1}^B \sum_{l \in \mathcal{R}_j} Q'_{il}(X_j(t) - X_l(t)). \quad (\text{B.6})$$

Let \mathcal{F} be the set of servers for which (B.1) holds. Replacing in (B.6) from (A.2) and (B.5), we get

$$\sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q'_{il}(X_i(t) - X_j(t)) \\ \leq - \sum_{i \in \mathcal{F}} \frac{1}{\alpha_i(t)} (T - \delta) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + 4M(T + \delta)^2 + NB^2 M^2 T^2 \\ \leq - \sum_{i \in \mathcal{F}} \left(1 - \sum_{j \in \mathcal{B}_i} u'_j \right) \frac{1}{\alpha_i(t)} T \max_{j \in \mathcal{B}_i} \\ \cdot \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + 4M(T + \delta)^2 + NB^2 M^2 T^2 \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ + \sum_{i \in \mathcal{F}} \frac{\delta}{\alpha_i(t)} \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \left(\frac{1}{\alpha_i(t)} - 1 \right) \max_{j \in \mathcal{B}_i} \\ \cdot \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \quad (\text{B.7})$$

To simplify the right side of inequality (B.7), we upper bound the terms appearing in it in the following. Based on the definition of u and m in (A.19a), the nonincreasingness of

$g(\cdot)$, and the definition of $\alpha_i(t)$, we have

$$\sum_{i \in \mathcal{F}} \left(1 - \sum_{j \in \mathcal{B}_i} u'_j \right) \frac{1}{\alpha_i(t)} T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq u \frac{1}{g(m \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\})} T m \\ \times \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\}. \quad (\text{B.8})$$

Since $\alpha_i(t) > 1$, $i = 1, \dots, N$, $t > 0$, we have

$$\sum_{i \in \mathcal{F}} \frac{\delta}{\alpha_i(t)} \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \leq N \delta \mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \quad (\text{B.9})$$

Similarly, since $1/\alpha_i(t) < 1$, $i = 1, \dots, N$, $t > 0$, $\sum_{j \in \mathcal{B}_i} u'_j \leq 1$, and for μ as defined in (A.19a), we have (B.10), as found at the bottom of the page. From the definition of \mathcal{F} and (B.1), (B.10) becomes

$$\sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \left(\frac{1}{\alpha_i(t)} - 1 \right) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq NT \left(\frac{1}{g((2\alpha_i^T/\alpha_i^I - 1)MT)} - 1 \right) \mu \\ \cdot \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \\ \geq NT \left(\frac{1}{g(2MT)} - 1 \right) \mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \quad (\text{B.11})$$

From (B.7)–(B.9) and (B.11), we have

$$\sum_{j=1}^B \sum_{l \in \mathcal{R}_j} \sum_{i=1}^N Q'_{il}(X_i(t) - X_j(t)) \\ \leq -u \frac{1}{g(m \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\})} T m \\ \times \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} + 4M(T + \delta)^2 \\ + NB^2 M^2 T^2 + N \delta \mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \\ - NT \left(\frac{1}{g(2MT)} - 1 \right) \mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \\ - \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\}. \quad (\text{B.12})$$

$$\sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u'_j \right) T \left(\frac{1}{\alpha_i(t)} - 1 \right) \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \right\} \\ \geq NT \left(\frac{1}{\max_{i \in \mathcal{F}} \alpha_i(t)} - 1 \right) 2\mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \\ \geq NT \left(\frac{1}{g(\min_{i \in \mathcal{F}} \max_{j \in \mathcal{B}_i} \{ \mu_{ij} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\} \})} - 1 \right) \mu \max_{j=1, \dots, B} \max_{l \in \mathcal{R}_j} \{X_j(t) - X_l(t)\}. \quad (\text{B.10})$$

let $\hat{\mathcal{F}}$ be the set of all queues j for which

$$\min_{l \in \mathcal{R}_j} (X_j(t) - X_l(t)) > \frac{2\alpha_l^I}{(\alpha_l^T - 1)} MT \quad (\text{B } 13)$$

Then from (B 4), we have

$$\begin{aligned} \sum_{j=1}^B Q_j X_j(t) &\leq \sum_{j=1}^B \lambda_j(t) b_j \\ &\quad + T \sum_{j \in \mathcal{F}} \max_{k \in \mathcal{R}} \{X_j(t) - X_k(t)\} \sum_{l \in \mathcal{R}} f_{jl} \\ &\quad + B \sum_{i=1}^B a_i \frac{2\alpha_i^I}{\alpha_i^T - 1} MT \end{aligned} \quad (\text{B } 14)$$

Notice that

$$\begin{aligned} B \sum_{i=1}^B a_i \frac{2\alpha_i^I}{\alpha_i^T - 1} MT &< 2BMT \sum_{i=1}^B a_i + 2BMT \sum_{i=1}^B a_i \frac{1}{\min_{i=1}^B \alpha_i^T - 1} \\ &\leq 2BMT \sum_{i=1}^B a_i + 2BMT \sum_{i=1}^B a_i \frac{1}{q(\mu \max_{j=1}^B \frac{1}{B \sum_{l \in \mathcal{R}} \{X_j(t) - X_l(t)\}} - 1)} \end{aligned} \quad (\text{B } 15)$$

Defining $D = \sum_{j=1}^B X_j^2(t)$ we have

$$\sum_{j=1}^B \lambda_j(t) b_j \leq \sum_{j=1}^B B_j \sqrt{D} \quad (\text{B } 16)$$

From (B 15) and (B 16) relation (B 14) becomes

$$\begin{aligned} \sum_{j=1}^B Q_j X_j(t) &\leq \sum_{j=1}^B b_j \sqrt{D} + 2BMT \sum_{i=1}^B a_i + 2BMT \sum_{i=1}^B a_i \frac{1}{q(\mu \max_{j=1}^B \frac{1}{B \sum_{l \in \mathcal{R}} \{X_j(t) - X_l(t)\}} + 2MT) - 1} \\ &\quad + T \sum_{j \in \mathcal{F}} \max_{k \in \mathcal{R}} \{X_j(t) - X_k(t)\} \sum_{l \in \mathcal{R}} f_{jl} \end{aligned} \quad (\text{B } 17)$$

Note that from (B 13), if $j \in \mathcal{F}$ then all l 's such that $j \in \mathcal{B}_l$ belong to \mathcal{F} . Based on this fact, and arguing similarly as in the proof of Lemma 4.1 [relations (A 27), (A 28)], it easily follows that

$$\begin{aligned} T \sum_{j \in \mathcal{F}} \max_{k \in \mathcal{R}} \{X_j(t) - X_k(t)\} \sum_{l \in \mathcal{R}} f_{jl} &\leq \sum_{i \in \mathcal{F}} \left(\sum_{j \in \mathcal{B}_i} u_j' \right) T \max_{j \in \mathcal{B}_i} \left\{ \mu_{ij} \max_{l \in \mathcal{R}} \{X_j(t) - X_l(t)\} \right\} \end{aligned} \quad (\text{B } 18)$$

By replacing in (B 3) from (B 12), (B 17) and using (1) and Lemma B 1, we get

$$\begin{aligned} \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) &\leq -u \frac{1}{q(\mu \sqrt{D})} T \mu \sqrt{D} \\ &\quad + 1M(I+\delta)^2 + NB^2 \lambda^2 T \\ &\quad + N\delta \mu \sqrt{D} - N T \left(\frac{1}{q(2MT)} - 1 \right) \mu \sqrt{D} \\ &\quad + BM^2 T^2 + \sum_{i=1}^B b_i \sqrt{D} + 2BMT \sum_{i=1}^B a_i \\ &\quad + BMT \sum_{i=1}^B a_i \frac{1}{q(\mu \sqrt{D} + 2MT) - 1} \end{aligned} \quad (\text{B } 19)$$

If we select $I = (D)^{1/4}$ then (B 19) becomes

$$\begin{aligned} \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) &\leq \epsilon_1 D^{1/4} + \epsilon_2 \sqrt{D} - \epsilon_3 \frac{1}{q(\epsilon_4 \sqrt{D})} D^{1/4} \sqrt{D} \\ &\quad - \epsilon_5 \left(\frac{1}{q(2MD^{1/2})} - 1 \right) D^{1/4} \sqrt{D} \\ &\quad + \epsilon_6 D^{1/4} \frac{\sqrt{D}}{\sqrt{D}(q(\epsilon_7 \sqrt{D} + \epsilon_8 D^{1/4}) - 1)} \end{aligned} \quad (\text{B } 20)$$

where $\epsilon_1, \dots, \epsilon_8$ are constants that depend only on the system parameters. Since $\lim_{t \rightarrow \infty} q(t) = 1$ there exists $\epsilon_4 > 0$ such that for D sufficiently large,

$$-\epsilon_3 \frac{1}{q(\epsilon_4 \sqrt{D})} - \epsilon_5 \left(\frac{1}{q(2MD^{1/2})} - 1 \right) < -\epsilon_9 < 0 \quad (\text{B } 21)$$

Also there exists a ϵ_{10} such that for D sufficiently large

$$\epsilon_1 D^{1/4} + \epsilon_2 \sqrt{D} \leq \epsilon_{10} \sqrt{D} \quad (\text{B } 22)$$

Hence (B 20) becomes

$$\begin{aligned} \sum_{j=1}^B X_j^2(t+T) - \sum_{j=1}^B X_j^2(t) &\leq \epsilon_{10} \sqrt{D} - \epsilon_9 D^{3/4} + \epsilon_6 D^{1/4} \frac{D^{1/2}}{D^{1/2}(q(\epsilon_7 \sqrt{D} + \epsilon_8 D^{1/4}) - 1)} \\ &= \epsilon_{10} \sqrt{D} + D^{3/4} \left(\epsilon_6 \frac{1}{\sqrt{D}(q(\epsilon_7 \sqrt{D} + \epsilon_8 D^{1/4}) - 1)} - \epsilon_{10} \right) \end{aligned} \quad (\text{B } 23)$$

Since $\lim_{t \rightarrow \infty} t(q(t) - 1) = \infty$ we have that for D large enough, there exists $\epsilon_{11} > 0$ such that

$$\epsilon_6 \frac{1}{\sqrt{D}(q(\epsilon_7 \sqrt{D} + \epsilon_8 D^{1/4}) - 1)} - \epsilon_{10} < -\epsilon_{11} \quad (\text{B } 24)$$

From (B.23) and (B.24), we have for large \hat{D} that

$$\sum_{j=1}^B X_j^2(t) \leq c_{10} \sqrt{\hat{D}} - c_{11} \hat{D}^{3/4}. \quad (\text{B.25})$$

It is clear from (5.1) that if \hat{D} is large enough, then the right side of (B.25) becomes strictly negative, and the lemma follows. \diamond

ACKNOWLEDGMENT

The author would like to thank the reviewers for the thorough reviews that helped improve the final version of the paper.

an emphasis on wireless communications and high-speed networks, the control and optimization of stochastic systems, and parallel and distributed processing.

Dr. Tassiulas coauthored a paper that received the INFOCOM '94 Best Paper Award.

Stability of Queueing Networks and Scheduling Policies

P. R. Kumar, *Fellow, IEEE*, and Sean P. Meyn, *Member, IEEE*

Abstract—Usually, the stability of queueing networks is established by explicitly determining the invariant distribution. Outside of the narrow class of queueing networks possessing a product form solution, however, such explicit solutions are rare, and consequently little is also known concerning stability.

We develop here a programmatic procedure for establishing the stability of queueing networks and scheduling policies. The method uses linear or nonlinear programming to determine what is an appropriate quadratic functional to use as a Lyapunov function. If the underlying system is Markovian, our method establishes not only positive recurrence and the existence of a steady-state probability distribution, but also the geometric convergence of an exponential moment.

We illustrate this method on several example problems. For an example of an open re-entrant line, we show that all stationary nonidling policies are stable for all load factors less than one. This includes the well-known First Come First Serve (FCFS) policy. We determine a subset of the stability region for the Dai-Wang example, for which they have shown that the Brownian approximation does not hold. In another re-entrant line, we show that the Last Buffer First Serve (LBFS) and First Buffer First Serve (FBFS) policies are stable for all load factors less than one. Finally, for the Rybko-Stolyar example, for which a subset of the instability region has been determined by them under a certain buffer priority policy, we determine a subset of the stability region.

I. INTRODUCTION

USUALLY the stability of a queueing network is established by explicitly determining an invariant distribution. Outside of the relatively narrow class of queueing networks admitting a product form solution for the invariant distribution, however, such explicit solutions are rare. Consequently, stability results are also rare.

Here we develop a procedure for establishing the stability of a queueing network operating under a scheduling policy. It is based on just solving a linear program on the coefficients of a quadratic form. Alternatively, a nonlinear program can also be used. The goal is to programmatically construct a quadratic Lyapunov function on buffer levels that has a negative drift, whenever the mean number of parts in the system is large. This allows one to deduce the stability-in-the-mean of a system, even if it is not Markovian. For Markovian systems, such stability is equivalent to the existence of a steady-state

distribution, i.e., positive recurrence. Moreover, for Markovian systems, our method also establishes geometric convergence of an exponential moment.

Such stability results are important for a variety of reasons. First, they are a precursor to more fine grained questions concerning the performance levels of various scheduling policies. Second, several unstable scheduling policies have recently been discovered. Kumar and Seidman [2] and Chase and Ramadge [3] provide examples of deterministic systems which are unstable under all clearing, i.e., exhaustive service, policies. Lu and Kumar [1] provide an example of a re-entrant line with deterministic processing times, and deterministic bursty arrivals, for which a certain buffer priority policy is unstable. Rybko and Stolyar [4] provide an example of a stochastic network which is unstable under a certain buffer priority policy. Recently, Seidman [5] has demonstrated the instability of the well-known First Come First Serve (FCFS) policy, also for a deterministic model. Bramson [6] has recently constructed a stochastic re-entrant line that is also unstable under the FCFS policy. Third, there has been much recent interest in the use of heavy traffic Brownian approximations to construct scheduling policies for queueing networks, see Harrison [7] and Harrison and Wein [8]. Clearly, to establish heavy traffic limit theorems, it is necessary to establish the stability of the queueing networks involved. Dai and Wang [12] have constructed a counterexample where the Brownian approximation does not hold, see also Whitt [13] and Dai and Nguyen [14]. Indeed, heavy traffic limit theorems appear to be only available for systems that are already known to be stable, see Reiman [9], [10] and Peterson [11].

Quadratic Lyapunov functions find widespread use in linear system theory. For stochastic systems, Kingman [15] has used a quadratic Lyapunov function to analyze a random walk on \mathbb{Z}_+^2 . Fayolle [16] has used general quadratic forms to characterize ergodicity of random walks on \mathbb{Z}_+^n . Piecewise linear Lyapunov functions are used in Fayolle *et al.* [17] for establishing the stability of Jackson networks [19]. Meyn and Down [18] use the square of the workload to establish the stability of generalized Jackson networks, where the assumptions on the arrival processes and service times are relaxed. Coffman *et al.* [20] have used linear programming to find both linear and quadratic forms with negative or positive drift and thus the stability or instability of a certain bin packing algorithm. Then linear programs test for a drift of the appropriate sign at all the states on the boundary of a prescribed hypercube, our approach may be less computationally complex. Recently, Bertsimas *et al.* [21] and Kumar and Kumar [22] have used

quadratic forms to obtain performance bounds for queueing networks and scheduling policies, provided the system is stable and has a bounded second moment.

II. THE BASIC OPEN RE-ENTRANT LINE

To expose the idea in its simplest form, we begin with the treatment of an open re-entrant line; see [23].

The network consists of S machines $\{1, 2, \dots, S\}$; see Fig. 1. Parts arrive as a Poisson process of rate λ to buffer b_1 , located at machine $\sigma(1) \in \{1, \dots, S\}$. Upon completing service, they proceed to buffer b_2 located at machine $\sigma(2) \in \{1, \dots, S\}$. Let b_L at machine $\sigma(L)$ be the last buffer visited. The sequence $\{\sigma(1), \dots, \sigma(L)\}$ is the route of the part. Since one may have $\sigma(i) = \sigma(j)$ for some pairs i and j with $i \neq j$, we say that the system is a re-entrant line. Let us suppose that parts in b_i require an exponentially distributed service time, with mean $\frac{1}{\mu_i}$, from machine $\sigma(i)$.

Let $I(i) := \{j \mid \sigma(j) = \sigma(i)\}$, i.e., the set of indexes of buffers which are located at the same machine as b_i . Thus, the buffers with indexes in $I(i)$ are in "contention" for the same machine.

Let us denote

$x_i(t) :=$ Numbers of parts in buffer b_i at time t , including any in service

and

$w_i(t) :=$ 1 if machine $\sigma(i)$ is working on a part in buffer b_i at time t , and zero otherwise.

For simplicity, we suppose that a machine works on only one part at any given time.

The key problem in "scheduling" such queueing networks is to determine which part in which buffer the machine should serve, i.e., which $w_i(t)$ should be one. Clearly, an optimal choice for reasonable criteria will depend on the location, i.e., the buffer, occupied by the part. When the service priority depends on the buffer (i.e., "class" of a part), however, the steady-state distribution, if any, is not known, and, as mentioned earlier, neither is stability. As an example, the well-known FCFS policy can be stable or unstable for particular systems, when the μ_i 's are not the same for all buffers at a machine. Similarly, buffer priority policies can be stable or unstable for particular systems and values of parameters.

III. COPOSITIVE MATRICES

Let Q be a symmetric $L \times L$ matrix that gives rise to a quadratic form which is nonnegative on the positive orthant

in R^L , i.e.,

$$Q = Q^T \text{ and } (y_1, \dots, y_L)Q(y_1, \dots, y_L)^T \geq 0$$

whenever

$$y_i \geq 0 \text{ for all } i. \quad (1)$$

Such matrices are called symmetric copositive matrices. As will be shown in Section V, our methodology will automatically confine itself to the subclass of symmetric strictly copositive matrices. These are symmetric copositive matrices Q for which additionally

$$(y_1, \dots, y_L)Q(y_1, \dots, y_L)^T > 0, \text{ if } y_i \geq 0 \text{ for all } i, \text{ and } y_i \neq 0 \text{ for some } i.$$

Copositive and strictly copositive matrices have been extensively studied; see Cottle *et al.* [24]. They are characterized by the signs of certain determinants (see [24]).

Keller's Theorem: A symmetric matrix is copositive if and only if each principal submatrix, for which the cofactors of the last row are nonnegative, has a nonnegative determinant.

A recent algorithm for testing copositivity can be found in Andersson *et al.* [25]. The determination of copositivity is NP-Complete; see Murty and Kabadi [26].

The procedure we advocate below could be used with any Q satisfying (1). For concreteness, we will confine our attention to the following special types of copositive matrices.

It is easy to see that any symmetric, nonnegative matrix, i.e., one for which $Q^T = Q = [q_{ij}]$, with $q_{ij} \geq 0$ for all i, j , is copositive. Also, any positive semidefinite matrix, i.e., a Q for which, $Q = Q^T$ and $x^T Q x \geq 0$ for all x , is copositive. Moreover, any convex combination (or linear combination with positive weights) of such matrices is also copositive, since the set of symmetric copositive matrices is a convex cone.

IV. THE BASIC CHARACTERIZATION

We shall rescale time so that

$$\lambda + \sum_{i=1}^L \mu_i = 1 \quad (2)$$

and resort to "uniformization," see Lippman [27]. That is, we shall suppose that there is always either a real or a "virtual" part that is being served at every buffer b_i . Let $\{\tau_n\}$, with $\tau_0 = 0$, denote the sequence of all arrival and service times, real or virtual, and let \mathcal{F}_{τ_n} denote the σ -field generated by events up to time τ_n .

Let $x(t) := (x_1(t), \dots, x_L(t))^T$ denote the vector of queue lengths. In accordance with terminology of Markov Decision Processes, we will call $x(t)$ the "state." A policy whose action at any time t depends only on $x(t)$ is called stationary, again in accordance with the terminology of Markov Decision Processes. Under a stationary policy, the system is described by the Markov chain $\{x(t)\}$.

We will treat a larger class of scheduling policies than stationary policies. We will consider any scheduling policy which takes a constant action in intervals of the form $[\tau_n, \tau_{n+1})$, and call such a policy noninterruptive. (The term noninterruptive should not be confused with the term nonpreemptive.) As

Fig. 2 State transition diagram for basic open re-entrant line

an example, the well-known FCFS policy is noninterruptive. Note that any scheduling policy that does not change actions between real transition epochs is noninterruptive. Of course, all stationary policies are of this form and are hence automatically noninterruptive.

We will allow preemptive priority at an epoch, if the scheduling policy calls for it.

Let $e_i = (0, \dots, 0, 1, 0, \dots, 0)^T$ be the i th unit vector. The state transition diagram of the network is as shown in Fig. 2 for any noninterruptive policy.

Let us consider the quadratic form $r^T(\tau_n)Qr(\tau_n)$. Note that since $r(\tau_n)$ can grow no faster than linearly in n , the conditional expectation $E[r^T(\tau_{n+1})Qr(\tau_{n+1}) | \mathcal{F}_\tau]$ exists. From Fig. 2, for any noninterruptive policy we obtain

$$\begin{aligned} E[r^T(\tau_{n+1})Qr(\tau_{n+1}) | \mathcal{F}_\tau] &= \lambda(r(\tau_n) + e_1)^T Q(r(\tau_n) + e_1) \\ &+ \sum_{i=1}^{L-1} \mu_i w_i(\tau_n)(r(\tau_n) - e_i + e_{i+1})^T Q(r(\tau_n) - e_i + e_{i+1}) \\ &+ \mu_L w_L(\tau_n)(r(\tau_n) - e_L)^T Q(r(\tau_n) - e_L) \\ &+ \sum_{i=1}^L \mu_i (1 - u_i(\tau_n)) r^T(\tau_n) Q r(\tau_n) \end{aligned} \quad (3)$$

Using (2) and the symmetry of Q as in (1) we obtain

$$\begin{aligned} E[r^T(\tau_{n+1})Qr(\tau_{n+1}) | \mathcal{F}_\tau] &= r^T(\tau_n)Qr(\tau_n) + 2\lambda e_1^T Q r(\tau_n) + \lambda e_1^T Q e_1 \\ &+ 2 \sum_{i=1}^{L-1} \mu_i w_i(\tau_n)(e_{i+1} - e_i)^T Q r(\tau_n) \\ &+ \sum_{i=1}^{L-1} \mu_i w_i(\tau_n)(e_{i+1} - e_i)^T Q (e_{i+1} - e_i) \\ &- 2\mu_L w_L(\tau_n) e_L^T Q r(\tau_n) + \mu_L w_L(\tau_n) e_L^T Q e_L \end{aligned}$$

Note now that since $w_i(\tau_n) = 0$ or 1 , all the terms not featuring $r(\tau_n)$ above are bounded above by a constant, i.e.,

$$\begin{aligned} \lambda e_1^T Q e_1 + \sum_{i=1}^{L-1} \mu_i w_i(\tau_n)(e_{i+1} - e_i)^T Q (e_{i+1} - e_i) \\ + \mu_L w_L(\tau_n) e_L^T Q e_L \leq M < +\infty \end{aligned}$$

Hence

$$\begin{aligned} E[r^T(\tau_{n+1})Qr(\tau_{n+1}) | \mathcal{F}_\tau] &\leq r^T(\tau_n)Qr(\tau_n) + 2\lambda e_1^T Q r(\tau_n) \\ &+ 2 \sum_{i=1}^{L-1} \mu_i w_i(\tau_n)(e_{i+1} - e_i)^T Q r(\tau_n) \\ &- 2\mu_L w_L(\tau_n) e_L^T Q r(\tau_n) + M \end{aligned}$$

Let us suppose that the initial condition is deterministic (or more generally, a bounded random variable or even more generally, has a finite second moment). As noted earlier, $r(\tau_n)$ grows no faster than linearly in n . Hence $E[r^T(\tau_n)Qr(\tau_n)]$ exists for every n . By taking the unconditional expectation we obtain

$$\begin{aligned} E[r^T(\tau_{n+1})Qr(\tau_{n+1})] &\leq E[r^T(\tau_n)Qr(\tau_n)] + 2\lambda e_1^T Q E[r(\tau_n)] \\ &+ 2 \sum_{i=1}^{L-1} \mu_i E[u_i(\tau_n)(e_{i+1} - e_i)^T Q r(\tau_n)] \\ &- 2\mu_L E[w_L(\tau_n) e_L^T Q r(\tau_n)] + M \end{aligned} \quad (4)$$

Let us denote

$$z_{ij}(\tau_n) = w_i(\tau_n) e_j^T Q r(\tau_n) \quad (5)$$

Using (5), (4) can be written as

$$\begin{aligned} E[r^T(\tau_{n+1})Qr(\tau_{n+1})] &\leq E[r^T(\tau_n)Qr(\tau_n)] \\ &+ 2\lambda \sum_{j=1}^L q_{1j} E[r_j(\tau_n)] \\ &+ 2 \sum_{i=1}^{L-1} \mu_i \sum_{j=1}^L (q_{i+1,j} - q_{ij}) E[r_j(\tau_n)] \\ &- 2\mu_L \sum_{j=1}^L q_{Lj} E[r_j(\tau_n)] + M \end{aligned}$$

By summing over n , and telescoping, we obtain

$$\begin{aligned} \frac{1}{N+1} \sum_{n=0}^N \left[\lambda \sum_{j=1}^L q_{1j} E[r_j(\tau_n)] \right. \\ \left. - \sum_{i=1}^{L-1} \mu_i \sum_{j=1}^L (q_{i+1,j} - q_{ij}) E[r_j(\tau_n)] \right. \\ \left. + \mu_L \sum_{j=1}^L q_{Lj} E[r_j(\tau_n)] \right] \\ \leq \frac{1}{2(N+1)} (E[r^T(0)Qr(0)] \\ - E[r^T(\tau_{N+1})Qr(\tau_{N+1})]) \\ + \frac{M}{2} \leq M' < +\infty \text{ for all } N \end{aligned} \quad (6)$$

In the last inequality above, we have used the nonnegativity of $r^T(\tau_{N+1})Qr(\tau_{N+1})$, which is guaranteed by the copositivity condition (1), since $r(\tau_{N+1})$ lies in the nonnegative orthant.

Now note that if we can find a $\gamma > 0$ so that

$$\begin{aligned} & \lambda \sum_{j=1}^L q_{1j} E(x_j(\tau_n)) \\ & + \sum_{i=1}^{L-1} \mu_i \sum_{j=1}^L (q_{i+1,j} - q_{ij}) E(z_{ij}(\tau_n)) \\ & - \mu_L \sum_{j=1}^L q_{Lj} E(z_{Lj}(\tau_n)) \leq -\gamma \sum_{j=1}^L E(x_j(\tau_n)) \end{aligned}$$

then from (6) we would have stability-in-the-mean, i.e.,

$$\frac{1}{N+1} \sum_{n=0}^N \sum_{j=1}^L E(x_j(\tau_n)) \leq M'' < +\infty \text{ for all } N. \quad (7)$$

Before we pursue the issue of finding such a γ , we point out certain consequences of stability-in-the-mean for stationary, nonidling policies. In the rest of this paper we will restrict attention to scheduling policies that are nonidling, i.e., whenever one of the buffers at a machine is nonempty, then the machine cannot stay idle. For stationary, nonidling policies, $\{x(\tau_n)\}$ is a time-homogeneous, countable state, Markov chain, which has a single communicating class that is aperiodic (since the origin can be reached from every state, and the system can stay at the origin for two consecutive time steps). The condition (7) then guarantees positive recurrence, i.e., the existence of a unique steady state probability distribution. To see this, note that if the chain is not positively recurrent, then the probability that the chain is in a fixed finite set of states converges to zero as $n \rightarrow \infty$. Then, that is so even for the finite set of states $\{x: \sum_{j=1}^L x_j \leq M'', \text{ and all } x_j \geq 0 \text{ and integral}\}$. This contradicts (7). Moreover, the Markov chain has bounded first moment, and the mean total number of customers converges to a finite steady state value. In fact, we will show in the next section that it even establishes the geometric convergence of an exponential moment.

Let us now see how to assure (7) for some $\gamma > 0$. We will actually work at assuring that the inequality (7) holds without the expectation being taken, i.e.,

$$\begin{aligned} & \lambda \sum_{j=1}^L q_{1j} x_j(\tau_n) + \sum_{i=1}^{L-1} \mu_i \sum_{j=1}^L (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ & - \mu_L \sum_{j=1}^L q_{Lj} z_{Lj}(\tau_n) \leq -\gamma \sum_{j=1}^L x_j(\tau_n). \end{aligned} \quad (8)$$

Let us now motivate the reason for restricting our attention to nonidling policies in our tests for stability. Note that the coefficients λq_{1j} of the $x_j(\tau_n)$'s on the left-hand side (LHS) above are all nonnegative, while the corresponding coefficient $(-\gamma)$ on the right-hand side (RHS) is negative. Clearly, to assure (8) it is necessary that there exist some choice of constants $\{\alpha_{ij}\}$ for which

$$\sum_{j=1}^L x_j(\tau_n) \leq \sum_{i=1}^L \sum_{j=1}^L \alpha_{ij} z_{ij}(\tau_n).$$

Focusing on a fixed index j , one will in particular need $x_j(\tau_n)$ to be bounded above by some linear combination of

$\{z_{ij}(\tau_n): 1 \leq i \leq L\}$. This can only be assured if some machine is guaranteed to be working whenever $x_j > 0$; hence the restriction to nonidling scheduling policies in the sequel.

Let us return to (8). For notational convenience, let us define

$$q_{L+1,j} := 0 \text{ for all } j = 1, 2, \dots, L.$$

Focusing on a fixed value of the index j , it is clear that (8) is assured, if

$$\begin{aligned} & \lambda q_{1j} x_j(\tau_n) + \sum_{i=1}^L \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ & \leq -\gamma x_j(\tau_n) \text{ for all } j = 1, 2, \dots, L. \end{aligned} \quad (9)$$

Grouping the terms by machine, i.e., using $\{1, 2, \dots, L\} = \bigcup_{\sigma} \{i: \sigma(i) = \sigma\}$, we see that the LHS of (9) satisfies

$$\begin{aligned} & \lambda q_{1j} x_j(\tau_n) + \sum_{i=1}^L \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ & = \lambda q_{1j} x_j(\tau_n) + \sum_{\sigma=1}^S \sum_{\{i: \sigma(i)=\sigma\}} \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ & \leq \lambda q_{1j} x_j(\tau_n) + \sum_{\sigma=1}^S \max_{\{i: \sigma(i)=\sigma\}} \mu_i (q_{i+1,j} - q_{ij}) \\ & \quad \times \sum_{\{i: \sigma(i)=\sigma\}} z_{ij}(\tau_n) \\ & = \lambda q_{1j} x_j(\tau_n) + \max_{\{i: \sigma(i)=\sigma(j)\}} \mu_i (q_{i+1,j} - q_{ij}) \\ & \quad \times \sum_{\{i: \sigma(i)=\sigma(j)\}} z_{ij}(\tau_n) + \sum_{\{\sigma': \sigma' \neq \sigma(j)\}} \max_{\{i: \sigma(i)=\sigma'\}} \mu_i (q_{i+1,j} - q_{ij}) \\ & \quad \times \sum_{\{i: \sigma(i)=\sigma'\}} z_{ij}(\tau_n). \end{aligned} \quad (10)$$

We now investigate how to assure that the RHS of (10) can be bounded above by $-\gamma x_j(\tau_n)$. For nonidling policies

$$\sum_{\{i: \sigma(i)=\sigma\}} x_i(\tau_n) > 0 \Rightarrow \sum_{\{i: \sigma(i)=\sigma\}} w_i(\tau_n) = 1$$

and so

$$x_j(\tau_n) = \sum_{\{i: \sigma(i)=\sigma(j)\}} w_i(\tau_n) x_j(\tau_n).$$

Hence

$$x_j(\tau_n) = \sum_{\{i: \sigma(i)=\sigma(j)\}} z_{ij}(\tau_n). \quad (11)$$

Moreover, since other machines need not be working when b_j is nonempty, we have the nonidling inequalities

$$x_j(\tau_n) \geq \sum_{\{i: \sigma(i)=\sigma'\}} z_{ij}(\tau_n) \text{ for all } \sigma' \neq \sigma(j). \quad (12)$$

Employing (11), (12), in (10), we obtain

$$\begin{aligned} & \lambda q_{1j} + \sum_{i=1}^L \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ & \leq \lambda q_{1j} + \sum_{\{\sigma : \sigma(i) = \sigma(j)\}} \left[\max_{\{\sigma(i) = \sigma(j)\}} \mu_i (q_{i+1,j} - q_{ij}) \right] z_{ij}(\tau_n) \\ & \quad + \sum_{\{\sigma : \sigma \neq \sigma(j)\}} \left[\max_{\{\sigma(i) = \sigma\}} \mu_i (q_{i+1,j} - q_{ij}) \right]^+ z_{ij}(\tau_n) \end{aligned}$$

Above, $[y]^+ = \max\{y, 0\}$ denotes the positive part of y . The sign needs to be taken into account, since a negative sign of $\mu_i (q_{i+1,j} - q_{ij})$ may reverse the inequality.

Hence we see that if we can find an appropriate set of $\{q_{ij}\}$ for which

$$\begin{aligned} & \lambda q_{1j} + \max_{\{\sigma(i) = \sigma(j)\}} \mu_i (q_{i+1,j} - q_{ij}) \\ & \quad + \sum_{\{\sigma : \sigma \neq \sigma(j)\}} \left[\max_{\{\sigma(i) = \sigma\}} \mu_i (q_{i+1,j} - q_{ij}) \right]^+ \\ & \leq -\gamma \quad \text{for } j = 1, 2, \dots, I \end{aligned}$$

for some $\gamma > 0$, then (8), and hence (7), is assured. Thus we have arrived at the following theorem.

Theorem 1—The Basic Characterization. Consider the basic open re-entrant line. Suppose there exists asymmetric copositive matrix $Q = [q_{ij}]$ which satisfies the following conditions. For every $j = 1, 2, \dots, I$

$$\begin{aligned} & \lambda q_{1j} + \max_{\{\sigma(i) = \sigma(j)\}} \mu_i (q_{i+1,j} - q_{ij}) \\ & \quad + \sum_{\{\sigma : \sigma \neq \sigma(j)\}} \left[\max_{\{\sigma(i) = \sigma\}} \mu_i (q_{i+1,j} - q_{ij}) \right]^+ < 0 \quad (13) \end{aligned}$$

(Above $q_{I+1,j} = 0$ for all j .) Then, every nonidling, noninterruptive scheduling policy is stable in the mean, i.e., there exist constants ϵ, C' such that

$$\frac{1}{N} \sum_{n=0}^N \sum_{j=1}^I E(z_{ij}(\tau_n)) \leq \frac{\epsilon F(z^I(0)Qz(0))}{N} + C' \quad \text{for all } N$$

Moreover, if the scheduling policy is stationary, then there is a unique steady state probability distribution.

V FROM STABILITY TO GEOMETRIC CONVERGENCE OF AN EXPONENTIAL MOMENT

In fact, for a Markovian system, the above Lyapunov based negative drift argument actually establishes the geometric convergence of an exponential moment (defined below). Thus, in particular it establishes the finiteness of all (polynomial) moments and their geometric ergodicity.

To see this, we simply work with the square root of the earlier Lyapunov function. From Fig. 2, just as we obtained (3), we obtain

$$\begin{aligned} & L \left[\sqrt{z^I(\tau_{n+1})Qz(\tau_{n+1})} \middle| \mathcal{F}_{(\tau_n)} \right] \\ & = \lambda \sqrt{(z(\tau_n) + e_1)^T Q(z(\tau_n) + e_1)} \end{aligned}$$

$$\begin{aligned} & + \sum_{i=1}^{I-1} \mu_i w_i(\tau_n) \\ & \times \sqrt{(z(\tau_n) - e_i + e_{i+1})^T Q(z(\tau_n) - e_i + e_{i+1})} \\ & + \mu_L w_L(\tau_n) \sqrt{(z(\tau_n) - e_I)^T Q(z(\tau_n) - e_I)} \\ & + \sum_{i=1}^L \mu_i (1 - u_i(\tau_n)) \sqrt{z^I(\tau_n)Qz(\tau_n)} \quad (14) \end{aligned}$$

From the concavity of the square root we obtain

$$\begin{aligned} & L \left[\sqrt{z^I(\tau_{n+1})Qz(\tau_{n+1})} \middle| \mathcal{F}_{(\tau_n)} \right] \\ & \leq [z^I(\tau_n)Qz(\tau_n) + 2\lambda z^I(\tau_n)Qz(\tau_n) \\ & \quad + 2 \sum_{i=1}^{I-1} \mu_i w_i(\tau_n) (e_{i+1} - e_i)^T Qz(\tau_n) \\ & \quad - 2\mu_L w_L(\tau_n) e_I^T Qz(\tau_n) + M]^1/2 \quad (15) \end{aligned}$$

Now suppose the conditions of Theorem 1 are met. Then, from (8), the RHS above can be bounded as

$$\text{RHS of (15)} \leq \left[z^I(\tau_n)Qz(\tau_n) - 2\gamma \sum_{j=1}^I z_{ij}(\tau_n) + M \right]^1/2 \quad (16)$$

Now from Theorem 14.2.2 of [28] by taking τ there to be the first hitting time of the origin it follows that there exists a $\delta > 0$, such that $z^I Q z > \delta \|z\|^2$ for all large enough $\|z\|$ in the positive orthant.¹ (Or in the case where all $q_{ij} \geq 0$, the fact that $q_{ii} > 0$ follows trivially from inequality (iii) of Theorem 1.) Hence, there exists an $\epsilon > 0$ small enough so that

$$\text{RHS of (16)} \leq [z^I(\tau_n)Qz(\tau_n)]^1/2 - \epsilon$$

whenever

$$\sum_{j=1}^I z_{ij}(\tau_n) > M'''$$

for some large M''' .

Letting $W(\tau_n) = \sqrt{z(\tau_n)^T Q z(\tau_n)}$ we have thus shown that

$$E[W(\tau_{n+1}) | \mathcal{F}_{(\tau_n)}] \leq W(\tau_n) - \epsilon \quad \text{if } z(\tau_n) \text{ lies outside a compact set,}$$

and is bounded when $z(\tau_n)$ is in the compact set. Moreover, the state can jump by only a bounded amount at each transition, and hence $W(\tau_{n+1}) - W(\tau_n)$ is bounded. From these two facts, it follows that the Markov chain representing the evolution of the system has a geometrically converging exponential moment, see [28, Theorem 16.3.1].

¹Thus Q is actually strictly copositive.

Theorem 2—Geometric Convergence of an Exponential Moment: Consider the basic, open re-entrant line. Suppose that the scheduling policy is stationary and that all the conditions of Theorem 1 are satisfied. Then the Markov chain $\{x(\tau_n)\}$ has a geometrically converging exponential moment,² i.e., there exist $\epsilon > 0$, $r > 1$, and $C < \infty$, such that for any function f satisfying $|f(y)| \leq \exp(\epsilon\|y\|)$ for all y , and any initial condition $x(\tau_0) = x$,

$$\sum_{n=0}^{\infty} r^n |E[f(x(\tau_n))]| - \sum_y f(y) \pi(y) < C \exp(\epsilon\|x\|) \text{ for all } x.$$

Above, $\pi(y)$ denotes the steady-state probability of the state y . Hence, in particular, the Markov chain admits a finite exponential moment. That is, for some $C' < \infty$

$$E[\exp(\epsilon\|x(\tau_n)\|)] \leq C' \exp(\epsilon\|x\|) < \infty \text{ for all } n.$$

The reader is referred to Meyn and Tweedie [29] for estimates of the rate of convergence. It is worth mentioning that the uniformization procedure is just a way of computing the drift $\mathcal{A}^T Qx$, where \mathcal{A} is the extended generator for the unsampled Markov process. Thus one actually has, for some $\rho < 1$, $|E[f(x_t)] - \sum_y f(y) \pi(y)| < C\rho^t V(x)$ for all x and all $t \geq 0$, i.e., a similar geometric convergence for the original unsampled chain.

VI. A LINEAR PROGRAMMING CHARACTERIZATION

As noted earlier, if Q is a symmetric nonnegative matrix, then it is copositive. Note now that the LHS of (13) in Theorem 1 is homogeneous in Q . Hence, if (13) is valid, then by multiplying Q by arbitrarily large positive numbers, one can drive the value of the LHS of the inequality (13) in Theorem 1 to $-\infty$. This allows us to provide a sufficient condition for stability in terms of the unboundedness of a linear program.

Theorem 3—A Linear Programming Characterization: Consider the basic, open re-entrant line. Suppose that the following linear program has an unbounded solution

$$\text{Max } \gamma$$

subject to the constraints

$$\lambda q_{1j} + r_j + \sum_{\{\sigma' : \sigma' \neq \sigma(j)\}} s_{\sigma',j} + \gamma \leq 0 \quad \text{for all } j$$

$$r_j \geq \mu_i(q_{i+1,j} - q_{i,j}) \quad \text{for all } i \in I(j), \text{ and for all } j$$

$$s_{\sigma,j} \geq \mu_i(q_{i+1,j} - q_{i,j}) \quad \text{for all } i \text{ with } \sigma(i) = \sigma, \text{ and all } j$$

$$q_{i,j} = q_{j,i} \quad \text{for all } i, j$$

$$q_{L+1,j} = 0 \quad \text{for all } j$$

$$q_{i,j} \geq 0 \quad \text{for all } i, j$$

$$s_{\sigma,j} \geq 0 \quad \text{for all } \sigma, j$$

r_j unrestricted in sign.

Then, every nonidling, noninterruptive policy is stable in the mean. Moreover, every nonidling, stationary policy has a geometrically converging exponential moment.

²This property is called " $\exp(\epsilon\|x\|)$ -uniform ergodicity" in [28].

Fig. 3. Example of Sections VII and X

The number of variables $\{q_{ij}, r_k, s_{\sigma j}, \gamma\}$ in the above linear program is $\frac{L(L+1)}{2} + L + (S-1)L + 1$. (Note that the variables $s_{\sigma(j),j}$, $q_{i,j}$ with $i > j$, and $q_{L+1,j}$ are not really needed.) The number of constraints is $L + \sum_{j=1}^L |I(j)| + \sum_{j=1}^L \sum_{\sigma \neq \sigma(j)} |\{i : \sigma(i) = \sigma\}|$. It may be possible to rewrite the linear program more economically.

We find it convenient to slightly modify the linear program in Theorem 3 by bounding γ by 1. Thus if the value of the linear program is 1, then one deduces stability (rather than from the unboundedness of the value as in Theorem 3).

Corollary 1—A 0-1 Test of Stability: Consider the same linear program as in Theorem 3, except that we impose the additional constraint

$$\gamma \leq 1.$$

If the linear program has value one, then every nonidling noninterruptive policy is stable-in-the-mean. Moreover, every nonidling, stationary policy has a geometrically converging exponential moment. If the value of the linear program is zero, however, then no conclusion can be drawn regarding stability or instability.

VII. EXAMPLE: ALL NONIDLING POLICIES STABLE

Consider the system shown in Fig. 3. Then, to show that there exists a $Q = Q^T$ satisfying (7), it is sufficient to find $q_{i,j} = q_{j,i} \geq 0$, so that

$$\begin{aligned} & [\lambda q_{11}, \lambda q_{12}, \lambda q_{13}] \begin{bmatrix} x_1(\tau_n) \\ x_2(\tau_n) \\ x_3(\tau_n) \end{bmatrix} \\ & + [-\mu_1 q_{11} + \mu_1 q_{12}, -\mu_1 q_{12} + \mu_1 q_{22}, -\mu_1 q_{13} + \mu_1 q_{23}, \\ & \quad -\mu_2 q_{12} + \mu_2 q_{13}, -\mu_2 q_{22} + \mu_2 q_{23}, -\mu_2 q_{23} + \mu_2 q_{33}, \\ & \quad -\mu_3 q_{13}, -\mu_3 q_{23}, -\mu_3 q_{33}] \begin{bmatrix} z_{11}(\tau_n) \\ z_{12}(\tau_n) \\ z_{13}(\tau_n) \\ z_{21}(\tau_n) \\ z_{22}(\tau_n) \\ z_{23}(\tau_n) \\ z_{31}(\tau_n) \\ z_{32}(\tau_n) \\ z_{33}(\tau_n) \end{bmatrix} \\ & \leq -\gamma[x_1(\tau_n) + x_2(\tau_n) + x_3(\tau_n)]. \end{aligned}$$

By the nonidling condition, $x_1(\tau_n) = z_{11}(\tau_n) + z_{31}(\tau_n)$, $x_2(\tau_n) = z_{22}(\tau_n)$ and $x_3(\tau_n) = z_{13}(\tau_n) + z_{33}(\tau_n)$. We thus see that it suffices to show that one can choose $\{q_{11}, q_{12}, q_{13}, q_{22}, q_{23}, q_{33}\}$, all nonnegative, so that $\lambda q_{11} - \mu_1 q_{11} + \mu_1 q_{12} < 0$, $-\mu_1 q_{12} + \mu_1 q_{22} < 0$, $-\mu_1 q_{13} + \mu_1 q_{23} +$

Fig. 4 Dai Wang example of Section VIII

$$\begin{aligned} \lambda q_{11} < 0, -\mu_2 q_{12} + \mu_2 q_{13} < 0, -\mu_2 q_{22} + \mu_2 q_{23} + \lambda q_{12} < 0 \\ \mu_2 q_{23} + \mu_2 q_{33} < 0, -\mu_3 q_{13} + \lambda q_{11} < 0, -\mu_3 q_{23} < 0, \\ \mu_3 q_{33} + \lambda q_{11} < 0 \end{aligned}$$

Let us suppose that $\mu_1 = \mu_2 = \mu_3 = \mu$, and $\rho = \frac{2\lambda}{\mu}$. Then the above is equivalent to, $(1 - \rho/2)q_{11} > q_{12}$, $q_{12} > q_{22}$, $(1 - \rho/2)q_{13} > q_{23}$, $q_{12} > q_{13}$, $q_{22} > \rho q_{12}/2 + q_{23}$, $q_{24} > q_{13}$, $q_{13} > \rho q_{11}/2$, $q_{24} > 0$, $q_{33} > \rho q_{13}/2$.

It is easily checked that if $\rho < 1$ then one can choose $q_{ij} > 0$ which satisfy the above conditions.

Hence, we conclude that if $\mu_1 = \mu_2 = \mu_3 = \mu$ and $\rho = \frac{2\lambda}{\mu} < 1$, then all nonidling, noninterruptive, scheduling policies are stable in the mean. This includes the FCFS policy, which is already known to be stable since $\mu_1 = \mu_3$ see Kelly [30]. Moreover, every nonidling stationary policy has a geometrically converging exponential moment.

VIII THE DAI WANG EXAMPLE

Dai and Wang [12] (see also [14]) show that the system of Fig. 4 does not have a Brownian approximation. It is a basic open re-entrant line with service rates $\mu_1 = 10$, $\mu_2 = 20$, $\mu_3 = 10/9$, $\mu_1 = 20$, and $\mu_3 = 5/1$. Let $\rho = \lambda/\mu_1 + \lambda/\mu_2 + \lambda/\mu_3 = \lambda/10 + \lambda/20 + 9\lambda/10$ be the load factor on the two machines. Our goal is to determine whether the system is stable for all $\rho < 1$.

First note from the equations involving λ in (13) and Corollary 1 that if the value of the linear program is one for some λ' then it is one for all $\lambda < \lambda'$. Hence there will be critical value λ_{crit} , such that the linear program has value one for $\lambda < \lambda_{crit}$ and value zero for $\lambda > \lambda_{crit}$. Equivalently, there exists such a ρ_{crit} . So we wish to see if $\rho_{crit} = 1$.

Investigating the linear program from Corollary 1, we find that its value is one for $\lambda < 0.55587$ (approximately) and zero for $0.55587 < \lambda < 1$. Thus we can only assert stability for $\rho < 0.95(0.55587) = 0.528$.

IX BUFFER PRIORITY POLICIES

Consider the basic, open re-entrant line. Suppose that at every machine σ there is a rank ordering of the set of buffers $\{b_i : \sigma(i) = \sigma\}$ served by the machine according to which preemptive priority is given by the machine. To describe such a buffer priority policy more concisely, let $\{\theta(1) \dots \theta(L)\}$ be a permutation of $\{1, 2, \dots, L\}$, with preference given to b_i over b_j if $\theta(i) < \theta(j)$ and both b_i and b_j share the same machine, i.e. $\sigma(i) = \sigma(j)$. The policy is nonidling, stationary, and preemptive.

Then, $x_j(\tau_n) > 0 \Rightarrow w_j(\tau_n) = 0$, if $\theta(i) < \theta(j)$ and $\sigma(i) = \sigma(j)$. Hence $z_{ji} = w_j(\tau_n)z_i(\tau_n) = 0$, if $\theta(i) < \theta(j)$

and $\sigma(i) = \sigma(j)$. As a consequence

$$\begin{aligned} x_j(\tau_n) &= \sum_{\{i : i \in I(j), \theta(i) \leq \theta(j)\}} z_{ij}(\tau_n) \\ &\geq \sum_{\{i : \sigma(i) = \sigma\}} z_{ij}(\tau_n) \text{ for } \sigma' \neq \sigma \end{aligned}$$

Recall from Section IV that our goal is to determine symmetric copositive Q satisfying

$$\begin{aligned} \lambda q_{1j} r_j(\tau_n) + \sum_{i \in I(j)} \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ + \sum_{\{\sigma : \sigma \neq \sigma(j)\}} \sum_{\{i : \sigma(i) = \sigma\}} \mu_i (q_{i+1,j} - q_{ij}) z_{ij}(\tau_n) \\ \leq -\gamma r_j(\tau_n) \text{ for } j = 1, 2, \dots, L \end{aligned}$$

for some $\gamma > 0$. (This can be seen by rewriting the LHS of (9) as in the first equality of (10)). Using (17), (18) the conditions required to establish stability in Corollary 1 can be relaxed.

Theorem 4—Stability of Buffer Priority Policies. Consider the basic open re-entrant line. Let $\{\theta(1) \dots \theta(L)\}$ be a permutation of $\{1, 2, \dots, L\}$. Consider the preemptive buffer priority policy which gives preference to b_i over b_j if $\theta(i) < \theta(j)$ and both share the same machine. Then the buffer priority policy $\theta(\cdot)$ is stable, with a geometrically converging exponential moment, if the following linear program has value one.

$$\text{Max } \gamma$$

subject to

$$\begin{aligned} \lambda q_{1j} + \max_{\{i : i \in I(j) \text{ and } \theta(i) \leq \theta(j)\}} \mu_i (q_{i+1,j} - q_{ij}) \\ + \sum_{\{\sigma : \sigma \neq \sigma(j)\}} \left[\max_{\{i : \sigma(i) = \sigma\}} \mu_i (q_{i+1,j} - q_{ij}) \right] + \gamma \\ \leq 0 \text{ for } j = 1, 2, \dots, L \\ \gamma \leq 1 \\ q_{ij} - q_{ji} \geq 0 \text{ for } 1 \leq i, j \leq L \end{aligned}$$

X EXAMPLE LBFS AND FBFS ARE STABLE

Consider the system of Fig. 3. Unlike in Section VII we do not require that all the μ_i 's are equal.

First let us examine the class of nonidling policies. Can we prove that all nonidling, noninterruptive policies are stable? To investigate, we consider the following linear program

$$\text{Max } \gamma \quad (19)$$

subject to the constraints

$$\begin{aligned} \lambda q_{11} + \max\{\mu_1(q_{12} - q_{11}) - \mu_3 q_{13}\} \\ + \max\{\mu_2(q_{13} - q_{12}), 0\} + \gamma \leq 0 \end{aligned} \quad (20)$$

$$\begin{aligned} \lambda q_{12} + \mu_2(q_{23} - q_{22}) + \max\{\mu_1(q_{22} - q_{12}) \\ - \mu_3 q_{23}, 0\} + \gamma \leq 0 \end{aligned} \quad (21)$$

$$\begin{aligned} \lambda q_{13} + \max\{\mu_1(q_{23} - q_{13}) - \mu_3 q_{33}\} \\ + \max\{\mu_2(q_{33} - q_{23}), 0\} + \gamma \leq 0 \end{aligned} \quad (22)$$

Fig. 5. Value of LP for all nonidling, noninterruptive policies in example of Section X. The figure on the right is a more detailed view of one corner of the figure on the left.

Fig. 6. Value of LP for example of Section X for the LBFS policy and for the FBFS policy.

$$\gamma \leq 1 \quad (23)$$

$$q_{11}, q_{12}, q_{13}, q_{22}, q_{23}, q_{33} \geq 0. \quad (24)$$

Let $\rho_i := \frac{\lambda_i}{\mu_i}$, and consider $\rho_1 = \rho_3$. Fig. 5 plots the value of the linear program as a function of $2\rho_1$ and ρ_2 . It shows that there is a region where the value of the linear program is 0, and for such values of $\rho_1, \rho_2, \rho_3 (= \rho_1)$, no conclusion regarding stability or instability can be drawn.

Now consider the LBFS policy. The corresponding linear program is the same as (19)–(24), with exception that (22) is changed to

$$\lambda q_{13} - \mu_3 q_{33} + \max\{\mu_2(q_{33} - q_{23}), 0\} + \gamma \leq 0. \quad (25)$$

The plot of its value as a function of $2\rho_1$, and ρ_2 is given in Fig. 6. It shows that the system is stable for all values of $2\rho_1 < 1$ and $\rho_2 < 1$. Hence, for $\rho_1 = \rho_3$, the LBFS policy is stable in the entire capacity region.

Now turn to the FBFS policy. Its linear program is also almost the same as (19)–(24), except that (20) is changed to the following

$$\lambda q_{11} + \mu_1(q_{12} - q_{11}) + \max\{\mu_2(q_{13} - q_{12}), 0\} + \gamma \leq 0. \quad (26)$$

The plot of its value is the same as that of LBFS, as shown in Fig. 6. Hence it is also stable in the entire stability region, when $\rho_1 = \rho_3$.

XI. A NONLINEAR PROGRAMMING CHARACTERIZATION

Note that every symmetric positive semidefinite Q is copositive. Thus, in our stability tests, we could use the class of symmetric positive semidefinite matrices. Every such Q possesses a square root A , i.e., $Q = A^T A$. Hence, one may search over the unrestricted space of a_{ij} 's, rather than the space of q_{ij} 's. This yields the following Theorem.

Theorem 5—A Nonlinear Programming Characterization. Consider the basic, open, re-entrant line. Consider the nonlinear program

$$\text{Max } \gamma$$

subject to all the constraints of Corollary 1, except that every q_{ij} is replaced by $\sum_{k=1}^L a_{ki} a_{kj}$, and the nonnegativity constraint on the q_{ij} 's is removed. If this nonlinear program has value one, then, every nonidling, noninterruptive, scheduling policy is stable in the mean. Moreover, then, every nonidling, stationary policy gives rise to a Markov chain, with a geometrically converging exponential moment.

Also, one can extend this Theorem to search over convex combinations of a nonnegative matrix, and a positive semidefinite matrix. This yields the following theorem.

Theorem 6—A More General Nonlinear Programming Characterization Consider the basic, open, re-entrant line. Consider the nonlinear program

$$\text{Max } \gamma$$

subject to all the constraints of Corollary 1, except that every q_{ij} is replaced by $q'_{ij} + \sum_{k=1}^L a_{ki} a_{kj}$, and the nonnegativity constraint on the q_{ij} 's is replaced by nonnegativity constraints on the q'_{ij} 's, while the a_{ij} 's are unrestricted. If this nonlinear program has value one, then every nonidling, noninterruptive, scheduling policy is stable in the mean. Moreover, then, every nonidling, stationary policy gives rise to a Markov chain, with a geometrically converging exponential moment.

Both these theorems can be extended in the same ways as Theorem 1, to treat various kinds of systems and scheduling policies.

To go beyond Theorems 5 and 6 and obtain the most powerful test obtainable through our approach, one could simply check whether the value of the linear program in Theorem 3 is one, without imposing any sign restrictions on q_{ij} , i.e., after removing the constraints $q_{ij} \geq 0$. If the value is indeed one, one can then test whether the obtained Q is copositive, using an algorithm as in [25]. As noted in Section III, however, the test of copositivity is NP-Complete and may therefore be computationally complex for systems of large size.

XII. MORE GENERAL QUEUEING NETWORKS

Consider a queueing network with S machines and L buffers. Let us suppose every buffer b_i has an exogenous Poisson arrival process of rate λ_i . A part leaving buffer b_i goes to buffer b_j with probability p_{ij} and leaves the system with probability $(1 - \sum_{j=1}^L p_{ij})$. The service time of parts in buffer b_i is exponential with mean $\frac{1}{\mu_i}$. Let us rescale time so

Fig 7 State transition diagram for general queueing network of Section XII

that $\sum_{i=1}^I \lambda_i + \sum_{j=1}^L \mu_j = 1$. The state transition diagram is shown in Fig 7. Hence

$$\begin{aligned} & P'(I^T(\tau_{n+1})Q(I(\tau_{n+1}) | \mathcal{F}(\tau_n))) \\ &= \sum_{i=1}^L \lambda_i (I(\tau_n) + e_i)^T Q(I(\tau_n) + e_i) \\ &+ \sum_{i=1}^I \mu_i w_i(\tau_n) \sum_{j=1}^L p_{ij} (I(\tau_n) - e_i + e_j)^T \\ &\times Q(I(\tau_n) - e_i + e_j) \\ &+ \sum_{i=1}^L \mu_i w_i(\tau_n) \left(1 - \sum_{j=1}^L p_{ij}\right) (I(\tau_n) - e_i)^T \\ &\times Q(I(\tau_n) - e_i) + \sum_{i=1}^I \mu_i (1 - w_i(\tau_n)) I^T(\tau_n) Q(I(\tau_n)) \end{aligned}$$

Proceeding as in Section IV, one may obtain the following theorem.

Theorem 7—Stability of a General Network. Consider the more general queueing network above operated under any nonidling, noninterruptive policy. Then it is stable in the mean, provided there exists a symmetric copositive Q that satisfies the following inequalities for $j = 1, 2, \dots, L$:

$$\begin{aligned} & \sum_{i=1}^I \lambda_i q_{ij} + \max_{\{\sigma: \sigma(i) = \sigma(j)\}} \mu_i \left(-q_{ij} + \sum_{k=1}^L p_{ik} q_{kj} \right) \\ &+ \sum_{\{\sigma: \sigma \neq \sigma(j)\}} \left[\max_{\{\sigma: \sigma(i) = \sigma\}} \mu_i \left(-q_{ij} + \sum_{k=1}^L p_{ik} q_{kj} \right) \right]^+ < 0 \end{aligned}$$

This can also be written as a linear program if we restrict $q_{ij} \geq 0$ for all i, j , or as a nonlinear program if we take $Q = A^T A + [q'_{ij}]$, with nonnegative q'_{ij} 's. Moreover, if the policy is stationary, then the system is a Markov chain with a geometrically converging exponential moment.

XIII THE RYBKO-STOLYAR EXAMPLE

Consider the system shown in Fig 8. The arrivals to buffers b_1 and b_3 are Poisson of rate λ . The service times are all exponentially distributed, with mean $1/\mu_1$ at buffers b_1 and b_3 , and mean $1/\mu_2$ at buffers b_2 and b_4 . Consider the buffer priority policy with ordering $\{b_4, b_2, b_3, b_1\}$, i.e., with priority given to buffers earlier in this list. Let us define $\rho_1 = \lambda/\mu_1$, and $\rho_2 = \lambda/\mu_2$.

Rybko and Stolyar [4] have shown that this system is unstable for $\lambda = 1$, if $\rho_2 > 1/2$ and $\rho_1 > 0$, even if

Fig 8 The Rybko-Stolyar example of Section XIII

Fig 9 Value of the linear program for Rybko-Stolyar example of Section XIII. The figure on the right is a more detailed view of one portion of the figure on the left.

Fig 10 Stable, unstable and undetermined regions for Rybko-Stolyar example.

the service time requirements meet the capacity condition, $1/\mu_1 + 1/\mu_2 < 1$.

The following linear program tests the stability of the system for all ρ_1 and ρ_2 :

$$\text{Max } \gamma$$

subject to the constraints

$$\begin{aligned} & \text{Max}[\lambda q_{11} + \lambda q_{13} - \mu_1 q_{11} + \mu_1 q_{12} - \lambda q_{11} + \lambda q_{13} - \mu_1 q_{11}] \\ &+ \text{Max}[0 - \mu_3 q_{13} + \mu_3 q_{11}] < \gamma \end{aligned}$$

$$\lambda q_{12} + \lambda q_{23} - \mu_2 q_{22} + \text{Max}[0 - \mu_1 q_{11} + \mu_1 q_{22}] \leq \gamma$$

$$\begin{aligned} & \text{Max}[\lambda q_{13} + \lambda q_{33} - \mu_2 q_{23} - \lambda q_{13} + \lambda q_{33} - \mu_3 q_{33} + \mu_3 q_{13}] \\ &+ \text{Max}[0 - \mu_1 q_{13} + \mu_1 q_{23}] < \gamma \end{aligned}$$

$$\lambda q_{14} + \lambda q_{34} - \mu_1 q_{14} + \text{Max}[0 - \mu_3 q_{34} + \mu_3 q_{14}] \leq \gamma$$

$$\gamma < 1$$

$$q_{ij} \geq 0, \gamma \geq 0$$

Fig 9 plots the value of the linear program for $0 < \rho_1 < 1$ and $0 < \rho_2 < 1$. (The region $\rho_1 + \rho_2 \geq 1$ should be disregarded as it lies outside the capacity region.)

The following points are salient. First, the value of the linear program is zero in the region $\rho_2 > 1/2$ and thus noncontradictory with Rybko and Stolyar's result. Second, as shown in

Fig. 10, for most of the rest of the capacity region, the system is stable, since the value of the linear program is one. There is a small region, however, where the value of the linear program is zero; thus the stability remains unresolved there.

XIV. CONCLUDING REMARKS

We have provided here a programmatic procedure for establishing stability of queueing networks and scheduling policies.

There are several interesting questions which arise. First, it would be useful to study the structure of the linear or nonlinear programs and thus directly establish the stability of policies. We have done so analytically for the example of Section VII. Second, in all the examples tested by us, any Q giving a negative drift was always found to be a nonnegative matrix. It would be useful to determine whether there exists an example of a system where Q is copositive but not nonnegative. This should show that the more powerful tests of Section XI are in fact valuable. Third, it would be useful to implement a multi-step drift version of the above results. Finally, it would be useful to carry out a similar development for "instability" results, as in Fayolle [16] and Coffman *et al.*, [20].

ACKNOWLEDGMENT

The authors thank D. Down, S. Gowda, and J. Tsitsiklis for their useful comments.

From 1977–1984 he was a faculty at the University of Maryland. Since 1985 he has been at the University of Illinois, Urbana-Champaign. His current research interests are in manufacturing systems, adaptive control, and learning.

Dr. Kumar is an Associate Editor at Large for *IEEE TRANSACTIONS ON AUTOMATIC CONTROL* and an Associate Editor for the following journals: *Journal of Discrete Event Dynamic Systems: Theory and Applications*, *International Journal on Adaptive Control and Signal Processing*, and *Mathematics of Control, Signals, and Systems*.

Sean P. Meyn (M'86) received the B.S. degree in mathematics from the University of California, Los Angeles, in 1982 and the M.Eng. and Ph.D. degrees in electrical engineering from McGill University, Montreal, Canada, in 1987.

He spent two years as a postdoctoral fellow at the Department of Systems Engineering, Australian National University. Since 1989 he has been an Assistant Professor with the Coordinated Science Laboratory and the Department of Electrical and Computer Engineering at the University of Illinois at Urbana-Champaign.

Dr. Meyn serves as an Associate Editor of several journals in the systems and control area. He was a recipient of the NSF Research Initiation Award and is a member of Phi Beta Kappa. He is coauthor, with R. L. Tweedie, of the award-winning book, *Markov Chains and Stochastic Stability* (Springer-Verlag, London, 1993).

Second-Order Properties of Families of Discrete-Event Systems

Rajandran Rajan and Rajeev Agrawal, *Member, IEEE*

Abstract— We consider discrete-event systems (DES) whose logical component is characterized by a constraint set and whose temporal mechanism involves synchronization of the clock sequence with a master clock. We are interested in determining sufficient conditions on the constraint sets of a family of such synchronous DES that ensure that the event counting process of one system dominates the convex combination of the event counting processes of a collection of systems. Our point of departure is a result due to Glasserman and Yao [16], which established a sufficient condition based on characteristic functions. First we show that the characteristic function condition is equivalent to a simpler condition on the score spaces themselves. As both of these (equivalent) conditions are rather strong, however, we introduce coequality to obtain weaker sufficient conditions. To demonstrate the scope of these two results, we prove the near-concavity of the throughput in various parameters for min-linearly constrained DES. This not only covers various known concavity results for tandems, cycles, and fork-join networks of stations with general blocking and starvation, but also establishes new ones for certain classes of networks which involve splitting and merging traffic streams. These results are finally extended to the class of generalized min-linearly constrained DES.

I. INTRODUCTION

A timed discrete-event system (DES) has two aspects — the logical and the temporal. The logical aspect of the DES deals with the order in which events can occur. This is completely specified by a language which is the collection of all allowable strings of events. The temporal aspect of the DES determines which one of the allowable strings is actually realized, and the times of occurrence of the events in that string. Several mechanisms, such as state machines [1], Petri nets [2], and finitely recursive processes [3], have been proposed for generating different classes of DES languages. In this paper, we consider languages that are generated by constraint sets, $\mathcal{T} \subset \mathbb{Z}_+^m$, in a manner to be made precise in Section II. In that section, we also specify the temporal mechanism through the event counting process $\{D(t) = (D_1(t), \dots, D_m(t))\}_{t=0}^\infty$ where $D_\alpha(t)$ counts the number of occurrences of the event α up to time t . We are interested in structural properties of the event counting process $D^\mathcal{T}$ as a function of the constraint set \mathcal{T} . The main result that we obtain establishes sufficient conditions for $D^\mathcal{T}$ to be concave as a function of \mathcal{T} , in the following sense: If \mathcal{T}^p , $0 \leq p \leq r$,

satisfy $\mathcal{T}^0 \supset \left[\sum_{p=1}^r q_p \mathcal{T}^p \right]$, where

$$\left[\sum_{p=1}^r q_p \mathcal{T}^p \right] := \left\{ \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] : \mathbf{x}^p \in \mathcal{T}^p, 1 \leq p \leq r \right\} \quad (1.1)$$

for some $q_p \geq 0$, $p = 1, \dots, r$, and $\sum_{p=1}^r q_p = 1$, then the corresponding event counting processes $D^p = D^{\mathcal{T}^p}$, $0 \leq p \leq r$, satisfy

$$D^0(t) \geq \sum_{p=1}^r q_p D^p(t), \quad \text{for all times } t \geq 0. \quad (1.2)$$

While this definition of concavity is not standard, it serves to ease the exposition.

The above structural result may be used to deduce the concavity or near-concavity of the throughput of certain queueing networks in various parameters such as the buffer configuration, initial job configuration, and blocking parameters. This has important implications for optimal design and control problems arising in such networks. In particular, it allows one to establish the convergence of various "local search" based optimization algorithms to the globally optimal solution. Further, when combined with other structural properties in specific queueing networks, it enables the identification of the optimal solution or the reduction of the search space for optimal allocations (see [4]–[11]). For example, consider the problem of selecting the optimal job population in a closed cycle of $M/M/1/k$ stations with communication blocking. For this problem, concavity (see [6]) along with a certain symmetry property (see [12]) implies that the throughput is maximized when the total job population is equal to half the total buffer capacity in this cycle (see [13] for some generalizations of this result). Example 5.4 in Section V-B of this paper provides another instance of how concavity may be combined with a symmetry property to solve for the optimal job configuration. For an application to optimal control, see [14, Example 6.3a], where a generalization of the dominance result (1.2) is used to extend a result on optimal routing due to Ephremides *et al.* [15].

In the next section, we develop the terminology and notation that we will require for the rest of the paper. We present a self-contained introduction to synchronous discrete-event systems (SDES), with an emphasis on treating these systems through a language/score space approach, as opposed to one that emphasizes the state evolution mechanism.

Our point of departure in Section III is a result due to Glasserman and Yao [16, Theorem 7.2], a generalization of which is presented here as Theorem 3.2. This theorem establishes that the dominance of the characteristic function of one SDES over the convex combination of the characteristic functions of a family of others implies a similar relationship among their event counting processes. The first general theoretical results in this paper are Theorem 3.3 and Lemma 3.5, which establish that dominance of one characteristic function over a convex combination of others is equivalent to a similar relation among the constraint sets of the SDES, and hence the latter too implies the dominance of one event counting process over a convex combination of others. The chief merit of this theorem is that the dominance condition for constraint sets (1.1) is much easier to verify than the dominance condition for characteristic functions.

Theorems 3.2 and 3.3 require unnecessarily strong conditions on the score space for the desired properties between event counting processes to hold. We redress this by introducing the notion of coequality in Section IV. Theorem 4.1 uses coequality to give a weaker set of conditions on the score spaces, that are still sufficient to establish the concavity of the event counting processes.

Section V-A introduces the class of min-linearly constrained SDES that model a wide variety of queueing networks. Such systems correspond to forward conflict-free Petri nets, i.e., Petri nets in which each place is followed by at most one transition (see [17]). We apply Theorem 3.3 to show the near-concavity of the event counting processes as a function of the parameter sets that define these systems (Theorem 5.3). In Section V-B we extend the class of min-linearly constrained SDES to that of generalized min-linearly constrained SDES. Such systems arise from Petri nets (not necessarily forward conflict-free) where conflict resolution is managed by a switching mechanism (see [18]). Subsequently, we generalize Theorem 5.3 to obtain near-concavity in both the parameter sets and the switching mechanism. Many existing results on the concavity of the throughput of queueing networks in various network parameters, such as the configurations of buffers and jobs, fall within the framework of min-linearly constrained SDES. In particular, these include cyclic, tandem, and fork-join networks of queues with general blocking and starvation. In addition, the min-linearly constrained SDES framework also allows us to obtain similar results for a much wider class of queueing networks which involve splitting and merging of traffic streams. We also present several examples that illustrate the scope of these models and of the earlier theoretical results.

II. THE SET UP

In this section we describe the logical and temporal aspects of SDES. The first part of this section develops the terminology of languages and score spaces, while the second defines the associated event counting process and sequences of event occurrence times. The setup as described in this section is essentially the same as that of Glasserman and Yao [16], with the difference that we focus directly on languages rather than on an underlying state evolution mechanism such as generalized semi-Markov schemes.

A. Languages and Score Spaces

The logical aspect of a discrete-event system $\Delta(\mathcal{L})$ is described by its language \mathcal{L} which is the set of all feasible sequences of events. The alphabet or event set $\mathcal{A} := \{1, 2, \dots, m\}$ is the list of all possible events that can occur in the discrete-event system Δ . A string σ of events from \mathcal{A} is given by $\sigma = \alpha_1 \cdots \alpha_n$, $\alpha_k \in \mathcal{A}$, $1 \leq k \leq n$, $n \geq 0$. When $n = 0$, we have the null string which we denote by ϕ . The universal language \mathcal{A}^* is the collection all possible strings from \mathcal{A} , i.e., $\mathcal{A}^* := \{\sigma = \alpha_1 \alpha_2 \cdots \alpha_n : \alpha_k \in \mathcal{A}, 1 \leq k \leq n, n \geq 0\}$. Any subset $\mathcal{L} \subset \mathcal{A}^*$, with $\phi \in \mathcal{L}$, is called a language. Given two string $\sigma, \rho \in \mathcal{A}^*$, we say that ρ is a prefix of σ , denoted by $\sigma \geq \rho$, if there is another string μ such that $\sigma = \rho\mu$ (μ concatenated to ρ). The score of a string σ , denoted by $[\sigma]$, is the vector $\mathbf{x} \in \mathbb{Z}_+^m$ whose i th component x_i counts the number of occurrences of i in σ , $1 \leq i \leq m$. The event $i \in \mathcal{A}$ is enabled for the string $\sigma \in \mathcal{L}$, iff $\sigma i \in \mathcal{L}$, i.e., the event i can occur after the string σ has occurred. Let the event list for the string $\sigma \in \mathcal{L}$, $\mathcal{E}(\sigma)$, be the set of events enabled for the string σ .

Definition 2.1: A language \mathcal{L} is said to be

- 1) prefix-closed iff $\sigma \in \mathcal{L}, \rho \leq \sigma \Rightarrow \rho \in \mathcal{L}$.
- 2) permutable iff $\sigma, \rho \in \mathcal{L}, [\sigma] = [\rho] \Rightarrow \mathcal{E}(\sigma) = \mathcal{E}(\rho)$.
- 3) noninterruptive iff $\alpha \in \mathcal{E}(\sigma), \sigma\mu \in \mathcal{L}, [\mu]_\alpha = 0 \Rightarrow \alpha \in \mathcal{E}(\sigma\mu)$. (Here, $[\mu]_\alpha$ denotes the α th component of $[\mu]$.)
- 4) an antimatroid with repetition iff it is prefix-closed, permutable, and noninterruptive.

Let Λ denote the set of all antimatroids with repetition, i.e., $\Lambda := \{\mathcal{L} \subset \mathcal{A}^* : \mathcal{L} \text{ is prefix-closed, permutable, and noninterruptive}\}$ (see [19] or [16]).

The subset $\mathcal{S}(\mathcal{L})$ of \mathbb{Z}_+^m given by $\mathcal{S} = \{[\sigma] : \sigma \in \mathcal{L}\}$ is called the score space of \mathcal{L} . As $\phi \in \mathcal{L}$, we always have $\mathbf{0} \in \mathcal{S}(\mathcal{L})$. Given any subset \mathcal{T} of \mathbb{Z}_+^m , with $\mathbf{0} \in \mathcal{T}$, we can recursively define a language $\mathcal{M}(\mathcal{T})$, as follows:

- $\phi \in \mathcal{M}$.
- $\sigma \in \mathcal{M}$ and $[\sigma] + \mathbf{e}^\alpha \in \mathcal{T} \Rightarrow \sigma\alpha \in \mathcal{M}$.

Here, \mathbf{e}^α is the unit vector in the α th direction. \mathcal{T} is called the constraint set for the language $\mathcal{M}(\mathcal{T})$. This is equivalent to saying that a string σ belongs to \mathcal{M} , iff the scores of all its prefixes lie in \mathcal{T} .

Definition 2.2: A subset \mathcal{T} of \mathbb{Z}_+^m is said to be

- 1) *max-closed* iff $\mathbf{x}, \mathbf{y} \in \mathcal{T}$ and $\mathbf{z} = \mathbf{x} \vee \mathbf{y} := (x_1 \vee y_1, \dots, x_m \vee y_m)$ then $\mathbf{z} \in \mathcal{T}$.
- 2) *accessible* iff for each $\mathbf{x} \in \mathcal{T}$, $\mathbf{x} \neq \mathbf{0}$, there is some $i = i(\mathbf{x})$, $1 \leq i \leq m$, such that $(\mathbf{x} - \mathbf{e}^i) \in \mathcal{T}$.

Let $\Theta := \{\mathcal{T} \subset \mathbb{Z}_+^m : \mathcal{T} \text{ is accessible and max-closed}\}$.

Given a set $\mathcal{T} \subset \mathbb{Z}_+^m$, we can construct a language $\mathcal{M}(\mathcal{T}) \subset \mathcal{A}^*$, and its score space $\mathcal{S}(\mathcal{M}(\mathcal{T})) \subset \mathbb{Z}_+^m$. Similarly, starting with a language $\mathcal{L} \subset \mathcal{A}^*$ we can construct the score space $\mathcal{S}(\mathcal{L}) \subset \mathbb{Z}_+^m$, and from that another language $\mathcal{M}(\mathcal{S}(\mathcal{L})) \subset \mathcal{A}^*$. Next, we examine the relationship between the various sets and languages constructed through the above operations.

Lemma 2.3: 1) If $\mathcal{T} \in \Theta$, then $\mathcal{M}(\mathcal{T}) \in \Lambda$ and $\mathcal{S}(\mathcal{M}(\mathcal{T})) = \mathcal{T}$.

2) If $\mathcal{L} \in \Lambda$, then $\mathcal{S}(\mathcal{L}) \in \Theta$ and $\mathcal{M}(\mathcal{S}(\mathcal{L})) = \mathcal{L}$.

Thus, there is a one to one correspondence between Θ and Λ .

Proof: 1) That $\mathcal{M}(\mathcal{T})$ is prefix-closed and permutable follows from its construction. Its noninterruptiveness can be easily deduced from the max-closure of \mathcal{T} . Again, by construction, $\mathcal{S}(\mathcal{M}(\mathcal{T})) \subset \mathcal{T}$. Conversely, observe that for any point $\mathbf{x} \in \mathcal{T}$ that is accessible from the origin, there is at least one string $\sigma \in \mathcal{M}(\mathcal{T})$ such that $[\sigma] = \mathbf{x}$. Therefore $\mathcal{S}(\mathcal{M}(\mathcal{T})) \supset \mathcal{T}$. 2) As \mathcal{L} is prefix-closed, $\mathcal{S}(\mathcal{L})$ is accessible. The max-closure of $\mathcal{S}(\mathcal{L})$ follows from the permutability and noninterruptiveness of \mathcal{L} , as shown in [16, Section 2.3]. Alternatively, let $\mathbf{x} \in \mathbb{Z}_+^m$ be a minimal vector and $\sigma, \nu \in \mathcal{L}$ be two minimal strings, such that $\mathbf{x} = [\sigma] \vee [\nu]$, but there exists no string μ such that $\sigma\mu \in \mathcal{L}$ and $\mathbf{x} = [\sigma\mu]$. Without loss of generality (WLOG), assume that $\sigma = \alpha_1 \cdots \alpha_p \neq \phi$. Note that the minimality of σ forces

$$> [\nu]. \quad (2.1)$$

Let $\sigma' := \alpha_1 \cdots \alpha_{p-1}$. By the minimality of \mathbf{x} there exists a string μ' such that $\sigma'\mu' \in \mathcal{L}$ and $[\sigma'\mu'] = [\sigma'] \vee [\nu] = \mathbf{x} - \mathbf{e}^{\alpha_p}$. Note that (2.1) implies that $[\mu']_{\alpha_p} = 0$. By the noninterruptiveness of \mathcal{L} , $\sigma'\alpha_p \in \mathcal{L} \Rightarrow \sigma'\mu'\alpha_p \in \mathcal{L}$. Next, compare σ and $\sigma'\mu'$, and apply (2.1) and noninterruptiveness to deduce that $\sigma\mu' = \sigma'\alpha_p\mu' \in \mathcal{L}$. Finally, conclude that $[\sigma\mu'] = \mathbf{x}$, which contradicts the earlier assumption. Consequently, $\mathcal{S}(\mathcal{L})$ is max-closed.

Observe that as $\mathcal{L} \in \Lambda$, a string $\sigma \in \mathcal{L}$ iff the score of all its prefixes lie in $\mathcal{S}(\mathcal{L})$. It is easy to verify this of $\mathcal{M}(\mathcal{S}(\mathcal{L}))$ too, from its construction. Hence $\mathcal{L} = \mathcal{M}(\mathcal{S}(\mathcal{L}))$. \square

Remark 2.4: In fact, we can find a set Λ' of prefix-closed and permutable languages satisfying a weaker condition than noninterruption such that there is a one-to-one correspondence between this set and the set Θ' of all accessible subsets of \mathbb{Z}_+^m . We shall not examine this more general relation further, as the main concavity results hold only for the classes Λ and Θ .

Lemma 2.5: For any $\mathcal{T} \subset \mathbb{Z}_+^m$, let \mathcal{S} be its maximal accessible subset. Then,

1) $\mathcal{M}(\mathcal{T}) = \mathcal{M}(\mathcal{S})$, and consequently $\mathcal{S}(\mathcal{M}(\mathcal{T})) = \mathcal{S}(\mathcal{M}(\mathcal{S})) = \mathcal{S}$.

2) If \mathcal{T} is max-closed then so is \mathcal{S} .

Proof: Assume WLOG that $\mathbf{0} \in \mathcal{T}$, as \mathcal{S} is empty otherwise. 1) $\mathcal{S} \subset \mathcal{T}$ implies that $\mathcal{M}(\mathcal{S}) \subset \mathcal{M}(\mathcal{T})$. By construction, the scores of all prefixes of any string in $\mathcal{M}(\mathcal{T})$ lie in \mathcal{S} . Consequently, $\mathcal{M}(\mathcal{S}) \supset \mathcal{M}(\mathcal{T})$. 2) Let $\mathcal{U} = \{\mathbf{x} \in \mathbb{Z}_+^m : \mathbf{x} = \mathbf{y} \vee \mathbf{z}; \mathbf{y}, \mathbf{z} \in \mathcal{S}, \mathbf{x} \notin \mathcal{S}\}$. Let \mathbf{u} be some minimal element¹ of \mathcal{U} . Let (\mathbf{v}, \mathbf{w}) be a minimal ordered pair such that $\mathbf{v}, \mathbf{w} \in \mathcal{S}$ and $\mathbf{u} = \mathbf{v} \vee \mathbf{w}$. Automatically, $\mathbf{u} \in \mathcal{T}$. By the accessibility of \mathcal{S} , there is some i , $1 \leq i \leq m$, such that $\hat{\mathbf{v}} = \mathbf{v} - \mathbf{e}^i \in \mathcal{S}$. By the minimality of (\mathbf{v}, \mathbf{w}) and \mathbf{u} , if we define $\hat{\mathbf{u}} := \hat{\mathbf{v}} \vee \mathbf{w}$, then $\hat{\mathbf{u}} = (\mathbf{u} - \mathbf{e}^i) \in \mathcal{S}$. This implies that \mathbf{u} is in the maximal accessible component \mathcal{S} , a contradiction that establishes that \mathcal{U} is empty. \square

Assumption 2.6: In this paper, we shall focus exclusively on DES $\Delta(\mathcal{L})$ whose language \mathcal{L} is generated from a max-closed constraint set $\mathcal{T} \subset \mathbb{Z}_+^m$, i.e., $\mathcal{L} = \mathcal{M}(\mathcal{T})$. In view of Lemmas 2.3 and 2.5, it follows that $\mathcal{L} \in \Lambda$ and that $\mathcal{S}(\mathcal{L})$ is the maximal accessible subset of \mathcal{T} .

B. Synchronous Discrete-Event Systems

A SDES, $\Delta(\mathcal{L})$, specified by a language \mathcal{L} , is a mapping that takes a sequence of clock times $\omega = (\{\omega_j^i\}_{j=1}^\infty)_{i=1}^m$ to an event counting process $\{D(t, \omega) = (D_1(t, \omega), \dots, D_m(t, \omega)) : t \geq 0\}$. We sometimes suppress dependence on ω for ease of notation. The precise mechanism by which D can be obtained from ω is described below. First, let $\{D_i^*(t) : t \geq 0\}$ be the master counting process for event i , defined by

$$T_i^*(t) := \sum_{k=1}^{\infty} \omega_i^k, \quad n \geq 0, \\ D_i^*(t) := \max\{n \geq 0 : T_i^*(n) \leq t\}, \quad t \geq 0. \quad (2.2)$$

Take $t_0 = 0$. Let t_n be the n th jump time and α_n^* the corresponding event type (direction of jump) of the process $\{D^*(t) = (D_1^*(t), \dots, D_m^*(t)) : t \geq 0\}$. Call $\sigma^{*,n} = \alpha_1^* \alpha_2^* \cdots \alpha_n^*$ the master string at time t_n induced by ω . The string $\sigma^n \in \mathcal{L}$, defined inductively below, is said to be the realized string in the SDES Δ at t_n , $n = 0, 1, \dots$

$$\sigma^0 = \phi \\ \sigma^{n+1} = \begin{cases} \sigma^n, & \text{if } \alpha_{n+1}^* \notin \mathcal{E}(\sigma^n), \\ \sigma^n \alpha_{n+1}^*, & \text{if } \alpha_{n+1}^* \in \mathcal{E}(\sigma^n). \end{cases}$$

The event counting process $D(t)$ is given by

$$D(t) = [\sigma^n] \quad \text{for } t_n \leq t < t_{n+1}.$$

Note that if $\mathcal{L} = \mathcal{A}^*$, then $\sigma^n = \sigma^{*,n}$ and $D(t) = D^*(t)$. The synchronization mechanism described here for obtaining the process $\{D(t) : t \geq 0\}$ is identical to the one described by Glasserman and Yao in [16].

Let $\{\Delta^p = \Delta(\mathcal{L}^p) : p = 0, 1, \dots, r\}$, $r \geq 1$, be a family of SDES defined on a common alphabet \mathcal{A} . Let M^r be the unit simplex in \mathbb{R}^r , i.e.,

$$M^r := \{(q_1, \dots, q_r) \in \mathbb{R}^r : \sum_{p=1}^r q_p = 1, q_p > 0, p = 1, \dots, r\}. \quad (2.3)$$

Let $\mathbf{q} \in M^r$. In this paper, we investigate sufficient conditions for the event counting process of one system to dominate the \mathbf{q} -convex combination of the event counting processes of several others, i.e., for the relation

$$D^0(t, \omega) \geq \sum_{p=1}^r q_p D^p(t, \omega), \quad \forall \text{ clock sequences } \omega, \\ \text{and times } t \geq 0 \quad (2.4)$$

to hold, in terms of conditions on the corresponding score spaces, $\{\mathcal{S}^p = \mathcal{S}(\mathcal{L}^p) : p = 0, 1, \dots, r\}$.

III. SCORE SPACE CONCAVITY

Our point of departure is a result by Glasserman and Yao [16] which establishes that if the characteristic function (defined below) of one system dominates the ‘‘average’’ of the characteristic functions of two other systems, then the event counting processes of the corresponding systems satisfy the same relation (2.4). Below, we restate a generalized version

¹ All operators on ordered tuples are taken componentwise.

of their theorem. Even though the proof in [16] continues to hold for the following theorem with only minor modifications, we reproduce it here for the sake of completeness.

Definition 3.1: Given a language $\mathcal{L} \in \Lambda$, define its characteristic function $\chi = (\chi_1, \dots, \chi_m) : \mathcal{S}(\mathcal{L}) \rightarrow \mathbb{Z}_+^m$ by $\chi_i(\mathbf{x}) = x_i + 1_{\{i \in \mathcal{E}(\mathbf{x})\}}$, $1 \leq i \leq m$, where 1_A is the indicator function of the set A . Note that if \mathcal{L} has been derived from a set $\mathcal{T} \subset \mathbb{Z}_+^m$, then $\chi(\mathbf{x}) = \max\{\mathbf{x} + \mathbf{e}^p \in \mathcal{T} : 1 \leq p \leq m\}$, where the maximum is taken componentwise, as usual.

Theorem 3.2: Let $\{\Delta^p : 0 \leq p \leq r\}$, be a family of SDES with corresponding score spaces $\{S^p : 0 \leq p \leq r\}$, characteristic functions $\{\chi^p : 0 \leq p \leq r\}$, and event counting processes $\{D^p : 0 \leq p \leq r\}$. Let $\mathbf{q} \in M^r$ be such that

$$\begin{aligned} \mathbf{x}^0 &\geq \sum_{p=1}^r q_p \mathbf{x}^p, \mathbf{x}^p \in S^p, p = 0, 1, \dots, r \\ &\Rightarrow \chi^0(\mathbf{x}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p). \end{aligned} \quad (3.1)$$

Then

$$D^0(t, \omega) \geq \sum_{p=1}^r q_p D^p(t, \omega) \quad \forall \text{ clock sequences } \omega, \text{ and times } t \geq 0. \quad (3.2)$$

Proof: The proof is by an induction on the successive jump times $\{t_n\}_{n=1}^\infty$ of the master counting process $\{D^*(t) : t \geq 0\}$ (see discussion around (2.2) for notation used in this proof). The induction hypothesis is that (3.2) holds for t_j , $0 \leq j \leq k$. This is trivially true for $k = 0$. Next, let $l := \alpha_k^*$ be the event that occurs in the master counting process at t_{k+1} . Note that

$$D_i^p(t_{k+1}) = \begin{cases} D_i^p(t_k), & \text{for } i \neq l, \\ \chi_i^p(D^p(t_k)) & \text{for } i = l. \end{cases}$$

In either event the induction step follows easily. \square

We now show that the dominance of one characteristic function over a convex combination of others is equivalent to a similar relationship among the corresponding score spaces as subsets of \mathbb{Z}_+^m . This makes the above result more transparent and easier to apply, as we shall show in Section V.

For any $\mathbf{q} \in M^r$ we denote

$$\sum_{p=1}^r q_p S^p := \left\{ \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] : \mathbf{x}^p \in S^p, \text{ for } 1 \leq p \leq r \right\}$$

where $\lceil \mathbf{x} \rceil$ denotes the ceiling function applied componentwise, for $\mathbf{x} \in \mathbb{R}_+^m$.

Theorem 3.3: Let $\{\Delta^p : 0 \leq p \leq r\}$, be a family of SDES with corresponding score spaces $\{S^p : 0 \leq p \leq r\}$ and characteristic functions $\{\chi^p : 0 \leq p \leq r\}$. Let $\mathbf{q} \in M^r$. Consider the following assertions:

- 1) $\left[\sum_{p=1}^r q_p S^p \right] \subset S^0$, i.e., $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $\mathbf{x}^p \in S^p, p = 1, \dots, r \Rightarrow \mathbf{x}^0 \in S^0$.
- 2) $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $\mathbf{x}^p \in S^p, p = 0, 1, \dots, r \Rightarrow \chi^0(\mathbf{x}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p)$.

$$3) \mathbf{y}^0 \geq \mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right], \mathbf{y}^0 \in S^0, \mathbf{x}^p \in S^p, p = 1, \dots, r \Rightarrow \chi^0(\mathbf{y}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p).$$

Then, (1) \Leftrightarrow (2) \Leftrightarrow (3).

Proof: (1) \Rightarrow (2) Fix i , $1 \leq i \leq m$. For $1 \leq p \leq r$, define $\dot{\mathbf{x}}^p \in \mathbb{Z}_+^m$ by

$$\dot{x}_j^p := \begin{cases} \chi_j^p(\mathbf{x}^p), & \text{if } j = i, \\ x_j^p, & \text{otherwise.} \end{cases}$$

Note that $\dot{\mathbf{x}}^p \in S^p$ for $1 \leq p \leq r$, by definition of the characteristic function. Next by Assertion (1), $\mathbf{x}^0 \in S^0$ and

$$\dot{\mathbf{x}}^0 := \left[\sum_{p=1}^r q_p \dot{\mathbf{x}}^p \right] \in S^0.$$

Clearly, $\mathbf{x}^0 \leq \dot{\mathbf{x}}^0 \leq \mathbf{x}^0 + \mathbf{e}^i$. From the definition of the characteristic function, $\chi^0(\mathbf{x}^0) \geq \dot{x}_i^0$. Therefore

$$(\chi_i^0(\mathbf{x}^0)) \geq \dot{x}_i^0 = \left[\sum_{p=1}^r q_p \chi_i^p(\mathbf{x}^p) \right]. \quad 1 \leq i \leq m.$$

Since i was arbitrary, it follows that $\chi^0(\mathbf{x}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p)$, and consequently Assertion (2) holds.

(2) \Rightarrow (1) Assume that $\left[\sum_{p=1}^r q_p S^p \right] \setminus S^0$ is nonempty and let \mathbf{x} be some minimal element of this set. Let $(\sigma^1, \sigma^2, \dots, \sigma^r) \in \mathcal{L}^1 \times \mathcal{L}^2 \times \dots \times \mathcal{L}^r$ be a minimal ordered r -tuple of strings (in the prefix-ordering taken componentwise), such that

$$\mathbf{x} = \left[\sum_{p=1}^r q_p [\sigma^p] \right].$$

Let us write σ^p as $i_1^p i_2^p \dots i_{s_p}^p$, where $i_j^p \in \mathcal{A}$, $1 \leq j \leq s_p$, $1 \leq p \leq r$. We allow $s_p = 0$ if $\sigma^p = \phi$. As $0 \in S^0$, WLOG, we may take $q_1 > 0$, $s_1 \geq 1$ and $i_1^1 = 1$. Define $\rho^1 = i_1^1 i_2^1 \dots i_{s_1-1}^1$, and let

$$\mathbf{y} := \left[(q_1 [\rho^1]) + \sum_{p=2}^{r-1} q_p [\sigma^p] \right].$$

By minimality of \mathbf{x} and $(\sigma^1, \sigma^2, \dots, \sigma^r)$, we have $\mathbf{y} = \mathbf{x} - \mathbf{e}^1$ and $\mathbf{y} \in S^0$. Since $\mathbf{x} \notin S^0$, it follows that $\chi_1^0(\mathbf{y}) = y_1$. Moreover, $\chi_1^1([\rho^1]) = [\rho^1]_1 + 1 = [\sigma^1]_1$. From this we have

$$\begin{aligned} q_1 \chi_1^1([\rho^1]) + \sum_{p=2}^r q_p \chi_1^p([\sigma^p]) &\geq \sum_{p=1}^r q_p [\sigma^p]_1 \\ &= x_1 \\ &> y_1 \\ &= \chi_1^0(\mathbf{y}) \end{aligned}$$

which contradicts (2). Hence the result.

(1) & (2) \Rightarrow (3) This follows directly from the noninterruptiveness condition, which implies the monotonicity of the characteristic function, i.e.,

$$\mathbf{y}^0, \mathbf{x}^0 \in S^0, \mathbf{y}^0 \geq \mathbf{x}^0 \Rightarrow \chi^0(\mathbf{y}^0) \geq \chi^0(\mathbf{x}^0).$$

(See [16, Theorem 2.3] for more details).

(3) \Rightarrow (2) Obvious. \square

In light of Theorem 3.2, any of the above equivalent conditions implies (3.2).

Remark 3.4: Letting $r = 1$ in Theorem 3.3, we see that the event counting processes of SDES are monotone as functions of the score spaces. This result is the monotonicity of the event counting processes across schemes proved by Glasserman and Yao for synchronized GSMS [20, Theorem 6.4]. For the case of $r \geq 2$, the above theorem provides a score space concavity result analogous to the score space monotonicity result.

In the lemma below we show that it suffices to check Assertion 1 of the above theorem, with the constraint set \mathcal{T}^p instead of the score space S^p , where $\mathcal{T}^p \subset \mathbb{Z}_+^m$ generates the SDES Δ^p .

Lemma 3.5: Let $\{\mathcal{T}^p : 0 \leq p \leq r\}$ be subsets of \mathbb{Z}_+^m and let $\{S^p : 0 \leq p \leq r\}$ be their corresponding maximal accessible subsets. Then

$$\mathcal{T}^0 \supset \left[\sum_{p=1}^r q_p \mathcal{T}^p \right] \Rightarrow S^0 \supset \left[\sum_{p=1}^r q_p S^p \right].$$

Proof: Assume that $\mathbf{x}^p \in S^p$, $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] \in \mathcal{T}^0 \setminus S^0$, $1 \leq p \leq r$, and that $(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r)$ are a componentwise minimal tuple satisfying this. Without loss of generality, assume that $\mathbf{x}^1 - \mathbf{e}^1 \in S^1$. Let $\mathbf{y}^0 := \left[q_1(\mathbf{x}^1 - \mathbf{e}^1) + \sum_{p=2}^r q_p \mathbf{x}^p \right]$. By the minimality of $(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r)$, $\mathbf{y}^0 = \mathbf{x}^0 - \mathbf{e}^1 \in S^0$. By accessibility, $\mathbf{x}^0 \in S^0$, which contradicts our earlier assumption. Hence the result. \square

IV. COEVALITY

Theorems 3.2 and 3.3 require unnecessarily strong conditions on the score space to obtain the dominance of one event counting process over the convex combination of several others. There, we require (3.1) of Theorem 3.2 to hold for all choices of $\{\mathbf{x}^p \in S^p : 0 \leq p \leq r\}$. Note, however, that we really need to verify that condition only for those $\{\mathbf{x}^p \in S^p : 0 \leq p \leq r\}$ that can occur simultaneously. In this section we introduce the notion of coeuality to exploit this basic idea and to obtain weaker conditions for one event counting process to dominate a convex combination of others.

Let $\{\Delta^p : 0 \leq p \leq r\}$ be a family of SDES. We say that $(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r)$ is coeval, iff there exists a clock sequence ω and a time $t \geq 0$, such that the string σ^p realized in Δ^p at time t has score $[\sigma^p] = \mathbf{x}^p$ (See Section II-B). Then, σ^* , the master string at time t , is called an enabling string of $(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r)$. Let

$$S^{0,1,\dots,r} := \{(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r) \in S^0 \times S^1 \times \dots \times S^r : (\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r) \text{ is coeval}\}$$

and let

$$S^{1,2,\dots,r} := \{(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^1 \times \dots \times S^r : (\mathbf{x}^1, \dots, \mathbf{x}^r) \text{ is coeval}\}.$$

Theorem 4.1: Let $\{\Delta^p : 0 \leq p \leq r\}$ be a family of SDES with corresponding score spaces $\{S^p : 0 \leq p \leq r\}$ and characteristic functions $\{\chi^p : 0 \leq p \leq r\}$. Let $q \in \mathbb{Q}$. Consider the following assertions:

- 1) $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{1,2,\dots,r}$, $\mathbf{x}^0 \in S^0$.
- 2) $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $\mathbf{x}^0 \in S^0$, $(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{1,2,\dots,r} \Rightarrow \chi^0(\mathbf{x}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p)$.
- 3) $\mathbf{y}^0 \geq \mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $\mathbf{y}^0 \in S^0$, $(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{1,2,\dots,r} \Rightarrow \chi^0(\mathbf{y}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p)$.
- 4) $(\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{0,1,2,\dots,r} \Rightarrow \mathbf{x}^0 \geq \sum_{p=1}^r q_p \mathbf{x}^p$.

Then, (1) \Leftrightarrow (2) \Leftrightarrow (3) \Rightarrow (4).

Proof: (1) \Rightarrow (2) Let $(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{1,2,\dots,r}$. By Assertion (1), $\mathbf{x}^0 := \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] \in S^0$. Fix i , $1 \leq i \leq m$. For $1 \leq p \leq r$, define $\hat{\mathbf{x}}^p$ by

$$\hat{x}_j^p := \begin{cases} x_j^p(\mathbf{x}^p), & \text{if } j = i, \\ x_j^p & \text{otherwise.} \end{cases}$$

By the definition of the characteristic functions, it is easy to see that $(\hat{\mathbf{x}}^1, \dots, \hat{\mathbf{x}}^r) \in S^{1,2,\dots,r}$. Therefore by Assertion (1)

$$\hat{\mathbf{x}}^0 := \left[\sum_{p=1}^r q_p \hat{\mathbf{x}}^p \right] \in S^0. \quad (4.1)$$

Clearly, $\mathbf{x}^0 \leq \hat{\mathbf{x}}^0 \leq \mathbf{x}^0 + \mathbf{e}^i$. Again, from the definition of the characteristic function $\chi^0(\mathbf{x}^0) \geq \chi^0(\hat{\mathbf{x}}^0)$, which implies that

$$\chi_i^0(\mathbf{x}^0) \geq \hat{x}_i^0 = \left[\sum_{p=1}^r q_p \chi_i^p(\mathbf{x}^p) \right]. \quad (4.2)$$

Since i was arbitrary, it follows that $\chi^0(\mathbf{x}^0) \geq \sum_{p=1}^r q_p \chi^p(\mathbf{x}^p)$, and consequently Assertion (2) holds.

(2) \Rightarrow (1) Let $\mathcal{U} = \{(\mathbf{x}^1, \dots, \mathbf{x}^r) \in S^{1,2,\dots,r} : \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] \notin S^0\}$ be nonempty, and let $(\mathbf{x}^1, \dots, \mathbf{x}^r)$ be some (componentwise) minimal element of \mathcal{U} , and $\sigma^{*,s} = \alpha_1^* \alpha_2^* \dots \alpha_s^*$ be some (prefixwise) minimal enabling string of $(\mathbf{x}^1, \dots, \mathbf{x}^r)$. Let $\sigma^{*,s-1} = \alpha_1^* \alpha_2^* \dots \alpha_{s-1}^*$ be the enabling string of $(\hat{\mathbf{x}}^1, \dots, \hat{\mathbf{x}}^r)$, for $\hat{\mathbf{x}}^p \in S^p$.

First, note that $(\hat{\mathbf{x}}^1, \dots, \hat{\mathbf{x}}^r) \in S^{1,2,\dots,r}$, and $\chi_{\alpha_s^*}^p(\hat{\mathbf{x}}^p) = x_{\alpha_s^*}^p$, for all p . Further, the minimality of $(\mathbf{x}^1, \dots, \mathbf{x}^r) \in \mathcal{U}$ and $\sigma^{*,s}$ implies that

$$\hat{\mathbf{x}}^0 := \left[\sum_{p=1}^r q_p \hat{\mathbf{x}}^p \right] = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right] - \mathbf{e}^{\alpha_s^*} \quad (4.3)$$

and that $\hat{\mathbf{x}}^0 \in S^0$. Using the fact that $\hat{\mathbf{x}}^0 + \mathbf{e}^{\alpha_s^*} \notin S^0$ we conclude that

$$\begin{aligned} \chi_{\alpha_s^*}^0(\hat{\mathbf{x}}^0) &= \hat{x}_{\alpha_s^*}^0 \\ &< \left[\sum_{p=1}^r q_p x_{\alpha_s^*}^p \right] \quad \text{by (4.3)} \\ &= \left[\sum_{p=1}^r q_p \chi_{\alpha_s^*}^p(\mathbf{x}^p) \right] \end{aligned}$$

which contradicts Assertion (2). Therefore \mathcal{U} is empty and Assertion (1) holds.

(1)&(2) \Rightarrow (3) This follows directly from the noninterruptiveness condition.

(3) \Rightarrow (2) Obvious.

(3) \Rightarrow (4) Assertion (4) is a restatement of (3.2) of Theorem 3.2. The proof is very similar to that of Theorem 3.2. \square

The simplest situation in which coequality proves itself strictly more general than the score space result (Theorem 3.3) is when the DES Δ has a nonconvex score-space, \mathcal{S} , i.e., when the ceiling of a convex combination of scores from \mathcal{S} falls outside \mathcal{S} . This happens, for example, when $\mathcal{S} = \{x \in \mathbb{Z}_+^2 : x_2 \leq \frac{1}{2}x_1\}$. Then, $x = (0, 0)$, $y = (2, 1) \in \mathcal{S}$, but $z = \lceil (x + y)/2 \rceil = (1, 1) \notin \mathcal{S}$. Since $\mathcal{S} \not\supseteq (\mathcal{S} + \mathcal{S})/2$, it is not possible to use the score space result to prove the obvious result that $D(t) \geq \frac{1}{2}(D(t) + D(t))$. But in this case, the coeval sets are easy to characterize, and therefore we can show from Theorem 4.1 that relation (3.2) holds among the event counting processes.

It is not usually necessary to explicitly characterize coeval sets across different systems. Often, Theorem 3.3 is inapplicable because of the existence of tuples (x^1, \dots, x^r) , $x^p \in S^p$, $p = 1, \dots, r$, whose convex combination falls outside S^0 . If it can be shown that these tuples are noncoeval, then Theorem 4.1 can be used to prove that one event counting process dominates the convex combination of others.

V. APPLICATIONS TO CONSTRAINED SDES

In Section II, we explained how SDES may be generated from constraint sets $\mathcal{T} \subset \mathbb{Z}_+^m$. Typically, the constraint sets that we shall examine will have the form

$$\mathcal{T} = \{x \in \mathbb{Z}_+^m : x \leq f(x)\}$$

for some increasing constraint function, $f : \mathbb{Z}_+^m \rightarrow \mathbb{Z}_+^m$. Such constrained SDES arise naturally in many queueing networks, as may be seen from the examples to follow. In Section V-A, we introduce min-linearly constrained SDES and show that the structure of the event counting process of such systems relates naturally to the structure of their constraining family of functions. Subsequently, in Section V-B, we extend this to generalized min-linearly constrained SDES.

A. Min-Linearly Constrained SDES

Let

$$A := \{a_{ijk} : 1 \leq i, j \leq m, 1 \leq k \leq n\},$$

$$B := \{b_{jk} : 1 \leq j \leq m, 1 \leq k \leq n\}$$

be two parameter sets of nonnegative real numbers. Consider the set $\mathcal{T} \subset \mathbb{Z}_+^m$ defined by a min-linear constraint function based on the above parameter sets

$$\mathcal{T}(A, B) = \left\{ x \in \mathbb{Z}_+^m : x_j \leq \min_{1 \leq k \leq n} \left\{ \sum_{i=1}^m a_{ijk} x_i + b_{jk} \right\}, \quad 1 \leq j \leq m \right\}. \quad (5.1)$$

Fig. 1. Portion of a forward conflict-free Petri-net

It is easy to see that $0 \in \mathcal{T}$ and that \mathcal{T} is max-closed. Consequently, by Lemmas 2.3 and 2.5, its maximal accessible component $\mathcal{S}(A, B)$ can be used to define a prefix-closed, permutable and noninterruptive language $\mathcal{L}(A, B)$. The SDES $\Delta(A, B)$ defined by $\mathcal{L}(A, B)$ is said to be min-linearly constrained.

Remark 5.1: When $n = m$, $a_{ijk} = 1$ if $j \neq i = k$, $1 \leq i, j, k \leq m$, and $a_{ijk} = 0$ otherwise, the set $\mathcal{T} \subset \mathbb{Z}_+^m$ is given by

$$\mathcal{T}(A, B) = \left\{ x \in \mathbb{Z}_+^m : x_j \leq x_k + b_{jk}, 1 \leq j, k \leq m, j \neq k \right\}. \quad (5.2)$$

This corresponds to the class of all conflict-free Petri nets² (also called decision-free), i.e., Petri nets where each place is preceded and followed by exactly one transition. Baccelli and Liu [2] have shown the concavity of the throughput of such Petri nets in the initial marking. Several important classes of networks for which concavity results are already known, such as tandems and cycles of queues with general blocking and starvation [21], [13], and fork-join networks [21], are special cases of the above. In such networks, the constraint in (5.2) can be interpreted as restricting the number of jobs processed by server j from exceeding the number of jobs processed by any other server k , by more than a fixed quantity b_{jk} .

The class of min-linearly constrained SDES includes the much larger class of structurally forward conflict-free Petri nets, i.e., Petri nets with at most one transition following each place, but with no restrictions on the number of transitions that may precede a place (see [17]). Thus, in such a Petri-net, a place preceding a transition j cannot precede another transition $i \neq j$. WLOG, we assume that exactly n places precede each transition j , and denote each such place by the pair (j, k) , $k = 1, \dots, n$, where $j = 1, \dots, m$ are the possible transitions. Let there be m_{jk} tokens present initially in place (j, k) . We assume that the firing of transition (occurrence of event) i deposits s_{ijk} tokens in place (j, k) , and that transition j requires r_{jk} tokens from the place (j, k) to fire. Thus, when the score is $x = (x_1, \dots, x_m)$, i.e., transition i has fired x_i times, $i = 1, \dots, m$, then the transition j is enabled iff

$$(x_j + 1) \leq \min_{1 \leq k \leq n} \left\{ \left[\sum_{i=1}^m s_{ijk} x_i + m_{jk} \right] / r_{jk} \right\}.$$

It is easy to see that the constraint set of this system is precisely $\mathcal{T}(A, B)$ given by (5.1) with $a_{ijk} = s_{ijk}/r_{jk}$ and $b_{jk} = m_{jk}/r_{jk}$.

²Petri nets are a special class of discrete-event systems, with transitions in Petri nets corresponding to events in SDES.

In the next theorem, we apply Theorem 3.3 to investigate the effect of varying the parameter set B (with a fixed A) on the event counting process D of the min-linearly constrained SDES $\Delta(A, B)$. For this we need to define the slack $s(q)$ associated with any $q \in M'$ as

$$s(q) = \sup \left\{ \left[\sum_{p=1}^r q_p t^p \right] - \sum_{p=1}^r q_p t^p \mid t^p \in \mathbb{Z}_+, p=1, \dots, r \right\} \quad (5.3)$$

In the following theorem we give an explicit formula for the slack

Proposition 5.2 Let $q = (q_1, \dots, q_r) \in M'$

1) If q is rational, i.e., if $q_p = \frac{t_p}{\delta_p}$ where t_p and δ_p are co-prime integers for $p = 1, \dots, r$, then

$$s(q) = 1 - \frac{1}{\text{lcm}(\delta_1, \dots, \delta_r)}$$

Here, $\text{lcm}(\delta_1, \dots, \delta_r)$ denotes the least common multiple of $\delta_1, \dots, \delta_r$.

2) If q is irrational, i.e., q_l is irrational for some $p = 1, \dots, r$, then $s(q) = 1$.

Proof See Appendix \square

Theorem 5.3 Let $\{\Delta(A, B^p) \mid 0 \leq p \leq r\}$ be a family of min-linearly constrained SDES with corresponding score spaces $\{S^p \mid 0 \leq p \leq r\}$ and departure processes $\{D^p \mid 0 \leq p \leq r\}$. Let $q \in M'$ be such that for all $1 \leq j \leq m$, $1 \leq l \leq n$

$$b_{jk}^0 \geq \sum_{i=1}^r q_i b_{jk}^i + s(q) \quad (5.4)$$

Then $S^0 \supset \left[\sum_{i=1}^r q_i S^i \right]$ and consequently

$$D^0(t, \omega) \geq \sum_{i=1}^r q_i D^i(t, \omega) \quad \forall \text{ clock sequences } \omega \quad (5.5)$$

and times $t > 0$

In addition, if $\{a_{ijk} \mid 1 \leq i \leq m\}$ are all nonnegative integers for some (j, k) , $1 \leq j \leq m$, $1 \leq k \leq n$, then for those (j, k) (5.4) can be replaced by the weaker condition

$$b_{jk}^0 \geq \left[\sum_{i=1}^r q_i b_{jk}^i \right] \quad (5.6)$$

Proof In light of Theorem 3.3 and Lemma 3.5, it is enough to show that $T(A, B^0) \supset \left[\sum_{i=1}^r q_i T(A, B^i) \right]$. Let $y^p \in T(A, B^p)$, $p = 1, \dots, r$, and define $y^0 = \left[\sum_{i=1}^r q_i y^i \right]$. Then for any j , $1 \leq j \leq m$

$$\begin{aligned} y_j^0 &= \left[\sum_{p=1}^r q_p y_j^p \right] \\ &\leq \left[\sum_{p=1}^r q_p \min_{1 \leq k \leq n} \left[\sum_{i=1}^m a_{ijk} y_i^p + b_{jk}^p \right] \right] \\ &\leq \min_{1 \leq k \leq n} \left[\sum_{p=1}^r q_p \left[\sum_{i=1}^m a_{ijk} y_i^p + b_{jk}^p \right] \right] \quad (5.7) \end{aligned}$$

Fig. 2. Closed welding type join network.

Moreover, for any k , $1 \leq k \leq n$

$$\begin{aligned} \left[\sum_{i=1}^r q_i \left[\sum_{j=1}^m a_{ijk} y_j^i + b_{jk}^i \right] \right] &\leq \sum_{p=1}^r q_p \left[\sum_{j=1}^m a_{ijk} y_j^p + b_{jk}^p \right] + s(q) \\ &\leq \sum_{i=1}^m a_{ijk} \sum_{j=1}^r q_j y_j^i + \sum_{i=1}^m q_i b_{jk}^i + s(q) \\ &\leq \sum_{i=1}^m a_{ijk} y_i^0 + b_{jk}^0 \quad (\text{by 5.4}) \quad (5.8) \end{aligned}$$

Thus $y^0 \in T(A, B^0)$.

If $\{a_{ijk} \mid 1 \leq i \leq m\}$ are all nonnegative integers for some k , $1 \leq k \leq n$, then we have

$$\begin{aligned} \left[\sum_{i=1}^r q_i \left[\sum_{j=1}^m a_{ijk} y_j^i + b_{jk}^i \right] \right] &\leq \left[\sum_{i=1}^m a_{ijk} \sum_{j=1}^r q_j y_j^i + \sum_{i=1}^r q_i b_{jk}^i \right] \\ &\leq \sum_{i=1}^m a_{ijk} \left[\sum_{j=1}^r q_j y_j^i \right] + \left[\sum_{i=1}^r q_i b_{jk}^i \right] \\ &< \sum_{i=1}^m a_{ijk} y_i^0 + b_{jk}^0 \quad (\text{by 5.6}) \end{aligned}$$

In this case too $y^0 \in T(A, B^0)$ \square

Note that most of the concavity results obtained so far in the literature for specific SDES fall within the scope of Remark 5.1 and condition (5.6) of Theorem 5.3. We now present an example to illustrate how Theorem 5.3 can be used to obtain near concavity results for more complex systems.

Example 5.4 (Welding Station With Constant Work In Progress (WIP)) Consider the two-station cycle shown in Fig. 2. This models a production line with constant WIP where each pair of successive jobs that depart from station 1 is welded together at station 2. As soon as a job leaves station 2, two parts enter station 1 simultaneously. We assume that station i , $i = 1, 2$, has a buffer of size k_i with $0 \leq J \leq k_i$ jobs initially. Server i is blocked (communication blocking) if the buffer downstream is full. Let $D_i(t)$ denote the number of jobs that complete service at station i up to time t for $i = 1, 2$. Note that at any time t , $D_1(t)$ cannot exceed twice $D_2(t)$ by more than the number of jobs initially present at station 1 or the number of empty spaces initially present at station 2. Similarly, $D_2(t)$ cannot exceed one half $D_1(t)$ by more than the number of jobs initially present at station 2 or the number of empty spaces initially present at station 1. From this, we can see that the constraint set T that specifies the

SDES corresponding to this network is given by

$$\mathcal{T} = \left\{ \mathbf{x} \in \mathbb{Z}_+^2 : x_1 \leq 2x_2 + ((k_2 - J_2) \wedge J_1) \right. \\ \left. x_2 \leq \frac{1}{2}J_1 + \frac{1}{2}((k_1 - J_1) \wedge J_2) \right\}.$$

This is a min-linearly constrained SDES with appropriately defined parameter sets \mathbf{A} and \mathbf{B} .

Let $\{\Delta(\mathbf{A}, \mathbf{B}^p) : p = 0, 1, \dots, r\}$ be a synchronized family of such systems. Then the conditions (5.4)–(5.6) are satisfied with $\mathbf{q} \in M^r$, if

$$k_2^0 - J_2^0 \geq \left[\sum_{p=1}^r q_p (k_2^p - J_2^p) \right], \\ \frac{1}{2}(k_1^0 - J_1^0) \geq \sum_{p=1}^r q_p \frac{1}{2}(k_1^p - J_1^p) + s(\mathbf{q}), \\ J_1^0 \geq \left[\sum_{p=1}^r q_p J_1^p \right], \\ \frac{1}{2}J_2^0 \geq \sum_{p=1}^r q_p \frac{1}{2}J_2^p + s(\mathbf{q}).$$

We may deduce the near-concavity of the throughput jointly in the number of jobs and in the number of empty spaces.

Remark 5.5: The slack $s(\mathbf{q})$ obtained through Lemma 5.3 cannot be tightened in general, in the sense that there do exist families of systems where that slack is the best we can do. For instance, take $r = 2$, $J_1^0 = 1$, $J_1^1 = 0$ and $J_2^1 = 2$, and $J_2^0 = J_2^1 = J_2^2 = 0$. In this case no departures take place from station 2 of the systems Δ^0 and Δ^1 , while departures do occur in the system Δ^2 . Consequently, the $D^0(t)$ does not dominate a \mathbf{q} -convex combination of the other two, with $\mathbf{q} = (\frac{1}{2}, \frac{1}{2})$ (say). On the other hand, for certain families of min-linearly constrained SDES the slack can indeed be tightened by more careful analysis.

B. Generalized Min-Linearly Constrained SDES

Let the parameter set \mathbf{A} be as before, and let

$$\mathbf{I} = \{I_{jk} : \mathbf{R}_+ \rightarrow \mathbf{R}_+; k = 1, \dots, n, j = 1, \dots, m\}$$

be a set of nondecreasing switching functions. Consider the set $\mathcal{T} \subset \mathbb{Z}_+^m$ defined by a generalized min-linear constraint function based on the parameter \mathbf{A} and the switching function \mathbf{I} as follows

$$\mathcal{T}(\mathbf{A}, \mathbf{I}) := \left\{ \mathbf{x} \in \mathbb{Z}_+^m : x_j \leq \min_{1 \leq k \leq n} \left\{ I_{jk} \left(\sum_{i=1}^m a_{ijk} x_i \right) \right\}, \quad 1 \leq j \leq m \right\}.$$

This represents an extension of min-linearly constrained SDES model, as the constraint $\sum_{i=1}^m a_{ijk} x_i + b_{jk}$ has been replaced by $I_{jk}(\sum_{i=1}^m a_{ijk} x_i)$, where I_{jk} is a nondecreasing function. A SDES which is defined from the maximal accessible subset of the set $\mathcal{T}(\mathbf{A}, \mathbf{I})$ is said to be a generalized min-linearly constrained SDES. This allows us to model a bigger class of Petri nets — those for which structural consumption conflicts

are resolved through a predefined “switching” mechanism (see [18]).

We have the following near-concavity result for generalized min-linearly constrained SDES.

Theorem 5.6: Let $\{\Delta(\mathbf{A}, \mathbf{I}^p) : 0 \leq p \leq r\}$ be a family of generalized min-linearly constrained SDES with corresponding score spaces $\{S^p : 0 \leq p \leq r\}$, and departure processes $\{D^p : 0 \leq p \leq r\}$. Let $\mathbf{q} \in M^r$ be such that for all $\mathbf{x}^0 = \left[\sum_{p=1}^r q_p \mathbf{x}^p \right]$, $\mathbf{x}^p \in S^p$, $1 \leq p \leq r$, and for all $1 \leq j \leq m$, $1 \leq k \leq n$

$$I_{jk}^0 \left(\sum_{i=1}^m a_{ijk} x_i^0 \right) \geq \left[\sum_{p=1}^r q_p \left[I_{jk}^p \left(\sum_{i=1}^m a_{ijk} x_i^p \right) \right] \right]. \quad (5.9)$$

Then $S^0 \supset \left[\sum_{p=1}^r q_p S^p \right]$, and consequently,

$$D^0(t, \omega) \geq \sum_{p=1}^r q_p D^p(t, \omega), \quad \forall \text{ clock sequences } \omega, \\ \text{and times } t \geq 0. \quad (5.10)$$

Proof Proceeds on the same lines as Theorem 5.3. Let $\mathbf{y}^p \in \mathcal{T}(\mathbf{A}, \mathbf{I}^p)$, $p = 1, \dots, r$ and define $\mathbf{y}^0 = \left[\sum_{p=1}^r q_p \mathbf{y}^p \right]$. Then for any j , $1 \leq j \leq m$

$$y_j^0 = \left[\sum_{p=1}^r q_p y_j^p \right] \\ \leq \left[\sum_{p=1}^r q_p \left[\min_{1 \leq k \leq n} I_{jk}^p \left(\sum_{i=1}^m a_{ijk} y_i^p \right) \right] \right] \\ = \left[\sum_{p=1}^r q_p \min_{1 \leq k \leq n} \left[I_{jk}^p \left(\sum_{i=1}^m a_{ijk} y_i^p \right) \right] \right] \\ \leq \min_{1 \leq k \leq n} \left[\sum_{p=1}^r q_p \left[I_{jk}^p \left(\sum_{i=1}^m a_{ijk} y_i^p \right) \right] \right] \\ \leq \min_{1 \leq k \leq n} \left\{ I_{jk}^0 \left(\sum_{i=1}^m a_{ijk} y_i^0 \right) \right\}.$$

Thus, $\mathbf{y}^0 \in \mathcal{T}(\mathbf{A}, \mathbf{I}^0)$. \square

Note that the above result strictly generalizes Theorem 5.3. The following lemma can be used to deduce the near-concavity of Petri nets with conflict resolution in the initial markings.

Lemma 5.7: Suppose that for some j, k

$$I_{jk}^p(\cdot) = H_{jk}^p(\cdot) + b_{jk}^p, \quad p = 0, 1, \dots, r$$

for some nondecreasing function $H_{jk}^p(\cdot)$, and that there exists a constant c_{jk} such that

$$b_{jk}^0 \geq \sum_{p=1}^r q_p b_{jk}^p + s(\mathbf{q}) + c_{jk},$$

and that for all $z^0, z^1, \dots, z^r \in \mathbf{R}_+$, with $z^0 \geq \sum_{p=1}^r q_p z^p$,

$$H_{jk}^0(z^0) + c_{jk} \geq \sum_{p=1}^r q_p H_{jk}^p(z^p). \quad (5.11)$$

Then the $\{I_{jk}^p : p = 0, 1, \dots, r\}$ satisfy (5.9).

Fig. 3 Closed network with splitting and merging

Fig. 4 Open network with splitting and merging

Proof Let $\mathbf{x}^p \in \mathcal{S}^j$, $1 \leq p \leq i$, and $\mathbf{x}^0 = M^j$ be such that $[\sum_{p=1}^i q_p \mathbf{x}^p]$. Then

$$\begin{aligned} I_{jk}^0 \left(\sum_{i=1}^m a_{ijk} x_i^0 \right) &= H_{jk}^0 \left(\sum_{i=1}^m a_{ijk} x_i^0 \right) + b_{jk}^0 \\ &\geq H_{jk}^0 \left(\sum_{i=1}^i q_i \sum_{i=1}^m a_{ijk} x_i^i \right) \\ &\quad + \sum_{i=1}^i q_i b_{jk}^i + s(\mathbf{q}) + \alpha_{jk} \\ &\geq \sum_{i=1}^i q_i H_{jk}^i \left(\sum_{i=1}^m a_{ijk} x_i^i \right) \\ &\quad + \sum_{i=1}^i q_i b_{jk}^i + s(\mathbf{q}) \\ &\geq \left[\sum_{i=1}^i q_i \left(H_{jk}^i \left(\sum_{i=1}^m a_{ijk} x_i^i \right) + b_{jk}^i \right) \right] \\ &= \left[\sum_{i=1}^i q_i \left[I_{jk}^i \left(\sum_{i=1}^m a_{ijk} x_i^i \right) \right] \right] \end{aligned}$$

□

Example 5.8 (Closed Network with Splitting and Merging)
Consider the closed network shown in Fig. 3. The i th job to depart station 1 is sent to station $H(i) \in \{2, 3\}$ where $H(\cdot)$ is some routing (splitting) mechanism. Define $H_j(i) = \sum_{q=1}^i 1_{\{H(q)=j\}}$, $j = 2, 3$. The output streams from these two stations are merged into station 4 from where they cycle back to station 1.

We assume that there is no blocking, i.e. all buffers have unlimited capacities. Let $\mathbf{J} = (J_1, J_2, J_3, J_4)$ be the initial configuration of jobs in the system. The constraint set \mathcal{T} that specifies the SDES corresponding to this network is given by

$$\begin{aligned} \mathcal{T} = \{ \mathbf{x} \in \mathbb{Z}_+^4 : & i_1 \leq i_1 + J_1 \\ & i_2 \leq H_2(i_1) + J_2 \\ & i_3 \leq H_3(i_1) + J_3 \\ & i_4 \leq i_2 + i_3 + J_4 \} \end{aligned}$$

Let the routing mechanism satisfy

$$\beta_j i - \epsilon_j \leq H_j(i) \leq \beta_j i + \alpha_j, \quad i \in \mathbb{Z}_+, j = 2, 3 \quad (5.12)$$

This is a generalized min-linearly constrained SDES with an appropriately defined parameter set \mathbf{A} and switching mechanism \mathbf{I} ($J_j(i) = H_j(i) + J_j$, $i \in \mathbb{Z}_+$, $j = 2, 3$). Let $\{\Delta(J^p) : 0 \leq p \leq i\}$ be a synchronized family of such systems, parameterized by the initial configurations. Let $\mathbf{q} \in$

$$\begin{aligned} I_j^0 &\geq \left[\sum_{p=1}^i q_p J_j^p \right], \quad j = 1, 1 \\ I_j^0 &= \sum_{p=1}^i q_p J_j^p + s(\mathbf{q}) + \epsilon_j + \alpha_j, \quad j = 2, 3 \quad (5.13) \end{aligned}$$

Then, (5.11) is satisfied with $\epsilon_j = \epsilon_j + \alpha_j$ for $j = 2, 3$ as for all $z^0 \in \mathbb{Z}_+^4$, $\mathbf{z}^i \in \mathbb{R}_+$ with $z^0 \geq \sum_{i=1}^i q_i \mathbf{z}^i$

$$\begin{aligned} H_j(z^0) + \epsilon_j + \alpha_j &\geq \beta_j z^0 + \alpha_j \\ &\geq \sum_{p=1}^i q_p (\beta_j z^p + \alpha_j) \\ &\geq \sum_{p=1}^i q_p H_j(z^p) \end{aligned}$$

Thus from Lemma 5.7 and Theorem 5.6 we may deduce that the corresponding departure processes satisfy $\mathbf{D}^0 \geq \sum_{i=1}^i q_p \mathbf{D}^p$.

For the case of round-robin routing, the routing functions as defined at the beginning of this example are given by $H_2(i) = \lceil i/2 \rceil$, and $H_3(i) = \lfloor i/2 \rfloor$. Note that the functions $H_2(i) = i/2 + 1/2$, and $H_3(i) = i/2$ also lead to the same constraint set \mathcal{T} . Further, this latter choice of functions gives us a stronger result as (5.12) is satisfied with

$$\beta_1 = \beta_2 = \frac{1}{2}, \quad -\epsilon_2 = \alpha_2 = \frac{1}{2}, \quad \text{and} \quad -\epsilon_3 = \alpha_3 = 0$$

Example 5.9 (Open Network with Splitting and Merging)
Consider the network shown in Fig. 4 that was used in the previous example, with the modification that there is an unlimited supply of jobs at station 1, i.e. $J_1 = \infty$. This corresponds to an open network where the first server models the exogenous arrival process. The initial configuration of jobs in this open network is given by $\mathbf{J} = (J_2, J_3, J_4)$ and the constraint set is defined by

$$\begin{aligned} \mathcal{T} = \left\{ \mathbf{x} \in \mathbb{Z}_+^4 : & i_2 \leq H_2(i_1) + J_2 \\ & i_3 \leq H_3(i_1) + J_3 \\ & i_4 \leq i_2 + i_3 + J_4 \right\} \end{aligned}$$

Now consider a synchronized family $\{\Delta(J^p) : p = 0, 1, \dots, i\}$ of such systems parameterized by their initial config-

urations. Let $q \in M^r$ be such that³

$$J^0 \geq \left\lceil \sum_{p=1}^r q_p J^p \right\rceil. \quad (5.14)$$

It is easy to see that whenever (x^1, \dots, x^r) are coeval, and $x^0 := \left\lceil \sum_{p=1}^r q_p x^p \right\rceil$, then $x_1^0 = x_1^1 = \dots = x_1^r$. Moreover, for $j = 2, 3$

$$\begin{aligned} x_j^0 &= \left\lceil \sum_{p=1}^r q_p x_j^p \right\rceil \\ &\leq \left\lceil \sum_{p=1}^r q_p (H_j(x_1^p) + J_j^p) \right\rceil \\ &= H_j(x_1^0) + \left\lceil \sum_{p=1}^r q_p J_j^p \right\rceil \\ &\leq H_j(x_1^0) + J_j^0. \end{aligned}$$

It is easy to see that x_1^0 also satisfies the required condition. Thus, Assertion (1) of Theorem 4.1 is satisfied, and hence

$$D^0(t) \geq \sum_{p=1}^r q_p D^p(t), \quad \forall t \geq 0. \quad (5.15)$$

Moreover, we also have

$$D_1^0(t) = D_1^1(t) = \dots = D_1^r(t), \quad \forall t \geq 0. \quad (5.16)$$

The total number of jobs, $N(t)$, in the system comprising of stations 2, 3, and 4, at time $t \geq 0$, is given by

$$N(t) = J_2 + J_3 + J_4 + D_1(t) - D_4(t). \quad (5.17)$$

Now if we assume that $J_2^p + J_3^p + J_4^p = J$ (const.) for $p = 0, 1, \dots, r$, then by (5.15), (5.16), and (5.17), we get

$$\begin{aligned} N^0(t) &= J_2^0 + J_3^0 + J_4^0 + D_1^0(t) - D_4^0(t) \\ &\leq J_2^0 + J_3^0 + J_4^0 + D_1^0(t) - \sum_{p=1}^r q_p D_4^p(t) \\ &= \sum_{p=1}^r q_p (J_2^p + J_3^p + J_4^p) + \sum_{p=1}^r q_p D_1^p(t) - \sum_{p=1}^r q_p D_4^p(t) \\ &= \sum_{p=1}^r q_p N^p(t). \end{aligned}$$

This establishes that the number of jobs in the system is convex in the initial configuration (J_2, J_3, J_4) under the constraint that $J_2 + J_3 + J_4 = J$ (const.).

The results obtained above are pathwise. We now consider a probabilistic routing mechanism that is symmetric, i.e.,

$$\{I_2(x); x \geq 1\} \stackrel{D}{=} \{I_3(x); x \geq 1\}. \quad (5.18)$$

Also assume that the servers at stations 2 and 3 are identical, and $J_4^1 = J_4^2$, $J_2^1 = J_3^2$, $J_3^1 = J_2^2$. Then because of the symmetry

$$\{N^1(t); t \geq 0\} \stackrel{D}{=} \{N^2(t); t \geq 0\}. \quad (5.19)$$

³Note that (5.14) is a strictly weaker condition than (5.13) which is what we would have required if we had not made use of coequality.

Thus, for the (symmetric) system with a symmetric routing mechanism and identical servers at stations 2 and 3, $E[N^J(t)]$, $t \geq 0$, is convex and symmetric in (J_2, J_3) with $J_2 + J_3 = \text{const.}$ and $J_4 = \text{const.}$. Thus $E[N^J(t)]$, $t \geq 0$, is increasing in $|J_2 - J_3|$, and therefore a more balanced load is better than a less balanced one (in the sense of majorization). So if at any time one has the option of "jockeying" jobs between queues 2 and 3, it is better to transfer jobs from the longer queue to the shorter one.

APPENDIX

PROOF OF PROPOSITION 5.2

1) α is rational, i.e., $\alpha_p = \frac{\nu_p}{\delta_p}$ where $\nu_p, \delta_p \in \mathbb{Z}_+$ are co-prime, $p = 1, \dots, r$. Let $\lambda = \text{l.c.m.}\{\delta_1, \dots, \delta_r\}$. Then, it is easy to see that $\text{g.c.d.}\{\frac{\lambda\nu_1}{\delta_1}, \dots, \frac{\lambda\nu_r}{\delta_r}\} = 1$. (If the above g.c.d. is $\gamma > 1$, then the l.c.m. will be $\frac{\lambda}{\gamma}$). Now consider the set

$$D := \left\{ \sum_{p=1}^r \frac{\lambda\nu_p}{\delta_p} x^p : x^p \in \mathbb{Z}_+, p = 1, \dots, r \right\}.$$

Clearly, D is closed under addition, and $\text{g.c.d.}(D) = 1$. Then, it follows that D contains all sufficiently large positive integers (see [22, Lemma 1-66]). Thus there exists $k, x^1, \dots, x^r \in \mathbb{Z}_+$, such that $\sum_{p=1}^r \frac{\lambda\nu_p}{\delta_p} x^p = k\lambda + 1$. This implies that $\sum_{p=1}^r \frac{\nu_p}{\delta_p} x^p = k + \frac{1}{\lambda}$. Thus

$$\left\lceil \sum_{p=1}^r \frac{\nu_p}{\delta_p} x^p \right\rceil - \sum_{p=1}^r \frac{\nu_p}{\delta_p} x^p = 1 - \frac{1}{\lambda}. \quad (A.1)$$

Moreover, for any $x^1, \dots, x^r \in \mathbb{Z}_+$, we have $\sum_{p=1}^r \frac{\lambda\nu_p}{\delta_p} x^p \in \mathbb{Z}_+$, and hence

$$\left\lceil \sum_{p=1}^r \frac{\nu_p}{\delta_p} x^p \right\rceil - \sum_{p=1}^r \frac{\nu_p}{\delta_p} x^p \leq 1 - \frac{1}{\lambda}. \quad (A.2)$$

That $s(\alpha) = 1 - \frac{1}{\lambda}$, follows by combining (A.1) and (A.2).

2) α is irrational. Assume, WLOG, that α_1 is irrational. It suffices to show that

$$\sup\{\lceil \alpha_1 x \rceil - \alpha_1 x : x \in \mathbb{Z}_+\} =: s = 1. \quad (A.3)$$

Since α_1 is irrational, (A.3) is equivalent to showing that

$$\inf\{\alpha_1 x - \lfloor \alpha_1 x \rfloor : x \in \mathbb{Z}_+, x \geq 1\} =: c = 0. \quad (A.4)$$

Let $C := \{\alpha_1 x - \lfloor \alpha_1 x \rfloor : x \in \mathbb{Z}_+, x \geq 1\}$. Now assume that $c > 0$. Let $l := \min\{k : kc \geq 1\}$. Note that $(l-1)c < 1 \leq lc < 1+c$. Let $\epsilon := 1+c-lc$. By the definition of c , we can choose a $d \in C$, such that $c \leq d < c + \frac{\epsilon}{l}$. It is easy to check that if $d \in C$, then $nd - \lfloor nd \rfloor \in C$ for any $n \in \mathbb{Z}_+, n \geq 1$. But $1 \leq lc \leq ld < lc + \epsilon = 1+c$, and thus $ld - \lfloor ld \rfloor = ld - 1 < c$. This gives us a contradiction, which establishes that $c = 0$. \square

Regional Pole Placement of Multivariable Systems Under Control Structure Constraints

S. Sathiya Keerthi and Makarand S. Phatak

Abstract—Many controller realizations are structurally constrained. Some typical examples are static output feedback, constant gain feedback for multiple operating points of a system, two-controller feedback, and decentralized feedback. A general class of problems of regional pole placement of multivariable systems with such control structure constraints is considered and a unified numerical method is given to solve them. First a problem in this class is converted to a problem of solving a system of equalities and inequalities. This system is then solved by using a modified homotopy method.

I. INTRODUCTION

Consider structurally constrained controllers, such as static output feedback, constant gain feedback for multiple operating points of a system, two-controller feedback, and decentralized feedback. With such constrained controllers it is in general not possible to place the eigenvalues arbitrarily in the complex plane. For satisfactory dynamical behavior of a system, it usually suffices to place the eigenvalues in some desired stability region, S in the complex plane, i.e., to S -stabilize the system. With structurally constrained controllers S -stabilization is quite possible. In this paper we consider a general class of problems of S -stabilization (or regional pole placement) of multivariable systems with control structure constraints and give a numerical method to solve them. This work is a nontrivial extension of the authors' earlier work [6] to the multivariable case. While doing the extension the possible overlap between [6] and this note is kept at a minimum by omitting the most repetitive details.

The problems mentioned here have also been considered in many earlier papers from which we choose references somewhat arbitrarily and point to [3] for the case of static output feedback, [8] for the case of constant gain feedback for multiple operating points of a system, [9] for the case of two-controller feedback, and [5] for the case of decentralized feedback. Our method is fundamentally different from the above methods and treats different problems under a single framework.

In our method we formulate (Section II) each of the regional eigenvalue placement problems as a problem of solving a system of equalities and inequalities, which we solve (Section III) by employing a modified homotopy framework. An example is presented (Section IV) to show the efficacy of our method.

II. PROBLEM FORMULATION

Consider the multivariable dynamical system

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) \quad (2.1)$$

Fig. 1. An example of a popular stability region S in the complex plane.

where $x \in R^n$, $u \in R^m$, $y \in R^p$, and A , B , C are constant matrices of appropriate dimensions. We will assume the following throughout: system (2.1) is controllable and observable, $\text{rank } B = m$ and $\text{rank } C = p$. The feedback we consider is of the form

$$u(t) = -Kx(t). \quad (2.2)$$

Our objective is to S -stabilize, i.e., to place the eigenvalues of $(A - BK)$ in some desired stability region, S in the complex plane under given control structure constraints. S comes from specifications of the desirable dynamical behavior of the closed-loop system. In particular we focus our attention on the popular stability region, S shown in Fig. 1. Control structure constraints are imposed by the way feedback is realized. For example, in the case of static output feedback the constraint is that rows of K must belong to the range space of rows of C so that state feedback (2.2) can be realized as static output feedback. To solve this constrained problem we formulate a system of inequalities and equalities

$$g(v) \leq 0 \quad (2.3)$$

$$h(v) = 0 \quad (2.4)$$

where v is some set of intermediate variables. It is worth mentioning here that a neat transformation of our control problem to an instance of (2.3)–(2.4) is by no means trivial; so our way of doing it is interesting in its own right. Once a v satisfying (2.3)–(2.4) is found the gain matrix required for stabilization can easily be found. In Section II-A we present details of how v is chosen and how to formulate the inequalities. The equalities will be derived in Section II-B.

A. Choice of Variables and Formation of Inequalities

Given a controllable pair (A, B) the feedback matrix K which gives a specified characteristic polynomial for $(A - BK)$ is not unique. K , however, is determined uniquely by a specified matrix polynomial $P(s)$ [1]. $P(s)$ is defined by

$$P(s) = \bar{P}(s) + \Gamma \bar{\Gamma}^*(s) \quad (2.5)$$

where Γ is a constant (i.e., independent of s) $m \times n$ matrix

$$\bar{P}(s) = \text{diag}[s^{n_1}, \dots, s^{n_m}].$$

$$V(s) = \text{block diag}[(1 \ s \ -a^{n_1-1})^T, \dots, (1 \ s \ -a^{n_l-1})^T]$$

and n_1, \dots, n_l are the controllability indexes of the pair (A, B) he K which satisfies

$$\det(sI - A + BK) = \det(P(s)) \quad (2.6)$$

is given by

$$K = I^{-1}(\bar{K} + \Gamma T) \quad (2.7)$$

where the matrices I (nonsingular and upper triangular), \bar{K} and T (nonsingular) depend on (A, B) see [1] for details of the dependency. Since the relationship between K and I is affine as given by (2.7) Γ is an attractive choice for the set of variables, γ . However the problem of finding conditions on the elements of Γ so that the set of eigenvalues, $\Lambda = \lambda(A - BK) \subset S$ is very hard. On the other hand suppose we denote

$$\det(P(s)) = \det(P(s) + \Gamma V(s)) = \left[\prod_{i=1}^l (s + a_i s + b_i) \right] (s - \lambda) \quad (2.8)$$

where $l = \lfloor n/2 \rfloor$ the integer part of $n/2$ and the last term $(s - \lambda)$ occurs when n is odd. Then the following proposition shows that the constraint $\lambda(A - BK) \subset S$ can be easily reformulated in terms of the elements of γ where

$$- [a_1 b_1 \dots a_l b_l \lambda]^T \quad (2.9)$$

Proposition 2.1 Let S be as shown in Fig. 1 then $\lambda(A - BK) \subset S$ is equivalent to

$$\alpha_+ \leq -a/2 \leq \alpha_- \quad b \leq (1 + \tan \theta)(a/2)^+$$

$$\alpha_+ + \alpha_+ a + b \geq 0 \quad \alpha_- + \alpha_- a + b \geq 0 \quad \forall i \in \{1, \dots, l\}$$

$$\alpha_+ \leq \lambda \leq \alpha_- \quad (2.10)$$

By using the results on representation of general stability regions in terms of inequalities [1 p. 298–299] Proposition 2.1 can be easily proved. We omit the details for the sake of brevity.

The use of quadratic factors in (2.8) avoids the need to work with complex numbers. We define the set of variables γ by

$$\gamma = \{\Gamma\} \quad (2.11)$$

It is clear that the elements of γ are not independent. The reason for choosing such an overdetermined set, γ , is given later in Remark 2.2. In Section II-B we develop equality constraints which must be satisfied by the elements of Γ and γ to ensure (2.6) and (2.8). The system of inequalities (2.10) define $q(\gamma) \leq 0$ (truly $q(\gamma) \leq 0$) in (2.3).

B. Equalities

We first formulate the equalities which are directly associated with the definition of the set of variables, γ in (2.11).

Assumption 2.1 Let $p_i(s) = s^2 + a_i s + b_i$, $i = 1, \dots, l$, and $p_{l+1}(s) = s - \lambda$. For each $i, j \in \{1, \dots, l+1\}$, $i \neq j$, $p_i(s)$ and $p_j(s)$ are relatively prime.

Proposition 2.2 Suppose that Assumption 2.1 holds. It is equivalent to the system of n equalities given by

$$\epsilon_1 [\text{block det}(\bar{P}(C) + \Gamma V(C))] = 0$$

$$\det(\bar{P}(\lambda) + \Gamma V(\lambda)) = 0$$

where

$$\epsilon_1 = [1 \ 0] \quad C = \begin{bmatrix} 0 & 1 \\ -1 & -a \end{bmatrix} \quad \text{and}$$

$$\text{block det}(P(C)) = \det(P(s))$$

Proof. We can eliminate s in (2.8) by substituting it by C , $i = 1, 2, \dots, l$ and λ so that the right-hand side of (2.8) is zero by Cayley-Hamilton's theorem. Then we get an intermediate system of equations which is the same as (2.12) except that the term ϵ_1 is absent. This intermediate system of equations contains a total of $4l+1 = (n+2l)$ equations. Out of these $2l$ are redundant and when they are eliminated we get (2.12). Thus (2.8) implies (2.12).

We now show using Assumption 2.1 that (2.12) implies (2.8). Let $p_i(s)$ be as in Assumption 2.1. If we show that for each $i = 1, \dots, l+1$

$$p_i(s) \text{ divides } \det(\bar{P}(s) + \Gamma V(s)) \quad (2.13)$$

then we are done because of Assumption 2.1 and the fact that the degree of $\det(\bar{P}(s) + \Gamma V(s))$ is equal to n . By the second level equation in (2.12) it directly follows that (2.13) holds for $i = l+1$. Now take $i \in \{1, \dots, l\}$. To show (2.13) we need to consider two cases: (1) $\lambda_1 = \lambda$, (2) $\lambda_1 \neq \lambda$ where λ_1 and λ are the roots of $s^2 + a_i s + b_i = 0$.

In case 1, $s^2 + a_i s + b_i = 0$ has a root λ_1 of multiplicity two. We have

$$C = \begin{bmatrix} 1 & 0 \\ \lambda_1 & 1 \end{bmatrix} \begin{bmatrix} \lambda_1 & 1 \\ 0 & \lambda_1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ \lambda_1 & 1 \end{bmatrix}^{-1}$$

and

$$\begin{aligned} & \text{block det}(\bar{P}(C) + \Gamma V(C)) \\ &= \begin{bmatrix} 1 & 0 \\ \lambda_1 & 1 \end{bmatrix} \\ & \quad \left[\begin{array}{cc} \det(\bar{P}(\lambda_1) + \Gamma V(\lambda_1)) & \frac{1}{\lambda_1} \det(\bar{P}(\lambda_1) + \Gamma V(\lambda_1)) \\ 0 & \det(\bar{P}(\lambda_1) + \Gamma V(\lambda_1)) \end{array} \right] \\ & \quad \begin{bmatrix} 1 & 0 \\ \lambda_1 & 1 \end{bmatrix}^{-1} \end{aligned} \quad (2.14)$$

From (2.12) and (2.14) it follows that

$$\det(\bar{P}(\lambda_1) + \Gamma V(\lambda_1)) = 0 \quad \frac{d}{d\lambda_1} \det(\bar{P}(\lambda_1) + \Gamma V(\lambda_1)) = 0$$

and hence (2.13) holds. A similar (actually easier) proof holds for case 2. This completes the proof of the proposition. ■

Remark 2.1 Equations in (2.12) are independent. The proof of this is implicit in Lemma 3.2 which is stated and proved in Section III.

Remark 2.2 In the single-input case K is determined uniquely by γ and can be expressed directly in terms of the elements of γ as [using factorization of the scalar polynomial $P(s)$ in (2.8)] $K = q \cdot [\prod_{i=1}^l (s^2 + a_i s + b_i I)](sI - A)^{-1}$, where q is as defined in [1]. So (2.12) is not required in the single-input case [6]. In the multi-input case K is determined uniquely by Γ and cannot be expressed directly in terms of the elements of γ and some other variables required for its unique determination. This is because of the lack of a factorized parameterization of the matrix polynomial $P(s)$. So we define the overdetermined set γ in (2.11) and the constraining equations (2.12) for the multi-input case.

The block determinant in (2.12) and its partial derivatives with respect to the elements of v , which are required in the numerical solution described in Section III, can be obtained by using a transformation of a polynomial matrix to Hermite form [2]. This transformation uses elementary operations to reduce a square polynomial matrix to triangular form. First $\det(P(s))$ is obtained from the Hermite form of $P(s)$ as $\det(P(s)) = s^n + \beta_1 s^{n-1} + \dots + \beta_n$. Then block $\det P(C)$ is obtained by evaluating the above polynomial at C , i.e., (subscript i in C , a , and b is dropped in the following expressions for notational simplicity) block $\det P(C) = \det(P(s))|_{s=C} = C^n + \beta_1 C^{n-1} + \dots + \beta_n I_2$. Partial derivatives of block determinant with respect to elements of Γ are obtained as follows. From $P(s)$ equal to the expression found at the bottom of the page where γ_i^{jk} 's are the elements of Γ ; the partial derivative of block $\det P(C)$ with respect to, say, γ_1^{11} , is nothing but $C^{n-1}[\text{adj } P(s)]_{11}|_{s=C}$, where $[\text{adj } P(s)]_{11}$ is the (1, 1) element of the adjoint of $P(s)$. The partial derivatives with respect to other γ_i^{jk} 's are similarly obtained. Partial derivatives of block determinant with respect to elements of C are obtained from the partial derivatives of power of C which are given below

$$\begin{aligned}\frac{\partial}{\partial a} C^n &= \sum_{j=1}^n C^{(j-1)} \frac{\partial}{\partial a} (C) C^{n-j}, \\ \frac{\partial}{\partial b} C^n &= \sum_{j=1}^n C^{(j-1)} \frac{\partial}{\partial b} (C) C^{n-j}, \quad 1 \leq r \leq n\end{aligned}$$

where

$$\frac{\partial}{\partial a} (C) = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}, \quad \frac{\partial}{\partial b} (C) = \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix}.$$

Remark 2.3: Assumption 2.1 can be enforced by simple inequalities, using 2×2 McDuffe resultants [2]. These inequalities along with (2.10) actually define $g(v) \leq 0$ in (2.3). In the actual implementation, however, we have preferred to omit these extra inequalities arising from enforcing Assumption 2.1. We have also observed, on all the examples tried, that this omission does not lead to any difficulties in obtaining the final solution. We will discuss more about this in Section III (Remark 3.1).

Remark 2.4: An important observation is worth mentioning here. Our algorithm for solving the constrained stabilization problems, which will be discussed later, starts from an initial guess point and varies a , and b , continuously, while satisfying (2.12), so as to reach a solution. Since (2.12) allows a pair of repeated roots, a continuous change between a pair of real roots and a pair of complex conjugate roots is possible.

Now we consider the equalities which arise from structural constraints on state feedback. By appropriately appending (2.12) to these equalities we get (2.4). We demonstrate the setting up of the equalities only for the control structure of decentralized state feedback. Details for the other control structures mentioned earlier are straightforward and can be found in [6]. The K given by (2.7) is function of Γ , a part of v , and so we denote K by $K(v)$. The control structure constraints on K are treated as constraints on v .

Decentralized State Feedback

Let r be the number of subsystems of a large scale system for which a decentralized feedback is to be realized. The state feedback gain matrix, K typically takes the block diagonal form: $K = \text{block diag}[K_1, \dots, K_r]$. The control structure constraints corresponding to this form can be expressed as

$$E_i^L K(v) E_i^R = 0, \quad i = 1, 2, \dots, r \quad (2.15)$$

where the matrices E_i^L, E_i^R are constant matrices of appropriate dimensions which select all blocks in the i th block row except the i th one. Sometimes there exists an overlap between the state variables of the subsystems. In such a case K cannot be expressed in block diagonal form. The structural constraints can still be represented as in (2.15), however, with an appropriate choice of E_i^L and E_i^R , $i = 1, \dots, r$. Together (2.15) along with (2.12) define (2.4).

Remark 2.5: The equations in (2.12) involve characteristic polynomials and determinants, quantities which are known to have bad sensitivity properties. In other words, in the presence of finite precision arithmetic, the difference between the set of eigenvalues of $(A - BK)$ and the set of roots of (2.8) can be large even when the errors in the satisfaction of (2.12) are small. Therefore, when a K is determined using the numerical method proposed in this paper, it is necessary to evaluate the eigenvalues of $(A - BK)$ and check whether they belong to S . If this check fails then it indicates that our method has suffered from numerical instability. If computations are done with a high precision this would not happen. See for instance, the example of Section IV.

III. A MODIFIED HOMOTOPY METHOD

We solve the system of equalities and inequalities obtained in the previous section by using a modified homotopy method. Homotopy methods are popularly used to find zeros of a square system of non linear equations. Our main reason for preferring homotopy methods over the usual iterative methods is that it has been observed in practice that the domain of attraction of a solution point for iterative methods is usually much smaller than that for homotopy methods. A good survey of homotopy (or, continuation) methods together with guiding references on theory, numerical methods and applications is given in [7]. We devise a modification of a homotopy method to solve the system of equalities (2.4) (which is typically underdetermined) along with the inequalities (2.3).

Let $H(v, t)$ be a function with the following properties: a) when $t = 0$, the system of equations $H(v, 0) = 0, g(v) \leq 0$ is trivial in the sense that it is easy to find a \bar{v} satisfying them, and b) when $t = 1$, $H(v, 1) = h(v)$. Thus when $t = 0$ we know that \bar{v} is a solution to $H(v, 0) = 0, g(v) \leq 0$. In a homotopy method one starts from this known solution $(\bar{v}, 0)$, and moves on the solution hypersurface defined by $\{(v, t): H(v, t) = 0, g(v) \leq 0, 0 \leq t \leq 1\}$ in an attempt to reach a solution v^* , if it exists. Our choice of the H function is

$$H(v, t) = \begin{bmatrix} h^1(\Gamma) + (t-1)h^1(\bar{\Gamma}) \\ h^2(\Gamma, \gamma) \end{bmatrix} \quad (3.1)$$

where: the h^1 function represents the given control structure constraint, see for example, (2.15) for the case of decentralized state

$$\begin{bmatrix} s^{n_1} + \gamma_1^{11} s^{n_1-1} + \dots + \gamma_{n_1}^{11} & \gamma_1^{12} s^{n_1-1} + \dots + \gamma_{n_1}^{12} & \dots & \gamma_1^{1m} s^{n_1-1} + \dots + \gamma_{n_1}^{1m} \\ \gamma_1^{21} s^{n_1-1} + \dots + \gamma_{n_1}^{21} & s^{n_2} + \gamma_1^{22} s^{n_2-1} + \dots + \gamma_{n_2}^{22} & \dots & \gamma_1^{2m} s^{n_1-1} + \dots + \gamma_{n_2}^{2m} \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_1^{m1} s^{n_1-1} + \dots + \gamma_{n_1}^{m1} & \gamma_1^{m2} s^{n_2-1} + \dots + \gamma_{n_2}^{m2} & \dots & s^{n_m} + \gamma_1^{mm} s^{n_m-1} + \dots + \gamma_{n_m}^{mm} \end{bmatrix}$$

feedback; the h^2 function is the left-hand side of (2.12); and $\bar{\Gamma}$ is chosen as explained below. Recall that $v = \{\Gamma, \gamma\}$. When $t = 0$, we obtain a solution \bar{v} to $H(v, 0) = 0$ as follows. Choose a $\bar{\gamma}$ so that $g(\bar{\gamma}) < 0$. Note that it is easy to get such a $\bar{\gamma}$ because of the decoupled nature of the inequalities; see (2.10). Once a $\bar{\gamma}$ is chosen, choose a $\bar{\Gamma}$ so that $h^2(\bar{\Gamma}, \bar{\gamma}) = 0$. Again, it is easy to choose such a $\bar{\Gamma}$; for example one possibility is to choose $\bar{\Gamma}$ which corresponds to a diagonal matrix $P(s)$. Then, \bar{v} is nothing but $\{\bar{\Gamma}, \bar{\gamma}\}$.

To move on the solution hypersurface from $t = 0$ to $t = 1$ we devise a numerical method by using an optimization set-up. Here our description of the optimization set-up will be very brief; see [6] for its detailed discussion and the algorithm based on it.

Since $t = 1$ has to be reached for the homotopy method to be successful, and $t = 1$ has to be reached before crossing over to $t > 1$, $(1 - t)$ is a good choice for the objective function to be minimized. So we define the following optimization problem

$$\min(1 - t) \text{ subject to } H(v, t) = 0, \quad g(v) \leq 0. \quad (3.2)$$

It is important to note that, with $(1 - t)$ as the cost function, the aim is not to solve the optimization problem (3.2). It is formulated only to drive the motion from $t = 0$ to $t = 1$. It is easy to maintain feasibility with respect to the inequalities $g(v) \leq 0$ simply by using a barrier method [4] and replacing (3.2) by

$$\min(1 - t) + c_k B(v) \text{ subject to } H(v, t) = 0 \quad (3.3)$$

where $B(v)$ is a barrier function which is smooth and which tends to ∞ , i.e., establishes a barrier, as v approaches the boundary of $\{v: g(v) \leq 0\}$ and c_k is positive. Problem (3.3) is repeatedly solved for a sequence of c_k values (which monotonically decrease to zero). This solution process is terminated as soon as $t = 1$ is reached and there is no need to go for an actual minimization of (3.2). Therefore, unlike usual barrier methods, our method requires that the solution of (3.3) is repeated only for a few c_k values. In our numerical implementation we have used a logarithmic barrier function [4]. See [6] for the rationale used to choose the decreasing sequence $\{c_k\}$. In all the test examples it was observed that the initial choice $c_1 = 0.1$ worked well in that it was sufficient to solve (3.3) only once, i.e., $t = 1$ was reached while solving (3.3) with c_1 .

Suppose that the S -stabilization problem does not have a solution. In that case the method will reach a stage where the solution trajectory comes close to making one or more of the inequalities active and, as a result t gets stuck at a value less than one. In that case the region S can be expanded by appropriately changing the active inequalities and the procedure can be restarted.

Problem (3.3) is only an equality constrained problem. We solve (3.3) by a continuous realization of the gradient projection method [4, 6]. Let

$$Z = \{(v, t): H(v, t) = 0\} \quad (3.4)$$

and $\nabla f_p(v, t)$ be the projection of the gradient of $f = (1 - t) + c_k B(v)$ onto the tangent space of Z at (v, t) . In the gradient projection method one moves on Z along the trajectory of the vector field defined by $-\nabla f_p$. Careful tracking of the solution manifold Z using the vector field $-\nabla f_p$ can be done by using a simple modification of any state-of-the-art ODE solving package [10]. Such a tracking allows continuous check on any deviation from the solution manifold caused by the propagation and accumulation of numerical errors and applies a correction to get back to the solution manifold whenever necessary.

Let C denote the curve on Z starting from $(\bar{v}, 0)$ and defined using the above process. The tracking of C requires Z to be smooth. The smoothness of H does not automatically guarantee smoothness of Z . The following result describes the smoothness of Z .

Theorem 3.1: Let Z be as defined in (3.4) and assume that $\{(v, t): \text{Assumption 2.1 holds}\} \subset R^N$. Suppose that the Jacobian of h^1 with respect to Γ , has full row rank for every $(v, t) \in Z \cap V$. Then $Z \cap V$ is a differentiable manifold.

Remark 3.1: Typically C cuts ∂V , the boundary of V , transversally and so there is really no need to worry about any difficulties imposed by any crossing of ∂V (if at all it occurs) during the tracking of C . In doing all the numerical examples we have simply ignored Assumption 2.1 and yet did not face any difficulties in reaching a solution $(v^*, 1)$.

Remark 3.2: The assumption that h^1 has full row rank usually comes directly from the way the control structure constraints are formulated.

To prove Theorem 3.1 we use the following lemma.

Lemma 3.2: Suppose v is such that Assumption 2.1 holds and $h^2(v) = h^2(\Gamma, \gamma) = 0$, where h^2 is as in (3.1). Then $h^2_\gamma(\Gamma, \gamma)$, the Jacobian of h^2 with respect to γ , is nonsingular.

Proof: Let $\delta(s) = \det(\bar{P}(s) + \Gamma V(s))$. With straightforward algebra it is easy to see that $h^2_\gamma(\Gamma, \gamma)$ has block diagonal structure with i th ($i \in \{1, \dots, l\}$) block given by

$$\begin{bmatrix} \frac{\partial \delta(C_i)}{\partial a_i} \\ \frac{\partial \delta(C_i)}{\partial b_i} \end{bmatrix} = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} \prod_{j=1, j \neq i}^{l+1} G_j(C_i),$$

$$G_j(C_i) = C_i^2 + a_j C_i + b_j I_2, \quad j = 1, \dots, l$$

$$G_{l+1}(C_i) = C_i - \lambda I_2.$$

The last $((l+1)$ th) block is $\partial \delta(\lambda)/\partial \lambda = \prod_{i=1}^l (\lambda^2 + a_i \lambda + b_i)$. If Assumption 2.1 holds then for each i, j , $G_j(C_i)$ (which is the McDuffe resultant associated with $p_i(s)$ and $p_j(s)$) is nonsingular [2] and $\lambda^2 + a_i \lambda + b_i$ is nonzero. Hence Lemma 3.2 follows. ■

Proof of Theorem 3.1: To prove Theorem 3.1 it is sufficient to show that the Jacobian J of H with respect (Γ, γ, t) has full row rank for every $(v, t) = (\Gamma, \gamma, t) \in Z \cap V$. We have

$$J = \begin{bmatrix} h^1_\Gamma & 0 & h^1(\bar{\Gamma}) \\ h^2_\Gamma(\Gamma, \gamma) & h^2_\gamma(\Gamma, \gamma) & h^2(\bar{\Gamma}, \bar{\gamma}) \end{bmatrix}. \quad (3.5)$$

Then from (3.5) and Lemma 3.2, Theorem 3.1 follows directly. ■

It is very important that C connects the points $(\bar{v}, 0)$ and $(v^*, 1)$ (if v^* exists). This connectivity condition depends on the choice of H . For any of the S -stabilization problems which are considered in this paper choosing an H such that the connectivity condition is satisfied is a very hard problem. We believe that it can only be solved when complete system theoretic solutions to these problems become available. Our choice of H given in (3.1) is not guaranteed to satisfy the connectivity condition. Tests on several problems have shown, however, that the homotopy method based on the H as in (3.1) and the optimization formulation (3.2) has good empirical success. On all the problems tried we were always successful in reaching $t = 1$ without encountering any local minima of (3.2) or any unboundedness on the elements of Γ .

IV. EXAMPLE

We carried out numerical tests on several constrained S -stabilization problems using the VAX-88 computer. Here we present only one example to demonstrate the effectiveness of our approach.

Power System: We consider the example of seven-state, two-input model of load frequency control of a two-area power system. The numerical data for the A, B matrices are taken from [5]. Here we also take into consideration integral control action which is employed to reject step disturbances due to changes in load. Thus we append the state vector by two more variables which represent the integrals of the area control errors defined as $\Delta p_{tie} + \Delta f_1$ and $-\Delta p_{tie} + \Delta f_2$.

$E_1^T K E_1^R$	$E_1^T K E_1^R = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$ $E_2^T K E_2^R = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$
K	$(k_1, k_{1s}) = \begin{bmatrix} 0.238848 & 0.959565 & 1.84323 & 0.643260 & -0.580120 \end{bmatrix}$ $(k_{2s}, k_2) = \begin{bmatrix} 2.70128 & 0.637658 & 1.621895 & 2.159241 & 1.07738 \end{bmatrix}$

see [5] for the physical meanings of $-\Delta p_{i1}$ and Δf_i , $i = 1, 2$ and the other state variables. The feedback is decentralized with some overlap. The 2×9 gain matrix K has the following structure

$$K = \begin{bmatrix} \times & \times & \times & \times & \times & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \times & \times & \times & \times & \times \end{bmatrix}$$

$$= \begin{bmatrix} k_1 & k_{1s} & 0 \\ 0 & k_{2s} & k_2 \end{bmatrix}$$

where the \times 's represent the free gain elements. Results obtained by our method on this example are tabulated in Table I. We used the stability region of Fig. 1 with $\alpha_1 = -1$, $\alpha_2 = -10$ and $\theta = 45^\circ$. For doing homotopy curve tracking we used relative tolerance of 10^{-4} . In view of Remark 2.5 we compared the eigenvalues of $(A - BK)$ and the roots of (2.8). They matched up to three decimal digits.

V. CONCLUSION

In this note we have given a numerical method for solving a general class of multivariable regional pole placement problems with control constraints, which has worked well on many examples. Given that for general control structure constraints the problem is very hard, such a method should prove very useful.

Continuous Robust Control Design for Nonlinear Uncertain Systems Without a Priori Knowledge of Control Direction

J. Kaloust and Z. Qu

Abstract—In this paper, a robust control scheme is proposed for a class of nonlinear systems that have not only additive nonlinear uncertainties but also unknown multiplicative signs. These signs are called control directions since they represent effectively the direction of motion under any given control. Except for the unknown control directions, the class of systems satisfy the generalized matching conditions. Nonlinear robust control is designed to identify on-line unknown control directions and to guarantee global stability of uniform ultimate boundedness without the knowledge of nonlinear dynamics except their size bounding functions. It is also shown that the proposed robust control can be made continuous through utilizing the so-called shifting laws that change smoothly and accordingly the signs of robust controls and that, no matter what time constants and gains of the shifting laws are, global stability is always ensured. The analysis and design is done using Lyapunov's direct method.

1. INTRODUCTION

Robust control of nonlinear systems in the presence of nonlinear uncertainties has been studied extensively. The important classes of stabilizable uncertain systems and their robust control laws can be found in [1], [3], [6], [9]-[11]. The uncertainties in those systems can be general nonlinear functions and input-related and/or input-unrelated. The input-related uncertainties studied so far in the previous results, however, are not only sign-invariant but also have known signs. These signs, called control directions, represent motion directions of the system under any control, and knowledge of these signs makes robust control design much easier. The objective of this paper is to develop a robust control design procedure based on Lyapunov's direct method that achieve global stability but does not require a priori knowledge of control directions. For practical implementation, designs of both continuous and discontinuous robust controls are considered and compared. It is shown that continuity of robust control can be achieved by designing the so-called shifting laws that change the signs of the robust control in a continuous fashion. The shifting laws are based on the results of on-line identification of unknown control directions.

It is worth mentioning that the problem of unknown control directions has been studied for the last 10 years in the area of adaptive control. Most results in that area are for linear time invariant systems with unknown parameter and unknown high-frequency gain (that is, control direction). The first result was proposed by Nussbaum [8] in which the adaptive control uses the so-called Nussbaum gain, a transcendental function whose sign changes an infinite number of times as its argument tends to infinity. Using the same principle in [8], Mudgett and Morse [7] developed adaptive control for general linear systems without knowledge of high-frequency gain. An alternative method called correction vector approach was proposed in [5]. Recently, efforts have been made to extend these results to nonlinear systems that have unknown control directions. In [2], [4] two adaptive control schemes have been proposed for simple first-order nonlinear systems.

Compared with these existing results (especially the two on nonlinear systems), the results proposed in this paper have several advantages. First, the class of systems studied here is second-order, and the basic idea and approach used can be extended to second-order vector and higher-order systems. Second, systems considered in this paper are general nonlinear systems with general nonlinear time-varying uncertainties, while those in [2], [4] are time-invariant, have only unknown constants, and satisfy the Lipschitz condition. Third, the robust control laws provided here can be selected to be continuous in contrast with discontinuous adaptive control schemes formulated in [2], [4]. Fourth, the proposed robust control scheme guarantees global stability of uniform ultimate boundedness in the presence of general nonlinear uncertainties. Finally, instead of stabilization problem formulated in [2], [4], output tracking problem is solved in this paper.

The outline of this paper is as follows. In Section II formulation of our robust control problem of nonlinear uncertain system is presented. Robust control and shifting laws are developed in Section III, followed by a simulation example. Finally, the conclusion is drawn in Section IV.

II. PROBLEM FORMULATION

We shall consider a second-order nonlinear uncertain system to be described by

$$\dot{x}_1 = f_1(x_1, t) + \Delta f_1(x_1, \eta_1, t) + g_1(x_1, a_1 x_2, \eta_1, t) \quad (1)$$

$$\begin{aligned} \dot{x}_2 = & f_2(x_1, x_2, t) + \Delta f_2(x_1, x_2, \eta_2, t) \\ & + g_2(x_1, x_2, a_2 u, \eta_2, t) \end{aligned} \quad (2)$$

where $x = [x_1 \ x_2]^T \in \mathbb{R}^2$ is the state, $u(\cdot) \in \mathbb{R}$ is the control input, the variables η_1 and η_2 represent bounded, uncertain time-varying parameters, and a_1 and a_2 are scaled (in the sense that $|a_1| = |a_2| = 1$), constant parameters which characterize directions of controlled motion. The control directions, $\text{sign}[a_1]$ and $\text{sign}[a_2]$, are unknown. The functions $f_1(x_1, t)$ and $f_2(x_1, x_2, t)$ are known, functions $\Delta f_1(x_1, \eta_1, t)$ and $\Delta f_2(x_1, x_2, \eta_2, t)$ represent uncertainties, and the functions $g_1(x_1, a_1 x_2, \eta_1, t)$ and $g_2(x_1, x_2, a_2 u, \eta_2, t)$ may contain uncertainty in addition to a_1 and a_2 as well.

The class of uncertain system is given by (1) and (2) is a special case of the class of nonlinear systems in [10]. These systems satisfy the structure specified by the so-called generalized matching conditions. The difference between [10] and this paper is that the above systems has unknown control directions. For simplicity of presentation, subsystems (1) and (2) are assumed to be scalar. Extension can be made to higher-order and vector systems in which the control directions a_i are diagonal and constant matrices of proper dimensions.

We introduce the following assumptions for system (1) and (2)

- A.1) Under a continuous control $u(x, t)$, system (1) has a classical solution.
- A.2) The uncertainties Δf_1 and Δf_2 are bounded, continuous, and locally uniformly bounded with $|\Delta f_1(x_1, \eta_1, t)| \leq \rho_1(x_1)$, and $|\Delta f_2(x_1, x_2, \eta_2, t)| \leq \rho_2(x_1, x_2)$, for all η_1 and η_2 in some prescribed sets and for all (x_1, x_2, t) .
- A.3) For the functions g_i , there exist known continuous, positive definite functions β_i and nonnegative functions φ_i such that, for $i = 1, 2$ and for all $(x_1, x_2, u, \eta_1, \eta_2, t)$

$$\beta_1(|x_2|)(1 + \varphi_1(x_1, a_1 x_2, t)) \leq a_1 x_2 g_1(x_1, a_1 x_2, \eta_1, t),$$

$$\beta_2(|u|)(1 + \varphi_2(x_1, x_2, a_2 u, t)) \leq a_2 u g_2(x_1, x_2, a_2 u, \eta_2, t).$$

Moreover, there exist known continuous positive definite functions ϕ_i such that inequality $\beta_i(\phi_1(\phi_2)) \leq \phi_1 \phi_2 \phi_i$ holds for $i = 1, 2$ and for constants $\gamma_i \geq 0$ and $1 \leq \epsilon_i \leq 2$.

- A.4) The functions $g_i(\cdot)$ have the property that $g_1(x_1, a_1 x_2, \eta_1, t) = q_1(a_1)g_1(x_1, x_2, \eta_1, t)$ and $g_2(x_1, x_2, a_2 u, \eta_2, t) = q_2(a_2)g_2(x_1, x_2, u, \eta_2, t)$, where $q_1(\cdot)$ and $q_2(\cdot)$ are known, odd and normalized functions with $q_i(1) = 1$. The inverse functions of $q_i(\cdot)$ are assumed to be locally well defined. Moreover, $\partial g_1 / \partial x_2 \neq 0$ if $x_2 \neq 0$, and, if the sign of x_2 is fixed, the sign of the partial derivative is fixed as well for all x_1, η_1 and t .
- A.5) The functions in the system can be bounded by known functions that are uniformly bounded with respect to time and locally uniformly bounded with respect to the state. That is, for all $(x_1, x_2, u, \eta_1, \eta_2, t)$, $|f_1(x_1, t)| \leq \bar{f}_1(x_1)$, $|f_2(x_1, x_2, t)| \leq \bar{f}_2(x_1, x_2)$, $|g_1(x_1, a_1 x_2, \eta_1, t)| \leq \bar{g}_1(x_1, x_2)$, and $|g_2(x_1, x_2, a_2 u, \eta_2, t)| \leq \bar{g}_2(x_1, x_2, u)$. Also, the functions in the subsystem (1) are differentiable once and their partial derivatives are bounded by known functions as, for all $(x_1, x_2, u, \eta_1, \eta_2, t)$

$$\left| \frac{\partial f_1}{\partial t} \right| + \left| \frac{\partial \Delta f_1}{\partial t} \right| + \left| \frac{\partial g_1}{\partial t} \right| \leq \kappa_1(x_1, x_2),$$

$$\left| \frac{\partial f_1}{\partial x_1} \right| + \left| \frac{\partial \Delta f_1}{\partial x_1} \right| + \left| \frac{\partial g_1}{\partial x_1} \right| \leq \kappa_{11}(x_1, x_2, t),$$

$$\left| \frac{\partial g_1}{\partial x_2} \right| \leq \kappa_{12}(x_1, x_2, t).$$

It is worth mentioning that Assumptions A.1)–A.3) come directly from the generalized matching conditions [10]. Assumption A.4) is somewhat implied by Assumption A.3). Assumption A.5) is needed for identification of control directions. With these assumptions, we can proceed with continuous robust control design in the next section.

III. ROBUST CONTROL DESIGN

Along the line of nonlinear robust control design for uncertain systems, the main approach is Lyapunov's direct method together with using deterministic bounding functions for uncertainties. There are several classes of uncertain systems in [1], [3], [6], [9], [11] for which global stabilizing robust controllers have been found if bounding functions of uncertainties are available. One of the common features among these results is that stability analysis and especially generation of robust controller is done through a Lyapunov argument in which robust control is chosen to compensate for uncertainties by dominating them in both magnitude and sign. In those results, control directions are known in the sense that, after choosing robust controller, the sign of robust control determines the sign of the time derivative of the state and the Lyapunov function.

In this paper, robust design is studied for systems with unknown control direction. Like the existing results, the process of designing a successful robust control is to use the Lyapunov argument and the concept of control dominating unknown dynamics. Since control direction is unknown, an initial guess is made on control direction, and the robust control is designed whose direction is changed by a so-called shifting law. The key results in this study are that unknown control direction can be identified using the domination concept and that, since continuous control can produce a better transient response, smooth transition of the direction of robust control can be achieved. Intuitively, the basic idea emanates as following: begin with some guess a_1 of a_1 to design robust control in terms of \hat{a}_1 , and identify a_1 on line (both parts use the domination concept in a slightly different way); then formulate shifting laws \hat{a}_1 , so that robust control is continuous and guarantees global stability.

The following four-step procedure is used to design a continuous robust control without *a priori* knowledge of control direction: On-line identification of control directions, shifting laws, state transformation and robust control design using the recursive procedure in [10].

Step 1: The first step is to determine $\text{sign}[a_1]$ and $\text{sign}[a_2]$ on line. Without correct identification of these signs, any control will fail to ensure stability. As explained earlier, if a robust control works for a given uncertain system, the robust control must dominate the uncertainties in the system in both sign and magnitude. This domination provides us with a mean of determining the unknown control directions of the system.

Let us first investigate the subsystem (2). If the robust control u is designed properly, the function g_2 will dominate in magnitude and sign the uncertainty Δf_2 . Due to the unknown control direction a_2 , a successful robust control must identify the control direction, and the identification can be done by designing robust control such that the function g_2 dominates the control-unrelated part of dynamics, $f_2 + \Delta f_2$, that is, $|g_2(x_1, x_2, a_2 u, \eta_2, t)| \geq |f_2(x_1, x_2, t)| + |\Delta f_2(x_1, x_2, t)|$. This inequality can be guaranteed if u is chosen such that

$$g_2(x_1, x_2, |u|, \eta_2, t) \geq [\bar{f}_2(x_1, x_2) + \rho_2(x_1, x_2)]. \quad (3)$$

Note that, although the above inequality appears conservative for choosing robust control, the condition is necessary in the worst case that both the known and unknown dynamics f_2 and Δf_2 may be unstable and therefore, the control has to dominate.

Integrating both sides of (2) yields, for all $[t_1, t_2] \subset [t_0, t]$

$$x_2(t_2) - x_2(t_1) = \int_{t_1}^{t_2} [f_2(x_1, x_2, \tau) + \Delta f_2(x_1, x_2, \eta_2, \tau) + g_2(x_1, x_2, a_2 u, \eta_2, \tau)] d\tau.$$

Note that the integrand functions are all continuous. Under condition (3), it follows that, if $g_2(\cdot)$ does not change its sign for $\tau \in [t_1, t_2]$, $\text{sign}[x_2(t_2) - x_2(t_1)] = \text{sign}[g_2(x_1, x_2, a_2 u, \eta_2, \tau)]$. Using Assumptions A.3) and A.4) we have, for any $[t_1, t_2] \subset [t_0, t]$

$$\begin{aligned} \text{sign}[a_2] &= \text{sign}[g_2(a_2)] \\ &= \text{sign}[g_2(x_1, x_2, u, \eta_2, \tau)] \text{sign}[x_2(t_2) - x_2(t_1)] \\ &= \text{sign}[u(\tau)] \text{sign}[x_2(t_2) - x_2(t_1)] \quad \forall \tau \in [t_1, t_2] \end{aligned} \quad (4)$$

as long as condition (3) holds and $u(\tau)$ does not change its sign.

There are two important observations needed to be made about the identifications of $\text{sign}[a_2]$. First, since we can and have to choose robust control to dominate uncertainties to achieve stability, $\text{sign}[a_2]$ can be identified almost instantaneously after system (1) to (2) runs. Second, since a_2 is a scaled constant, its identification needs to be performed only once. That is, condition (3) is required to be true

only at one time instant. This makes it possible for us to smoothly transfer the robust control with potentially wrong control direction to that with correct control direction.

Applying the recursive design procedure introduced in [10], we can design robust control u through designing a fictitious control for subsystem (1), but the design of fictitious control requires identification of control direction $\text{sign}[a_1]$. Differentiating (1) yields

$$\begin{aligned} \ddot{x}_1 &= \left[\frac{\partial f_1}{\partial t} + \frac{\partial \Delta f_1}{\partial t} + \frac{\partial g_1}{\partial t} \right] + \left[\frac{\partial f_1}{\partial x_1} + \frac{\partial \Delta f_1}{\partial x_1} \right] \dot{x}_1 \\ &\quad + \left[\frac{\partial g_1}{\partial x_1} \dot{x}_1 + \frac{\partial g_1}{\partial x_2} \dot{x}_2 \right] \end{aligned}$$

which implies that, after substituting (1) and (2) into the above equation

$$\begin{aligned} \ddot{x}_1 &= h(x_1, x_2, \eta_1, \eta_2, t) + \frac{\partial g_1(x_1, a_1 x_2, \eta_1, t)}{\partial x_2} \\ &\quad \times g_2(x_1, x_2, a_2 u, \eta_2, t) \\ &= h(x_1, x_2, \eta_1, \eta_2, t) + q_1(a_1) q_2(a_2) \\ &\quad \times \frac{\partial g_1(x_1, x_2, \eta_1, t)}{\partial x_2} g_2(x_1, x_2, u, \eta_2, t) \end{aligned} \quad (5)$$

where function $h(\cdot)$ is defined and, by Assumption A.5), bounded as follows

$$\begin{aligned} &h(x_1, x_2, \eta_1, \eta_2, t) \\ &\triangleq \left[\frac{\partial f_1}{\partial t} + \frac{\partial \Delta f_1}{\partial t} + \frac{\partial g_1}{\partial t} \right] + \left[\frac{\partial f_1}{\partial x_1} + \frac{\partial \Delta f_1}{\partial x_1} + \frac{\partial g_1}{\partial x_1} \right] \\ &\quad \times (f_1 + \Delta f_1 + g_1) + \frac{\partial g_1}{\partial x_2} (f_2 + \Delta f_2). \\ &|h(x_1, x_2, \eta_1, \eta_2, t)| \\ &\leq h_1(x_1, x_2) + h_{x_1}(x_1, x_2) [\bar{f}_1(x_1) + \rho_1(x_1) + \bar{g}_1(x_1, x_2)] \\ &\quad + h_{x_2}(x_1, x_2) [\bar{f}_2(x_1, x_2) + \rho_2(x_1, x_2)] \triangleq \bar{h}(x_1, x_2). \end{aligned}$$

Similar to the process of determining $\text{sign}[a_2]$, we can find $\text{sign}[a_1]$ if robust control u is designed such that the sign of right hand side of (5) is decided through domination by the term containing $g_2(\cdot)$. That is, robust control is designed such that

$$\begin{aligned} &|g_2(x_1, x_2, a_2 u, \eta_2, t)| \\ &\geq \left[\frac{\partial g_1(x_1, a_1 x_2, \eta_1, t)}{\partial x_2} \right]^{-1} h(x_1, x_2, \eta_1, \eta_2, t) \end{aligned}$$

or more conservatively

$$g_2(x_1, x_2, |u|, \eta_2, t) \geq \left| \frac{\partial g_1}{\partial x_2} \right|^{-1} \bar{h}(x_1, x_2). \quad (6)$$

Recall from Assumptions A.3)–A.4) that $g_2(x_1, x_2, u, \eta_2, t)$ has the same sign as that of u . Under condition (6), we know from (5) that \ddot{x}_1 has the same sign as that of $q_1(a_1) q_2(a_2) u [\partial g_1(x_1, x_2, \eta_1, t) / \partial x_2]$. Then, over any time interval in which u and $\partial g_1 / \partial x_2$ do not change their sign, the sign of \ddot{x}_1 is fixed, which in turn implies that the solution x_1 has a fixed concavity or convexity. Hence, it follows from this geometric property that

$$\begin{aligned} \text{sign} \left[\frac{x_1(t_1) + x_1(t_2)}{2} - x_1 \left(\frac{t_1 + t_2}{2} \right) \right] &= \text{sign}[\ddot{x}_1(\tau)] \\ &\quad \forall t_1 \leq \tau \leq t_2. \end{aligned}$$

Thus, we have that, whenever no sign change occurs over the interval $t_1 \leq \tau \leq t_2$ for $u(\tau)$ and $\partial g_1(x_1, x_2, \eta_1, \tau)/\partial x_2$

$$\begin{aligned} \text{sign}[a_1] = & \text{sign}[a_2] \text{sign} \left[\frac{x_1(t_1) + x_1(t_2)}{2} - x_1 \left(\frac{t_1 + t_2}{2} \right) \right] \\ & \times \text{sign}[u(\tau)] \text{sign} \left[\frac{\partial g_1(x_1, x_2, \eta_1, \tau)}{\partial x_2} \right] \end{aligned} \quad (7)$$

provided that condition (6) holds. The Eqs. (7) and (4) show how to identify on line the control directions. Once the $\text{sign}[a_i]$ are determined, they can be used to construct the so-called shifting laws which direct continuously (fictitious) robust controls with guessed control directions to those with correct control directions. This will be done in the next step.

It may appear from (5) or (6) that there is a singularity problem when $|\partial g_1/\partial x_2|$ becomes arbitrarily small. Although this singularity problem does make it impossible for us to choose robust control u to satisfy (6) at the time instant that singularity occurs, it does not present any obstacle for identification of control direction a_1 . This is because condition (6) needs to hold only for a very small period of time and because singularity cannot present persistently since u chosen to dominate uncertainties and known dynamics will cause x_2 to increase in magnitude. This reasoning will become much more obvious after we state robust control laws and basic stability analysis. Thus for now, we proceed with our analysis by assuming

$$\left| \frac{\partial g_1}{\partial x_2} \right| > C_n \quad (8)$$

where C_n is a constant chosen by the designer.

Step 2: After both $\text{sign}[a_i]$ are determined, one has two options to implement robust control. The first option is to change the directions \hat{a}_i of robust controls instantaneously (at most once for each direction) to the correct values. If this option is adopted, the results in [10] can be readily applied to generate robust control and to conclude global stability. Since instantaneous changes of signs exist only in theory, sign changes should be implemented as fast as possible. Although this option is used sometimes in practice, it is not our choice because of the following problems. First, it is unclear how fast the change of control directions must be to ensure stability. Second, the rate of change of control directions is usually limited by control bandwidth and, even if possible, sign change being very fast is not desirable since it may excite high-frequency dynamics neglected in the course of modelling.

Our choice, the second option, is to transfer robust controls smoothly from possibly wrongly guessed control directions to the identified, correct control directions, which will be accomplished by formulating shifting laws. It will be shown that, as long as direction-independent robust control laws u_r and w_r are designed properly and implemented, global stability is guaranteed no matter what time constants and gains of the shifting laws are. This result provides a theoretical guarantee of the freedom for the designer to choose the gains in the shifting laws to achieve good transient performance. In fact, our choice gives a complete answer to the stability question posed for the first option. That is, in order not to cause saturation of actuators or to excite unmodeled dynamics while avoiding large overshoot of the state, shifting laws should be chosen such that their gains are reasonably large but not too large.

Let the initial guesses of the control directions a_1 and a_2 be denoted by $\hat{a}_1(t_0)$ and $\hat{a}_2(t_0)$, then the shifting laws are given by

$$\begin{aligned} \dot{c}_1 = & \begin{cases} 0 & \text{until condition} \\ -k_s c_1 - k_m \text{sign}[c_1] |\bar{g}_1(x_1, w_r)| & \text{(8) becomes valid} \\ & \text{thereafter} \end{cases} \quad (9) \\ \dot{c}_2 = & -k_s c_2 - k_m \text{sign}[c_2] |\bar{g}_2(x_1, x_2, w_r)| \quad (10) \end{aligned}$$

where $|\hat{a}_i(t_0)| = 1$, $c_i \triangleq \hat{b}_i - a_i$, $\hat{b}_i \triangleq g_i(\hat{a}_i)$, the variables \hat{a}_i and w_r will be chosen in steps three and four, $\bar{g}_1 \triangleq q_2^{-1}(\hat{b}_2) \cdot g_1^{-1}(\cdot)$ represents the inverse function of g_1 , $k_s, k_m > 0$ are the gains of the shifting laws, and $1/L$ is a positive constant. Both k_s and k_m can be freely chosen by the designer. The variables $\hat{a}_i(t)$ will be used as multipliers in robust control laws. The above shifting laws require identification results from (7) and (3). The initial values $|\hat{a}_i(t_0)| = 1$, as well as the part of setting $\hat{b}_1 = 0$ in (9), are chosen such that domination of robust controls with \hat{a}_i are in effect at least initially to perform identification of control directions. The choices of (9) and (10) are made so that, as will be shown in the proof, stability is warranted during the transition of control directions of robust controls.

In the subsequent design and analysis, the state will be shown to be uniformly bounded. More importantly, it is worth noting that, even though a large control of the wrong sign may be applied, the transient response of the state will not have a very large magnitude. This can be seen from the following facts. First, the singularity region is small in the state space. Second, whenever the state escapes from the singularity region, sign identification is almost instantaneous. Third, the shifting laws makes c_i converge to zero exponentially (and possibly in finite time); robust control will have the corrected sign whenever $|c_1| < 1$ and $|c_2| < 1$; and, in a finite time interval that can be made arbitrarily small by adjusting k_s , $|c_i|$ will be small enough so that robust control has its full strength. This implies that the temporary but adverse effect of large control of the wrong sign on the state can be minimized by choosing a reasonably large k_s .

Step 3: In this step, state transformation is performed to introduce a fictitious control variable w . This allows us to design robust control u recursively and to facilitate stability proof.

Let x_1^d be a bounded, smooth desired trajectory for the output x_1 of the system to track. Based on x_1^d and $x_1(0)$, we choose a smooth "perturbed desired" trajectory y_d to avoid singularity. The exact way of choosing y_d will be explained in step 4. Define the new state $z_1 = x_1 - y_d$, then (1) can be rewritten as

$$\begin{aligned} \dot{z}_1 = & f_1(x_1, t) + \Delta f_1(x_1, \eta_1, t) + g_1(x_1, a_1 x_2, \eta_1, t) - \dot{y}_d \\ = & -k z_1 + \Delta f_1'(z_1, x_1, \eta_1, t) + g_1(x_1, a_1 w, \eta_1, t) \\ & + [g_1(x_1, a_1 x_2, \eta_1, t) - g_1(x_1, a_1 w, \eta_1, t)] \end{aligned} \quad (11)$$

where $k > 0$ is a feedback gain chosen to be the designer, and the lumped uncertainty $\Delta f_1'(\cdot)$ is $\Delta f_1'(z_1, x_1, \eta_1, t) = f_1(x_1, t) + \Delta f_1(x_1, \eta_1, t) + k z_1 - \dot{y}_d$. Similar to classical observer design, k should be selected such that $k_s > k$ for good transient performance. It follows that

$$\begin{aligned} |\Delta f_1'(z_1, x_1, \eta_1, t)| & \leq \bar{f}_1(x_1) + \rho_1(x_1) + 0.5(1 + k^2 z_1^2) + |\dot{y}_d| \\ & \triangleq \rho_1'(z_1, x_1). \end{aligned}$$

It also follows that there exists a known function $\psi(\cdot)$ such that

$$|g_1(x_1, a_1 x_2, \eta_1, t) - g_1(x_1, a_1 w, \eta_1, t)| \leq |x_2 - w| \psi(x_1, x_2, w).$$

The choice of fictitious control w will be done in the next step. It will be shown that $w = w(x_1, z_1, \hat{a}_1)$. Now, define the second new state $z_2 = x_2 - w$. Then, we can rewrite (2) as

$$\begin{aligned} \dot{z}_2 = & f_2(x_1, x_2, t) + \Delta f_2(x_1, x_2, \eta_2, t) \\ & - \dot{w} + g_2(x_1, x_2, a_2 u, \eta_2, t) \\ \triangleq & -k z_2 - \psi(x_1, x_2, w) |z_1| \text{sign}[z_2] \\ & + \Delta f_2'(z_1, x_1, z_2, x_2, w, \eta_2, t) \\ & + g_2(x_1, x_2, a_2 u, \eta_2, t) \end{aligned} \quad (12)$$

where the "lumped uncertainty" is $\Delta f_2'(z_1, x_1, z_2, x_2, w, \eta_2, t) = f_2(x_1, x_2, t) + \Delta f_2(x_1, x_2, \eta_2, t) + k z_2 + \psi(x_1, x_2, w) |z_1| \text{sign}[z_2]$

— \dot{u}_2 . The uncertainty can be bounded by a known function $\rho'_2(\cdot)$ as

$$\begin{aligned} & |\Delta f'_2(z_1, x_1, z_2, x_2, w, \eta_2, t)| \\ & \leq \bar{f}_2(x_1, x_2) + \rho_2(x_1, x_2) \\ & + 0.5(1 + k^2 z_2^2) + \psi(x_1, x_2, w) |z_1| \\ & + \left| \frac{\partial w}{\partial \hat{a}_1} \right| \cdot |\dot{\hat{a}}_1| + \left| \frac{\partial w}{\partial z_1} \right| \cdot |z_1| \\ & + \left| \frac{\partial w}{\partial x_1} \right| \cdot |\dot{x}_1| \leq \rho'_2(z_1, x_1, z_2, x_2) \end{aligned} \quad (13)$$

where $|z_1|$, $|\dot{x}_1|$ and $|\dot{\hat{a}}_1|$ can be easily bounded, and the partial derivatives of w with respect to its arguments can be bounded as well after w is explicitly designed in the next step. It has been shown in [10] that bounding functions and robust control can be made differentiable. Therefore, the bounding function $\rho'_2(\cdot)$ in (13) can be found.

Step 4: In this step, robust control u and fictitious control w are designed to guarantee global stability. Based on stability analysis presented in the appendix, they are chosen respectively to be of the form

$$w(z_1, x_1, \hat{a}_1) = -\hat{a}_1 \varrho_1(z_1, x_1) \phi_1(\rho''_1(z_1, x_1)) \triangleq -\hat{a}_1 w_1 \quad (14)$$

$$\begin{aligned} u(z_1, x_1, z_2, x_2, \hat{a}_2) &= -\hat{a}_2 \varrho_2(z_1, x_1, z_2, x_2) \\ &\quad \times \phi_2(\rho''_2(z_1, x_1, z_2, x_2)) \\ &\triangleq -\hat{a}_2 u_1 \end{aligned} \quad (15)$$

where

$$\begin{aligned} \varrho_1(z_1, x_1) &\triangleq \frac{\mu_1^2(z_1, x_1) + \epsilon^2}{|\mu_1(z_1, x_1)|^3 + \epsilon^3} \mu_1(z_1, x_1), \\ \mu_1(z_1, x_1) &= z_1 \rho''_1(z_1, x_1) \\ \varrho_2(z_1, x_1, z_2, x_2) &\triangleq \frac{\mu_2^2(z_1, x_1, z_2, x_2) + \epsilon^2}{|\mu_2(z_1, x_1, z_2, x_2)|^3 + \epsilon^3} \\ &\quad \times \mu_2(z_1, x_1, z_2, x_2), \\ \mu_2(z_1, x_1, z_2, x_2) &= z_2 \rho''_2(z_1, x_1, z_2, x_2) \end{aligned}$$

where $\phi_1(\cdot)$ and $\phi_2(\cdot)$ are functions defined in Assumption A.3), $\epsilon > 0$ is a design parameter. Note that $|\varrho_i| \leq 2$ and, if $|\mu_i| \geq \epsilon$, $|\varrho_i| \geq 1$. The bounding functions $\rho''_1(\cdot)$ and $\rho''_2(\cdot)$ should be chosen to be continuous and to satisfy the following conditions

$$\rho''_1(z_1, x_1) \geq \rho'_1(z_1, x_1), \quad \rho''_1(z_1, x_1)|_{t=t_0} \neq 0,$$

$$\rho''_2(z_1, x_1)|_{t=t_0} \neq 0,$$

$$\rho''_2(z_1, x_1, z_2, x_2) \geq \max \left\{ \rho'_2(z_1, x_1, z_2, x_2), \left[\bar{f}_2(x_1, x_2) + \rho_2(x_1, x_2) \right], \frac{\bar{h}(x_1, x_2)}{C_a} \right\}.$$

Implementation of the above robust controllers requires identification of control directions by domination. The domination can be ensured by choosing y_d and ϵ as follows. First, select $y_d(t_0)$ such that $z_2(t_0) \neq 0$ (which can be done by adjusting $z_1(t_0)$ through choosing y_d). Then, it follows that, at time t_0 , robust control u is nonzero. Note that $|\hat{a}_2(t_0)| = 1$. Also note that ϵ can be chosen freely and that, as will be shown later, the smaller ϵ the better the tracking performance. Thus, we can choose ϵ such that, at time $t = t_0$, $|\mu_2(z_1, x_1, z_2, x_2)| > \epsilon$, which implies that $1 \leq |\varrho_2(z_1, x_1, z_2, x_2)| \leq 2$ at time t_0 . Therefore, we know from Assumption A.3) that

$$\begin{aligned} g_2(x_1, x_2, |u|, \eta_2, t) &\geq \frac{\beta_2(|u|)}{|u|} = \frac{\beta_2(\varrho_2 \phi_2(\rho''_2))}{|u|} \\ &\geq \frac{\varrho_2 \phi_2(\rho''_2) \rho''_2}{|u|} = \rho''_2(z_1, x_1, z_2, x_2) \end{aligned}$$

which, based on the choice of $\rho''_2(\cdot)$, guarantees both inequalities (6) and (3). And these two inequalities can always be satisfied for any finite interval if ϵ is small and if $y_d(t)$ is perturbed from $x'_d(t)$ such that $z_2(t)$ is not zero in that interval. This concludes the four-step process of designing smooth robust control law.

Global stability of the system under robust control laws and shifting laws are analyzed by Lyapunov's direct method using Lyapunov function $L(z_1, z_2, \hat{a}_1, \hat{a}_2) = L_1(z_1, \hat{a}_1) + L_2(z_2, \hat{a}_2)$ where

$$L_1(z_1, \hat{a}_1) = z_1^2 + z_2^2,$$

$$L_2(z_2, \hat{a}_2) = \frac{1}{k_m} (a_1 q_1(\hat{a}_1) - 1)^2 + \frac{1}{k_m} (a_2 q_2(\hat{a}_2) - 1)^2. \quad (16)$$

The following theorem guarantees global uniform ultimate boundedness of the system in the form of (11) to (12). The proof can be found in the Appendix.

Theorem. Suppose that condition (8) is valid. Then, under the robust control laws (14) and (15) together with the shifting laws (9) and (10), the state of system (11) to (12) is globally uniformly ultimately bounded. Moreover, the system output x_1 tracks any smooth, bounded desired trajectory $x'_d(t)$ with error that can be made arbitrarily small in the sense that

$$\limsup_{t \rightarrow \infty} |x_1(\tau) - x'_d(\tau)| \leq \sqrt{\frac{2\epsilon k_m + \delta}{k k_m}}.$$

Although the above theorem excludes the singularity problem in its statement, one can extend the result of the theorem to a more general case through the following argument. First, nonsingularity condition (8) needs to be valid only for one instant or a small period of time. Second, C_a is a design parameter and can be made smaller to make singularity region in the state space smaller. Third, since uncertainties as well as known dynamics are bounded by well defined functions, \dot{x}_1 is finite at time t_0 for any initial conditions. Thus, when the system does start in the singularity region, robust control u dominates all dynamics and therefore, by choosing a small enough C_a , can make $|x_2|$ large and out of the singularity region quickly enough to identify the control directions. One may argue that this scheme does not work when subsystem (1) has arbitrarily small finite escape time if the state starts in the singularity region. However, the case does not exist since it contradicts \dot{x}_1 being finite. And, if this case would exist, there is no control, continuous or discontinuous, of finite magnitude that can stabilize the whole system.

Illustrative Example

Consider the following second-order nonlinear system

$$\dot{x}_1 = a_1^1 x_2^1 + \Delta f, \quad \dot{x}_2 = a_2 x_1 u$$

where the uncertainty $\Delta f = x_1^2 \cos(t) + 0.5 \sin(0.5t)$. Robust controls (14) and (15) are chosen with the design parameters $\epsilon = 0.1$, $k = 2$, $C_a = 0.2$, and with the following bounding functions

$$\rho''_1 = \rho'_1 = x_1^2 + 0.5 + \frac{k}{2}(1 + z_1^2),$$

$$\rho''_2 = \max \left\{ \rho'_2, \frac{\bar{h}}{3x_2^2} \right\},$$

$$\bar{h} = 0.25 + 2|x_1|(x_1^2 + 0.25 + |x_2|^4),$$

$$\begin{aligned} \rho'_2 &= k|z_2| + |z_1|z_2^2 + 12 \frac{\mu_1^2 + \epsilon_1^2}{|\mu_1|^3 + \epsilon_1^3} \rho_1'^2 [0.25 + x_1^2 + |a_1|^4 |x_2|^4] \\ &\quad + \left[\frac{\mu_1^2 + \epsilon_1^2}{|\mu_1|^3 + \epsilon_1^3} |z_1| \rho_1'^2 \right]^4 |z_1| \\ &\quad + \frac{k}{|a_1|^4} |a_1^1 \hat{a}_1^1 - 1| \left[\frac{\mu_1^2 + \epsilon_1^2}{|\mu_1|^3 + \epsilon_1^3} |z_1| \rho_1'^2 \right]. \end{aligned}$$

Fig 1 Robust control with $k = 10$ and $k = 1$

Fig 2 Robust control with $k = 5$ and $k = 0.1$

The simulation was carried out using SIMMON[©] with the following choices (1) desired trajectory is $y^T = x^T = 0$ (2) initial conditions are $x_1(0) = x_2(0) = 1$ $a_1(t_0) = -1$ $a_2(t_0) = 1$ (3) unknown control directions are chosen to be $a_1 = 1$ and $a_2 = -1$

The simulation results of the states and the shifting laws are shown in Figs. 1 and 2 respectively for two sets of choices k and k . It should be noted that there is no large overshoot in the state during and after sign identification.

IV. CONCLUSION

Robust output tracking control of a class of nonlinear uncertain systems is studied. A system in the class satisfies the generalized matching conditions but contains one or several parameters of unknown signs used to characterize control directions. Without *a priori* knowledge of control directions, a four step design procedure is proposed which consists of identification of control directions and construction of robust controls and shifting laws. The system may contain nonlinear uncertainties, and both continuous and discontinuous robust control can be designed using only bounding functions

of unknown dynamics. Under the condition that the subsystem(s) not directly controlled has no arbitrarily small finite escape time, the proposed robust control guarantees global uniform ultimate bounded stability with arbitrarily small ultimate output tracking error.

APPENDIX

Proof of the Theorem Taking the time derivative of $I_1(t)$ in (16) along the trajectory of system (11) and (12) under control (14) and (15) we get

$$\begin{aligned} \dot{I}_1 = & 2 \{ -k_1 + \Delta f'_1(x_1, x_2, u, \eta, t) + g_1(x_1, x_2, u, \eta, t) \\ & + [q_1(x_1, x_2, u, \eta, t) - q_1(x_1, x_2, u, \eta, t)] \} \\ & + 2 \{ -k_2 - \epsilon(x_1, x_2, u) | \text{sign}[\cdot] | \\ & + \Delta f'_2(x_1, x_2, u, \eta, t) + q_2(x_1, x_2, u, \eta, t) \} \\ \leq & -2k_1 L_1(x_1, x_2) + 2|\mu_1(x_1, x_2)| + 2|\mu_2(x_1, x_2)| \\ & + 2|q_1(x_1, x_2, u, \eta, t)| + 2|q_2(x_1, x_2, u, \eta, t)| \\ & + 2|-\epsilon| |q_1(x_1, x_2, u, \eta, t)| + 2|-\epsilon| |q_2(x_1, x_2, u, \eta, t)| \end{aligned}$$

Using the same arguments in [10], one can show by Assumption A.3) that $z_i g_i(\cdot) \leq 0$ and that, if $|\mu_i(\cdot)| > \epsilon$, $z_i g_i(\cdot) \leq -|\mu_i(\cdot)|$ for $i = 1, 2$. Therefore, we have that, for all (z_i, x_i, t)

$$\begin{aligned} \dot{L}_1 \leq & -2kL_1 + 4\epsilon + 2|z_1|c_1|\bar{g}_1(x_1, w_1) \\ & + 2|z_2|c_2|\bar{g}_2(x_1, x_2, u_1). \end{aligned} \quad (17)$$

Now we proceed by taking the time derivative of L_2 in (16) along shifting law (9) and (10). It follows from $\text{sign}[g_i(a_i)] = q_i(a_i) = a_i$ that

$$\begin{aligned} \dot{L}_2(\hat{a}_1, \hat{a}_2) = & \frac{2}{k_m} a_1(a_1 q_1(\hat{a}_1) - 1)\dot{r}_1 + \frac{2}{k_m} a_2(a_2 q_2(\hat{a}_2) - 1)\dot{r}_2 \\ \leq & -2\frac{k_s}{k_m} L_2(\hat{a}_1, \hat{a}_2) - 2|z_1|c_1|\bar{g}_1(x_1, w_1) \\ & - 2|z_2|c_2|\bar{g}_2(x_1, x_2, u_1). \end{aligned}$$

Combining the above inequality with (17) we have that, for all (x_1, z_1, x_2, z_2, t) , $\dot{L}_1 + \dot{L}_2 \leq -2kL_1 - 2k_s L_2/k_m + 4\epsilon$. The above inequality shows that the state of system (11) to (12) is globally uniformly ultimately bounded. Solving the inequality and noting that $|\hat{a}_i(0)| = 1$, we can show the ultimate bound on the output tracking error in the statement of the theorem.

On the Ordering of Optimal Hedging Points in a Class of Manufacturing Flow Control Models

George Liberopoulos and Jian-Qiang Hu

Abstract—The optimal flow control policy of a single-product unreliable manufacturing system that must meet a constant demand rate is known to be a threshold type policy: safety production surplus levels called hedging points (thresholds) are associated with each discrete stochastic capacity state of the system and serve to protect the production process from uncertainty in future capacity availability. This correspondence extends and generalizes previous results on the ordering of optimal hedging points. Our method is based on examining special properties of the Bellman optimality conditions of the underlying stochastic control problem.

1. INTRODUCTION

Manufacturing flow control models address the dynamic allocation of stochastic capacity among competing products in a just in time manufacturing environment. Several of these models assume that medium-term demand rates for a number of products are constant, while short-term production rates are continuous over time and must live within capacity constraints. These constraints are dictated by the configuration of operational machines in the manufacturing system modeled. When the state of machines (e.g., operational/failed) changes at random points in time, optimal policies are characterized by generally intractable dynamic programming Bellman equations [1]. To date, most analytical manufacturing flow control models have assumed that the machine state process is homogeneous and uncontrolled, implying that the failure rate of a machine does not depend on its production rate or its age, i.e., how long that machine has been operational since its most recent failure.

Akella and Kumar [2] were the first to perform rigorous analysis on a one-product, one-machine (with two machine states, up and down) manufacturing system with a discounted cost criterion. For the same system, but with a long-run average cost criterion, Bielecki and Kumar [4] derived the steady state probability distribution of production surplus. Sharifnia [17] extended this approach to one-product, multiple-machine-state systems, and Algoet [3] derived partial differential equations for the joint steady state probability density function of production surplus for multiple-product systems, but did not solve these equations. Caramanis and Sharifnia [5] used the results of [17] to design near optimal control policies for multiple-product systems by decomposing them to many analytically tractable one-product systems. Malhamé and Boukas [13] and Malhamé [14] demonstrated the Markov renewal nature of one-product manufacturing systems under hedging point policies and studied the ergodicity of such policies. Liberopoulos and Caramanis [12], Hu *et al.* [7], and Yu and Vakili [19] explored the optimal control structure for one-product systems with production dependent failure rates. Hu and Xiang [8] demonstrated the equivalence of a one-product, two-machine-state manufacturing system with a queueing system. Hu and Xiang [9], [10] showed that the ordering of optimal hedging points of certain one-product systems can be found analytically. Sethi *et al.* [16] analyzed the structure of turnpike sets that characterize optimal production

surplus levels when the demand is a Markov chain; they showed that the turnpike sets exhibit a monotone property with respect to capacity and demand. A more comprehensive list of references on manufacturing flow control may be found in a recently published book by Gershwin [6].

A key feature of the optimal control structure common to all models is the hedging point. A hedging point is a production surplus threshold level associated with each discrete machine state i , toward which the production surplus must be guided as quickly as possible while the machine state remains fixed at i . A hedging point is also referred to as a safety or buffer production surplus and is carried to protect the production process from the uncertainty in future capacity availability or other uncertainties (e.g., demand and processing time).

This correspondence mainly deals with systems similar to those studied in [14], [17], having one product with constant demand rate, and many machine states with constant transition rates. It is known that apart from a one-product, two-machine-state system [2], [4], it is practically impossible to derive explicit expressions for the optimal hedging points. With this in mind, the goal of this correspondence is to uncover properties on the relative ordering of optimal hedging points. Such properties have many important applications. They can be used to develop simple numerical and heuristic methods for obtaining optimal or near-optimal control policies, since they dramatically reduce the search space of optimal hedging points. Also, for systems where machine state transition rates are age dependent (age being the time elapsed since the most recent machine state change), they can be used to study properties of the corresponding optimal age dependent hedging curves or turnpikes. This can be done by approximating age dependent transition time distributions with phase type distributions, each phase having associated with it a hedging point. This correspondence extends and generalizes results reported by Hu and Xiang [9], [10], who showed that for some special systems optimal hedging points are ordered monotonically. The method we use to establish the relative ordering of optimal hedging points is based on the Hamilton–Jacobi–Bellman optimality conditions of the underlying stochastic control problem.

The remaining of the correspondence is organized as follows. In Section II the manufacturing flow control problem is formulated as an optimal control problem whose optimality conditions are given by a set of Hamilton–Jacobi–Bellman equations. In Section III certain properties on the ordering of optimal hedging points are derived based on ensuring consistency of signs on both sides of the derivative of the Hamilton–Jacobi–Bellman equation. In Section IV these properties are applied to several special systems, and in Section V several issues and extensions are discussed.

II. THE MANUFACTURING FLOW CONTROL MODEL

We consider a manufacturing system with the following features [17]:

- 1) The system produces a single part-type for which there is a constant demand rate denoted d .
- 2) The capacity state (also called machine state) of the system is an finite-state continuous-time irreducible Markov chain denoted $\alpha(t)$, with state space S .
- 3) The production rate of the system at time t , denoted $u(t)$, must belong to the closed interval $U_{\alpha(t)} = \{u: 0 \leq u \leq r_{\alpha(t)}\}$, where r_i is the maximum production rate of the system at machine state $i \in S$.
- 4) The production surplus of the system at time t , denoted $x(t)$, is the difference between the cumulative production and cumulative demand up to time t .
- 5) The production surplus cost rate, denoted $g(x)$, is a strictly convex function in x and has a unique minimum at x^* which implies

that $g(x) \rightarrow \infty$ as $x \rightarrow \pm\infty$; $g(x)$ represents the (per unit, backlog) cost when x is positive (respectively, backlog).

- 6) The transition time from machine state i to machine state j is exponentially distributed with constant transition rate $q(i, j)$, $i, j \in S$, with $q(i, i) = -\sum_{j \neq i} q(i, j) \in \mathbb{N}$, $0, i \neq j$ and $q(i, i) < 0, i \in S$.

The last feature implies that the machine state process $\{\alpha(t), t \geq 0\}$ is homogeneous and uncontrolled. With this in mind, $\{x(t), \alpha(t), t \geq 0\}$ is a stochastic process characterized by the following differential equation:

$$dx(t)/dt = u(t) - d, \quad \text{s.t. } 0 \leq u(t) \leq r_{\alpha(t)} \quad (1)$$

The objective is to find optimal production rates $u_i^*(x) \in U_i$ to minimize the long-run expected average cost

$$J = \lim_{t \rightarrow \infty} E \left\{ (1/t) \int_0^t g(x(s)) ds \right\}. \quad (2)$$

For the above limit to exist it is assumed that in the long-run the demand is strictly feasible, i.e., that the demand is less than the equilibrium mean of the capacity process. Under suitable regularity conditions imposed on the control [15],¹ the optimal feedback control of the system is characterized by the following Hamilton–Jacobi–Bellman (HJB) dynamic programming equation [6]:

$$J^* = g(x) + \min_{u \in U_{\alpha(x)}} \{V'_{\alpha(x)}(x)(u - d)\} + \sum_{i \neq \alpha(x)} q(i, \alpha(x)) [V_i(x) - V_{\alpha(x)}], \quad x \in S, \quad (3)$$

where $J^* = \inf_{\{u_i(\cdot)\}} J$, $V_i(x)$ is the optimal value or differential cost-to-go function starting from state (i, x) , and $'$ denotes the derivative w.r.t. x . According to (3), the optimal production rate $u_i^*(x)$ satisfies $u_i^*(x) = \arg \min \{V'_{\alpha(x)}(x)u: 0 \leq u \leq r_i\}$.

Theorem 1: $V_i(x)$ is strictly convex in x and has a unique minimum at $x_i^*, i \in S$.

Proof Outline The proof that $V_i(x)$ is strictly convex is similar to that of Theorem 5.1 in [18] and we shall omit it. We only note, however, that the strict convexity of $V_i(x)$ follows from the strict convexity of $g(x)$ and the convexity of the sets $U_i, i \in S$. In fact, exact solution of $V_i(x)$ for small systems [2], [4], [16] suggests that the value function may be strictly convex even if $g(x)$ is not strictly convex. For the results obtained in [18] to hold, it must be assumed that under any admissible control law some state (x_0, k) is a regeneration point of the process $\{x(t), \alpha(t)\}$ (for example k may be any machine state and x_0 any point such that $x_0 \leq x^*$). Denote by T_n successive visit (regeneration) times to (x_0, k) . The value $V_i(x)$ is well defined for regenerative control laws as

$$V_i(x) = \min_{\{u_i(\cdot)\}} E \left\{ \int_0^{T_1} (g(x(s)) - J) ds \mid x(0) = x, \alpha(0) = i \right\}. \quad (4)$$

That $V_i(x)$ has a unique minimum then follows from its strict convexity and the fact that $g(x) \rightarrow \infty$ as $x \rightarrow \pm\infty$, since, by (4) this fact implies that $V_i(x) \rightarrow \infty$ as $x \rightarrow \pm\infty$. Q.E.D.

Theorem 1 implies that

$$\begin{aligned} V'_i(x) &> 0, & V''_i(x) &> 0 & \text{for } x > x_i^*, \\ V'_i(x) &< 0, & V''_i(x) &> 0 & \text{for } x < x_i^*. \end{aligned} \quad (5)$$

In view of the above, the optimal control policy is given by,

$$u_i^*(x) = \begin{cases} r_i & \text{if } x < x_i^*, \\ \min(d, r_i) & \text{if } x = x_i^*, \\ 0 & \text{if } x > x_i^*. \end{cases} \quad (6)$$

¹As we consider the infinite horizon case we also require that admissible control laws be restricted to those for which the process $\{x(t), \alpha(t)\}$ is asymptotically stationary ergodic.

Point z_i is known as the optimal hedging point associated with machine state i . Unfortunately, the value of the $z_i, i \in S$, can not be explicitly calculated except for a system with one machine that dwells in two states (up and down) [2], [4]. For systems with more than two machine states, however, the optimal hedging points can be obtained numerically: first, the long-run average cost can be computed for each tentative choice of hedging points, $z_i, i \in S$, as follows:

$$J^* = E[g(x)] = \int_{-\infty}^{+\infty} g(x)f^*(x)dx,$$

where $f^*(x)$ is the steady-state probability density function of x and is readily available as an implicit function of the $z_i, i \in S$ [17]. Then, the optimal values of the z_i can be found numerically by minimizing J^* using a gradient search algorithm.

III. HEDGING POINT ORDERING PROPERTIES

Recognizing that it is practically impossible to derive explicit expressions for the optimal hedging points, we instead seek to uncover properties of the relative ordering of hedging points. To this end, we assume that the function $V_i(x), i \in S$, exist and are continuously differentiable,² and that the optimal control is characterized by (3). If $V_i(x), i \in S$, is continuously differentiable, $V_i''(x)$ is defined almost everywhere (except possibly at z_i and the points where $g'(x)$ is not defined). Differentiating (3) w.r.t. x yields

$$0 = g'(x) + V_i''(x)(u_i^*(x) - d) + \sum_{j \neq i} q(i, j)[V_j'(x) - V_i'(x)], \quad \text{a.e. } i \in S. \quad (7)$$

The proofs of the properties that follow are based on ensuring consistency of signs of quantities appearing on both sides of (7). Namely, the right-hand side of (7) cannot be strictly positive (or negative), since the left-hand side is 0.

In what follows it is assumed that $r_i \neq d$, for all $i \in S$. This assumption simplifies matters but is not essential. Under this assumption, there are two types of machine states, feasible and infeasible. State i is called feasible if $r_i > d$, and infeasible if $r_i < d$.

Moreover, it is assumed that there is at least one infeasible machine state. Otherwise, d can be met at all times, and there is no need to hedge beyond x^* , the minimizer of $g(x)$. If all states are feasible, all hedging points are equal to x^* .

Property 1: $x^* \leq \min_{k \in S} \{z_k\}$.

Proof: Suppose the opposite is true, i.e., suppose that $x^* > z_i = \min_{k \in S} \{z_k\}$. Then, for $x = z_i^+$, the first two terms on the right-hand side of (7) are strictly negative, the terms in the summation are nonpositive, whereas the left-hand side is 0. Therefore, $x^* > \min_{k \in S} \{z_k\}$ cannot be true. Q.E.D.

In most manufacturing systems $x^* = 0$, i.e., the cost rate is minimum when there is neither positive (inventory) nor negative (backlog) production surplus. In these cases, Property 1 states that safety production surplus levels must always be nonnegative.

In most of the work reported to date [17], [13], [14] it has been assumed, without proof, that optimal hedging points associated with infeasible machine states are larger than the largest of the hedging points associated with feasible machine states. This means that in infeasible machine states it is best to always produce at the maximum allowable rate. Although intuitively this seems reasonable, it has yet to be proved; however, we can show the following properties.

²For $V_i(x)$ to be continuously differentiable, one must further assume that $g(x)$ is Lipschitz continuous. Continuous differentiability of the $V_i(x)$ has been proved for special manufacturing flow systems [2], [4] with piece-wise constant cost rate function, as well as general piece-wise deterministic systems with jump Markov disturbances [15]; it has also been proved for systems with random demand [16].

Fig. 1. System 1.

Property 2: If $r_i > d$, for some $i \in S$, then $z_i \leq \max_{j: q(i, j) > 0} \{z_j\}$. Equivalently, if $z_i > \max_{j: q(i, j) > 0} \{z_j\}$, for some $i \in S$, then $r_i < d$.

Proof: For the first part, suppose the opposite is true, i.e., suppose that $z_i > \max_{j: q(i, j) > 0} \{z_j\}$. Then, for $x = z_i^+$, the first two terms on the right-hand side of (7) are strictly positive, the terms in the summation are nonnegative, whereas the left-hand side is 0. Therefore, $z_i > \max_{j: q(i, j) > 0} \{z_j\}$ cannot be true. The second part is dual to the first part and follows immediately from it. Q.E.D.

It is noteworthy that the inequality $z_i \leq \max_{j: q(i, j) > 0} \{z_j\}$ (respectively, $z_i > \max_{j: q(i, j) > 0} \{z_j\}$) in Property 2 becomes, $z_i < \max_{j: q(i, j) > 0} \{z_j\}$ (respectively, $z_i \geq \max_{j: q(i, j) > 0} \{z_j\}$), if either $z_i > x^*$ or $g(x)$ is continuously differentiable. A corollary of Property 2 is that the largest hedging point belongs to an infeasible machine state. This is stated as Property 3.

Property 3: $\max_{i: r_i < d} \{z_i\} \leq \max_{i: r_i > d} \{z_i\}$.

The following property concerns the ordering of any two hedging points.

Property 4: For $i \neq j, i, j \in S$, define

$$\bar{z} = \max_{k: q(i, k) \geq q(j, k), k \neq i, j} \{z_k\} \\ (\bar{z} = -\infty, \text{ if } \{k: q(i, k) \geq q(j, k), k \neq i, j\} = \emptyset), \\ \underline{z} = \min_{k: q(i, k) \leq q(j, k), k \neq i, j} \{z_k\} \\ (\underline{z} = \infty, \text{ if } \{k: q(i, k) \leq q(j, k), k \neq i, j\} = \emptyset).$$

If $r_i > d, z_i \geq \bar{z}, z_j \leq \underline{z}$, and $\bar{z} \leq \underline{z}$, then $z_i \leq z_j$.

Proof: Suppose the opposite is true, i.e., suppose that $z_i > z_j$. Subtract (7) for machine state j from that for machine state i . After rearranging terms, the result is

$$0 = V_i''(x)(u_i^*(x) - d) - V_j''(x)(u_j^*(x) - d) \\ + \sum_{k \neq i, j} [q(i, k) - q(j, k)]V_k'(x) \\ - q(i, k)V_i'(x) + q(j, k)V_j'(x) \\ + [q(i, j) + q(j, i)][V_j'(x) - V_i'(x)].$$

Then, for $x: \max\{\bar{z}, z_j\} < x < \min\{z_i, \underline{z}\}$, all but the terms in the summation on the right-hand side of the above equation are strictly positive, the terms in the summation are nonnegative, whereas the left-hand side is 0. Therefore, $z_i > z_j$ cannot be true. Q.E.D.

There may be little intuition about Property 4 at this point; more intuition about this property may be gained when it is seen in the context of the special system examples in Section IV. It should be pointed out that Properties 1–3 hold even if the $V_i(x), i \in S$ are not strictly convex.

IV. SPECIAL SYSTEM EXAMPLES

Hu and Xiang [9], [10] studied optimal hedging point ordering properties for systems with special Markov chain structure under a discounted cost criterion. In this section we demonstrate how optimal hedging point ordering properties of those and other systems are special cases of the general properties developed in Section III, for the average cost criterion. All the systems we study have only one infeasible machine state, labeled 0.

Fig. 2 System 2

Fig. 3 System 3

Fig. 4 System 4

Fig. 5 A system with two nonidentical unreliable machines. There are four possible machine states (0, 0), (0, 1), (1, 0), (1, 1) where a 1 (respectively 0) in position i indicates that the i th machine is up (respectively down). These states are denoted 0, 1, 2, 3 respectively. The failure and repair rates of the i th machine are p_i and b_i respectively.

System 1 is shown in Fig. 1 and is defined as follows.

System 1 Definition $S = \{0, 1, \dots, n\}$ where $r_0 < d$ and $r_i > d$, $i = 1, 2, \dots, n$. The following transitions *must* be allowed: $i \rightarrow i-1$, $i = 1, \dots, n$ and $i \rightarrow n$ for some $i < n$. The *only other* allowable transitions are $i \rightarrow j$, $j = i+1, \dots, n-1$.

The characteristic of System 1's Markov chain is that any transition from left to right is allowed, whereas transitions from right to left must be *skip free*. A special instance of System 1 is when transitions are skip free from left to right too (death-birth chain). A death-birth chain can be used to model a manufacturing system with n identical machines whose machine state is characterized by the number of machines that are up. System 1 has the following property.

Property 5 For System 1, $r^* < r$, $r_i \leq r$, $i = 1, 2, \dots, n$.

Proof By Property 1, $r^* \leq r$, $r_i = 0$, $i = 1, 2, \dots, n$. The rest of the proof is by induction. First by Property 2, $r_1 \leq r$. Now suppose that $r_i \leq r$, $i = 1, 2, \dots, i-1$, $0 < i < n$. We must prove that $r_i \leq r$. Suppose that the opposite is true, i.e., suppose that $r_i > r$. This implies that $r_i > \max\{r_{i-1}, r_{i+1}\} = \max\{r_{i-1}, r_{i+1}\}$. Consequently, by Property 2, $r_i < d$. However, $r_i < d$ is not true; therefore, $r_i > r$ cannot be true either. Instead, $r_i \leq r$ must be true. Q.E.D.

System 2 is shown in Fig. 2 and is defined as follows.

System 2 Definition $S = \{0, 1, \dots, n\}$ where $r_0 < d$ and $r_i > d$, $i = 1, 2, \dots, n$. The following transitions *must* be allowed: $i \rightarrow i-1$, $i = 1, 2, \dots, n$ and $0 \rightarrow n$. No other transitions are allowed.

A special instance of System 2 is when $r_0 = 0$ and $r_i = r$, $i = 1, 2, \dots, n$. This can be used to model a system with one machine that may be either up or down and whose down time is exponentially distributed and up time has a Coxian distribution with n stages. A special case of the latter system is a system where the only transition allowed to machine state 0 is from machine state 1. Such a system can be used to model an Erlang up time distribution with n phases. System 2 has the following property.

Property 6 For System 2,

- 1) If $q(n, 0) \leq q(n-1, 0) \leq \dots \leq q(1, 0)$ then $r^* \leq r$, $r_i \leq r$, $i = 1, 2, \dots, n$.
- 2) If $q(n, 0) \geq q(n-1, 0) \geq \dots \geq q(1, 0)$ then $r^* \leq r$, $r_i \leq r$, $i = 1, 2, \dots, n$.

- 3) If $q(n, 0) = q(n-1, 0) = \dots = q(1, 0)$ then $r^* = r$, $r_i = r$, $i = 1, 2, \dots, n$.

Proof We only prove 1) since the proof for 2) is very similar and 3) follows immediately from 1) and 2). By Property 1, $r^* \leq r$, $r_i = 0$, $i = 1, 2, \dots, n$. The rest of the proof is by induction. First by Property 2, $r_1 \leq r$. Now suppose that $r_i \leq r$, $i = 1, 2, \dots, i-1$, $0 < i < n$. We must prove that $r_i \leq r$. That $r_i \leq r$ follows immediately from Property 4 after substituting r_{i-1} by r_{i+1} , $r_i = r$ respectively and noting that $q(i+1, 0) \leq q(i, 0)$. Q.E.D.

System 3 is shown in Fig. 3 and is defined as follows.

System 3 Definition $S = \{0, 1, \dots, n\}$ where $r_0 < r$ and $r_i > d$, $i = 1, 2, \dots, n$. The following transitions *must* be allowed: $i \leftrightarrow 0$, $i = 1, 2, \dots, n$. No other transitions are allowed.

When $r_0 = 0$ and $r_i = r$, $i = 1, 2, \dots, n$, System 3 can be used to model a system with one machine that may be either up or down and whose down time is exponentially distributed and up time has a hyperexponential distribution with n states. System 3 has the following property.

Property 7 For System 3, $r^* \leq r$, $r_i = r$, $i = 1, 2, \dots, n$. Also, if $q(i, 0) \leq q(j, 0)$, $(i, j) \in \{1, 2, \dots, n\}$ then

Proof By Property 1, $r^* \leq r$, $r_0 = 0$, $r_i = r$, $i = 1, 2, \dots, n$. The last part follows immediately from Property 4 after substituting r_{i-1} by r_{j-1} respectively and noting that $q(i, 0) \leq q(j, 0)$. Q.E.D.

System 4 is shown in Fig. 4 and is defined as follows.

System 4 Definition $S = \{0, 1, \dots, n\}$ where $r_0 < d$ and $r_i > d$, $i = 1, 2, \dots, n$. The following transitions *must* be allowed: $i \leftrightarrow 0$ and $i \leftrightarrow n$, $i = 1, 2, \dots, n-1$. No other transitions are allowed.

System 4 can be used to model a production system that may enter one of many failure modes before failing completely. For example, a system with two nonidentical unreliable machines is a special case of System 4 with $n = 3$ (see Fig. 5). For System 4 we have the following result.

Property 8 For System 4,

- 1) $r^* < r \leq \max_{k=1, \dots, n} \{r_k\}$.
- 2) If there exists $j^* \in S$ such that $q(j^*, 0) = \max_{k=1, \dots, n} \{q(k, 0)\}$ and $q(j^*, n) = \min_{k=1, \dots, n} \{q(k, n)\}$ then $r_j = \max_{k=1, \dots, n} \{r_k\}$.

Proof:

1) It follows immediately from Properties 1, 2, and 3.
 2) Suppose the opposite is true, i.e., suppose that $z_{i^*} = \max_{k: 1 \leq k \leq n-1} \{z_k\}$, where $i^* \neq j^*$. Since $q(i^*, n) \geq q(j^*, n)$, $q(i^*, 0) \leq q(j^*, 0)$, and $x^* \leq z_n \leq z_{i^*} \leq z_0$, following the proof of Property 4, it can be easily shown that $z_{i^*} > z_{j^*}$ cannot be true; hence $z_{i^*} \leq z_{j^*}$ must be true. This implies that $z_{j^*} = \max_{k: 1 \leq k \leq n-1} \{z_k\}$. Q.E.D.

V. FURTHER ISSUES

In Sections III and IV it was seen that for a system whose machine state process is modeled as a homogeneous and uncontrolled Markov chain, the relative ordering of optimal hedging points can be determined, if this Markov chain has a special structure and, in some cases, its transition rates have a certain ordering. It is noteworthy that this ordering of hedging points does not depend on the specific values of r_i and $q(i, j)$, $i, j \in S$. A question that arises is the following. Once the ordering of hedging points has been established using the type of arguments presented in Section III, can similar arguments be used to also determine the ordering of the differences between consecutive hedging points? Based on numerical examples, our conjecture is that the ordering of the differences between consecutive hedging points depends on the specific values of r_i and $q(i, j)$, $i, j \in S$.

An extension of the manufacturing flow control model presented in Section II is a model with age-dependent machine state process. By age dependent we mean that transition rates of the machine state process depend on the age of the machine state, i.e., on how long the machine state process has been in a particular state. We first note that for a system with age dependent machine state process the optimal control may depend not only on the machine state of the system but also on the age of the machine state. Consequently, the optimal control is no longer a hedging point policy. Instead, it is a so-called hedging curve or turnpike policy—a generalized hedging point policy in which values of hedging points depend on the age of the machine state.

In [10] it is shown that any transition (failure) time with age dependent transition (failure) rate can be approximated arbitrarily closely (in the sense of weak convergence) by a random variable with Coxian³ distribution with many stages. The stages of the Coxian distribution correspond to different ages of the transition (failure) time, and the transition (failure) rates between the stages are proportional to the corresponding values of the hazard rate of the original age dependent transition (failure) time distribution. Since a random variable with Coxian distribution is a Markov process itself, a system with age dependent machine state process can be approximated by a system with homogeneous Markov machine state. This approximation provides a means to investigate ordering properties of the optimal control policy for a system with age dependent machine state process based on results obtained on a related system with homogeneous Markov machine state process.

Finally, an extension of systems with homogeneous Markov machine state processes is systems in which transition rates of machine states depend on machine production rates. Some results on such systems have been reported in [7], [12], [19].

Recursive Identification Method for MISO Wiener-Hammerstein Model

M. Boutayeb and M. Darouach

Abstract—A simple technique for recursive identification of the Wiener-Hammerstein model with extension to the multi-input single-output (MISO) case is presented. We use a new transformation of the input-output difference equation where parameters to be estimated are those of each subsystem of the initial and unique realization. After that, a weighted extended least squares (WELS) method is employed to estimate recursively and separately parameters of the linear subsystems and the static nonlinear element. Convergence analysis of the proposed procedure is also studied. Finally, a numerical example is provided to show the efficiency of the algorithm.

I. INTRODUCTION

Modeling, identification, and control design of nonlinear systems have been the subject of many research activities in the last decades. Indeed, for many dynamic systems the use of nonlinear models is often of great interest and generally characterizes adequately physical processes over their whole operating range [8]. Thus, accuracy and performances of the control law increase significantly. One of the nonlinear realizations frequently studied is the Hammerstein model, which is composed of a static nonlinearity in series with a linear dynamic system. Several identification techniques of this kind of models with an extension to the MISO model were performed. The literature is abundant about this subject and we refer the reader to [1], [9], and the references therein. However, all recursive identification methods of SISO and MISO Hammerstein model ([5], [6], and [11]) consist at first in transforming the initial realization to an equivalent representation with common denominator and extended numerators. Next to that, classical recursive methods are applied. The obtained parameter vector to be estimated by this approach, is of high dimension, particularly for large scale systems, and then computational requirements increase with possible numerical instabilities. Thus, control design becomes very complicated and too crude to be of use.

On the other hand, very few efforts have been done to extend these methods to the general representation, called the Wiener-Hammerstein model or G-model, particularly the MISO case. The G-model is defined as a linear system in cascade with a static nonlinear element followed by another linear system. In [1] and [2], Billings *et al.* have proposed an identification algorithm for the Wiener-Hammerstein model based on correlation analysis. This was earlier suggested by Korenberg [10]. However, in their algorithms, some restrictive assumptions are required for the kind of input sequences to preserve the separability principle. On the other hand, computational requirements are considerable. More recently, Yoshine *et al.* [18] have suggested another approach for identification of the G-model, this consists of estimating, in the SISO case, impulse responses of the linear subsystems and parameters of the nonlinear element.

In this paper, we present a recursive method to estimate parameters of the linear and nonlinear parts of the G-model, which is an extension

Fig. 1 MISO Wiener-Hammerstein model

of our previous work in [5]. We investigate a new formulation of the input-output difference equation, from which a WELS algorithm is established. Contrary to the approach developed in [6] and [11], the obtained algorithm has the advantage to estimate separately and recursively parameters of the linear and nonlinear subsystems of the initial realization where parameter number is of minimal dimension. All these results are extended to the MISO Wiener-Hammerstein model. Conditions for parameter convergence to the actual ones are established, it's also shown that the weighted factors are introduced to enhance the convergence of the proposed algorithm.

II. PROBLEM FORMULATION

Fig. 1 shows the general scheme of the Wiener-Hammerstein discrete time model with r inputs. The output signal y_k at time k is given by

$$y_k = y_{1k} + \dots + y_{rk} \quad (1)$$

where y_{rk} is the nonmeasured intermediate output related to the r th input

$$y_{rk} = \frac{B_r(q^{-1})}{A_r(q^{-1})} v_{rk} \quad (2)$$

with

$$v_{rk} = q_{r1} Z_k + \dots + q_{rn} Z_k \quad (3)$$

and

$$Z_k = \frac{C_r(q^{-1})}{D_r(q^{-1})} u_{rk} \quad (4)$$

The linear subsystems in the G-model are defined as

$$A_i(q^{-1}) = 1 + a_{i1}q^{-1} + \dots + a_{in_i}q^{-n_i} \quad (5)$$

$$B_i(q^{-1}) = b_{i0} + b_{i1}q^{-1} + \dots + b_{ip_i}q^{-p_i} \quad (6)$$

$$C_i(q^{-1}) = c_{i0} + c_{i1}q^{-1} + \dots + c_{is_i}q^{-s_i} \quad (7)$$

and

$$D_i(q^{-1}) = 1 + d_{i1}q^{-1} + \dots + d_{if_i}q^{-f_i} \quad \text{for } i = 1, \dots, r \quad (8)$$

q^{-1} is the delay operator, u_{rk} is the r th input of the system at time instant k and orders f_i, m_i, n_i, p_i and s_i are supposed to be known. These can be estimated from the input-output data [9]. For simplicity in the sequel, we note $A_i(q^{-1})$, $B_i(q^{-1})$, $C_i(q^{-1})$ and $D_i(q^{-1})$ by A_i , B_i , C_i and D_i , respectively, $i = 1, \dots, r$. The linear transfer functions $B_i(q^{-1})/A_i(q^{-1})$ and $C_i(q^{-1})/D_i(q^{-1})$ are assumed to be stable.

III. SOME PRELIMINARY TRANSFORMATIONS

Before giving the main results of this paper, let us make some important transformations which lead to a unique and equivalent realization of (1)–(9).

Manuscript received July 8, 1993; revised December 21, 1993 and April 11, 1994.

The authors are with CRAN-FARAI-CNRS UA 821, Université de Nancy I, 186, Rue de Lorraine, 54400 Cosnes et Romain, France.
IEEE Log Number 9406987.

We remark that there are an infinity of realizations, noted by $(A_i, B_i, C_i, D_i, g_{ij})$, equivalent to $(A_i, B_i, C_i, D_i, g_{ij})$ for $i = 1, \dots, r$ and $j = 1, \dots, m_i$. Indeed, the input output representation of the G-model may be written as

$$y_k = y_{1k} + \dots + y_{rk} \quad (10)$$

with

$$y_{ik} = \frac{B_i}{A_i} V_{ik} \quad (11)$$

$$V_{ik} = g_{i1} Z_{ik} + \dots + g_{im_i} Z_{ik}^{m_i} \quad (12)$$

$$Z_{ik} = \frac{C_i}{D_i} u_{ik} \quad (13)$$

$$B_i = b_{i0} + b_{i1}q^{-1} + \dots + b_{ip_i}q^{-p_i} \quad (14)$$

and

$$C_i = c_{i0} + c_{i1}q^{-1} + \dots + c_{is_i}q^{-s_i} \quad \text{for } i = 1, \dots, r \quad (15)$$

the obtained parameters are related to the previous ones by

$$b_{ij} = l_i b_{i,j}, \quad c_{ij} = t_i c_{i,j} \quad \text{and} \quad g_{ij} = \frac{g_{i,j}}{l_i t_i} \quad (16)$$

for any l_i and $t_i \in \mathbb{R}^*$. Polynomials A_i and D_i are those in (6) and (9). One interesting way to choose l_i and t_i is to set

$$l_i = b_{i0} \quad \text{and} \quad t_i = c_{i0} \quad (17)$$

polynomials B_i and C_i are then in the following form

$$B_i(q^{-1}) = 1 + b_{i1}q^{-1} + \dots + b_{ip_i}q^{-p_i} \quad (18)$$

and

$$C_i(q^{-1}) = 1 + c_{i1}q^{-1} + \dots + c_{is_i}q^{-s_i} \quad \text{for } i = 1, \dots, r. \quad (19)$$

The final realization, where the index i is omitted, is summarized as follows:

$$y_k = y_{1k} + \dots + y_{rk} \quad (20)$$

with

$$y_{ik} = \frac{B_i}{A_i} V_{ik} \quad (21)$$

$$V_{ik} = g_{i1} Z_{ik} + \dots + g_{im_i} Z_{ik}^{m_i} \quad (22)$$

$$Z_{ik} = \frac{C_i}{D_i} u_{ik} \quad (23)$$

$$B_i = 1 + b_{i1}q^{-1} + \dots + b_{ip_i}q^{-p_i} \quad (24)$$

and

$$C_i = 1 + c_{i1}q^{-1} + \dots + c_{is_i}q^{-s_i} \quad \text{for } i = 1, \dots, r. \quad (25)$$

We remark that the transformation in (16), (17) allows us to replace b_{i0} and c_{i0} by 1, then parameters number to be estimated is n_I instead of $(nr + 2r)$ in the initial realization. On the other hand we can show easily that (20)–(25) is unique, this property assures the uniqueness of the identified parameters. Order n_I is defined as

$$n_I = f + n + m + s + p$$

with $f = f_1 + \dots + f_r$, $n = n_1 + \dots + n_r$, $m = m_1 + \dots + m_r$, $s = s_1 + \dots + s_r$ and $p = p_1 + \dots + p_r$.

IV. RECURSIVE PARAMETER ESTIMATION OF SISO WIENER-HAMMERSTEIN MODEL

For the case of SISO Wiener-Hammerstein model, the output signal is

$$y_k = \frac{B}{A} \left(g_1 \frac{C}{D} u_k + \dots + g_m \left(\frac{C}{D} u_k \right)^m \right) \quad (26)$$

with

$$A = 1 + a_1 q^{-1} + \dots + a_n q^{-n} \quad (27)$$

$$B = 1 + b_1 q^{-1} + \dots + b_p q^{-p} \quad (28)$$

$$C = 1 + c_1 q^{-1} + \dots + c_s q^{-s} \quad (29)$$

and

$$D = 1 + d_1 q^{-1} + \dots + d_l q^{-l}. \quad (30)$$

Into the difference form and by making use of (26) the output signal may be written explicitly as

$$y_k = F(\theta, y_k, u_k, Z_k). \quad (31)$$

θ contains parameters to be estimated of the realization (26)–(30) and is defined as

$$\theta = (a_1 \dots a_n \quad b_1 \dots b_p \quad c_1 \dots c_s \quad d_1 \dots d_l \quad g_1 \dots g_m)^T \quad (32)$$

$$F(\theta, y_k, u_k) = -\bar{A}y_k + g_1 B Z_k + \dots + g_m B Z_k^m \quad (33)$$

$$Z_k = C u_k - \bar{D} Z_k \quad (34)$$

and

$$\bar{A} = a_1 q^{-1} + \dots + a_n q^{-n}, \quad \bar{D} = d_1 q^{-1} + \dots + d_l q^{-l}. \quad (35)$$

We note that Z_k was omitted on the left-hand side of (33). Indeed, computation of Z_k is recursively done by (34) and will depend only on the input signal for all initial values Z_0, \dots, Z_l (because the transfer function C/D is assumed to be stable).

Recursive parameter estimation of the Wiener-Hammerstein model is given by the following theorem.

Theorem 1. A WERLS estimation of the parameter vector θ of the Wiener-Hammerstein model is

$$\theta_{k+1} = \theta_k + K_{k+1}(y_{k+1} - F(\theta_k, y_{k+1}, u_{k+1}))$$

$$K_{k+1} = P_k f_{k+1} (f_{k+1}^T P_k f_{k+1} + \lambda_{k+1})^{-1}$$

$$P_{k+1} = (I - K_{k+1} f_{k+1}^T) P_k$$

with

$$f_{k+1} = \frac{\partial F(\theta, y_{k+1}, u_{k+1})}{\partial \theta} \bigg|_{\theta = \theta_k}$$

$\{\lambda_{k+1}\}$ is a sequence of weighted factors that are positive numbers.

Proof. The WERLS estimation of θ is obtained by minimizing the classical criterion function

$$J_{k+1} = \frac{1}{k+1} \sum_{j=1}^{k+1} \frac{1}{\lambda_j} (y_j - \hat{y}_j)^2 \quad (36)$$

where \hat{y}_j can be seen as a prediction of y_j and is defined as

$$\hat{y}_j = F(\hat{\theta}_k, y_j, u_j) \quad (37)$$

where $\hat{\theta}_k$ represents the parameter vector estimation of θ by minimizing J_k .

$\hat{\theta}_{k+1}$ is then obtained by setting the derivative of J_{k+1} , with respect to θ , equal to zero:

$$\frac{\partial J_{k+1}}{\partial \theta} = 0 \Leftrightarrow \sum_{j=1}^{k+1} \frac{1}{\lambda_j} \frac{\partial y_j}{\partial \theta} (y_j - \hat{y}_j) = 0 \quad (38)$$

$$\Leftrightarrow \hat{\theta}_{k+1} = \left[\sum_{j=1}^{k+1} \frac{1}{\lambda_j} f_j f_j^T \right]^{-1} \sum_{j=1}^{k+1} \frac{1}{\lambda_j} f_j y_j \quad (39)$$

where $\partial y_j / \partial \theta$ is approximated by

$$f_j = \left| \frac{\partial F(\theta, y_j, u_j)}{\partial \theta} \right|_{\theta = \theta_k} \quad (40)$$

Then we can prove easily that in the recursive form [14], we obtain

$$\theta_{k+1} = \theta_k + \Gamma_{k+1}(y_{k+1} - F(\theta_k, y_{k+1}, u_{k+1})) \quad (41)$$

$$\Gamma_{k+1} = P_k f_{k+1} (f_{k+1}^T P_k f_{k+1} + \lambda_{k+1})^{-1} \quad (42)$$

$$P_{k+1} = (I - \Gamma_{k+1} f_{k+1}^T) P_k \quad (43)$$

and

$$f_{k+1} = \left. \frac{\partial F(\theta, y_{k+1}, u_{k+1})}{\partial \theta} \right|_{\theta=\theta_k} \quad (44)$$

End of proof.

V RECURSIVE PARAMETER ESTIMATION OF MISO WIEBER HAMMERSTEIN MODEL

In this section a direct extension of the proposed method in the SISO case is presented. At first we introduce the signal vector as in (31) where θ contains parameters of each sub system of the realization (20)–(25) next we use the same principle as in the SISO case

From (20) the output signal may be written explicitly as

$$y_k = \frac{B_1}{A_1} \left(q_{11} \frac{C_1}{D_1} u_{k+1} + \dots + q_{1, l-1} \left(\frac{C_1}{D_1} u_{1k} \right)^{l-1} \right) + \frac{B}{A} \left(q_{11} \frac{C}{D} u_{k+1} + \dots + q_{1, l-1} \left(\frac{C}{D} u_{1k} \right)^{l-1} \right) \quad (45)$$

or

$$\prod_{i=1}^l A_i y_k = \sum_{i=1}^l F_i (q_{11} Z_k + \dots + q_{1, l-1} Z_k^{l-1}) \quad (46)$$

with

$$F_i = B_i \prod_{j=1}^l A_j \quad \text{and} \quad Z_k = C u_k - \bar{D} Z_k \quad (47)$$

As $A_i = 1$ for $i = 1$ contains the term $\prod_{i=1}^l A_i$ is always in the form

$$\prod_{i=1}^l A_i = 1 + \bar{A} \quad \text{and} \quad D = d_{11} q^{-1} + \dots + d_{1, l-1} q^{l-1} \quad (48)$$

\bar{A} is a polynomial nonlinear in parameters with a known structure

From (48) and by making use of (46) y_k becomes

$$y_k = F(\theta, y_k, u_k) \quad (49)$$

with

$$\theta = (a_{11}, a_{1, l-1}, a_{1, l-2}, \dots, a_{1, 1}, b_{11}, b_{1, l-1}, b_{1, l-2}, \dots, b_{1, 1}, c_{11}, c_{1, l-1}, c_{1, l-2}, \dots, c_{1, 1}, d_{11}, d_{1, l-1}, d_{1, l-2}, \dots, d_{1, 1}, q_{11}, q_{1, l-1}, q_{1, l-2}, \dots, q_{1, 1})^T \quad (50)$$

and

$$F(\theta, y_k, u_k) = -\bar{A} y_k + \sum_{i=1}^l F_i (q_{11} Z_k + \dots + q_{1, l-1} Z_k^{l-1}) \quad (51)$$

thus we obtain the same formulation as in the nonlinear SISO case with multiple inputs where θ contains parameters of each subsystem of the initial realization. The WERLS estimator of θ is then given by Theorem 1

VI CONVERGENCE ANALYSIS

Several approaches have been proposed for the parameter convergence analysis of RLS algorithms in the deterministic case. Here we extend the method developed in [19] to the general case of polynomial realization (49)

Theorem 2 If the assumptions

$$\lim_{k \rightarrow \infty} \lambda_{\min} [P_k^{-1}] = \infty$$

$$\limsup_{k \rightarrow \infty} \frac{\lambda_{\max} [P_k^{-1}]}{\lambda_{\min} [P_k^{-1}]} < \infty$$

$$1 - \sqrt{\Delta_{k+1}} < \alpha_{k+1} < 1 + \sqrt{\Delta_{k+1}}$$

hold then the estimator given by Theorem 1 ensures that

$$\lim_{k \rightarrow \infty} \theta_k = \theta \quad (55)$$

where

$$\Delta_{k+1} = 1 - \frac{f_{k+1}^T P_k f_{k+1}}{f_{k+1}^T P_k f_{k+1} + \lambda_{k+1}} \quad (56)$$

and $\lambda_{\min} [P_k^{-1}]$, $\lambda_{\max} [P_k^{-1}]$ are the minimum and maximum eigenvalues of $[P_k^{-1}]$ respectively. α_{k+1} will be determined later.

Proof Consider a quadratic function defined as

$$V_{k+1} = \theta_{k+1}^T P_{k+1}^{-1} \theta_{k+1} \quad (57)$$

with

$$\theta_{k+1} = \theta_k - \theta \quad (58)$$

By subtracting θ from both sides of (41) we obtain

$$\theta_{k+1} = \theta_k + \Gamma_{k+1} f_{k+1} (f_{k+1}^T P_k f_{k+1} + \lambda_{k+1})^{-1} \epsilon_{k+1} \quad (59)$$

with

$$\epsilon_{k+1} = y_{k+1} - F(\theta_k, y_{k+1}, u_{k+1}) \quad (60)$$

On the other hand from (42)–(43) we have

$$P_{k+1} f_{k+1} = \lambda_{k+1} P_k f_{k+1} (f_{k+1}^T P_k f_{k+1} + \lambda_{k+1})^{-1} \quad (61)$$

Substituting (61) into (59) and (59) into (57) respectively the quadratic function becomes

$$V_{k+1} = \left[\theta_k + \frac{1}{\lambda_{k+1}} P_{k+1} f_{k+1} \epsilon_{k+1} \right]^T P_{k+1}^{-1} \left[\theta_k + \frac{1}{\lambda_{k+1}} P_{k+1} f_{k+1} \epsilon_{k+1} \right] \quad (62)$$

$$\Leftrightarrow V_{k+1} = \theta_k^T P_{k+1}^{-1} \theta_k + \frac{2}{\lambda_{k+1}} \theta_k^T f_{k+1} \epsilon_{k+1} + \frac{1}{\lambda_{k+1}} f_{k+1}^T P_{k+1}^{-1} f_{k+1} \epsilon_{k+1}^2 \quad (63)$$

From (42)–(43) we have

$$P_{k+1}^{-1} = P_k^{-1} + f_{k+1} \frac{1}{\lambda_{k+1}} f_{k+1}^T \quad (64)$$

Then (63) becomes

$$V_{k+1} = \theta_k^T P_k^{-1} \theta_k + \theta_k^T f_{k+1} \frac{1}{\lambda_{k+1}} f_{k+1}^T \theta_k + \frac{2}{\lambda_{k+1}} \theta_k^T f_{k+1} \epsilon_{k+1} + \frac{1}{\lambda_{k+1}} f_{k+1}^T P_k^{-1} f_{k+1} \epsilon_{k+1}^2 \quad (65)$$

As $f_{k+1}^T \theta_k$ is an approximation of the innovation sequence ϵ_{k+1} we introduce an unknown factor α_{k+1} to correct this approximation such as

$$f_{k+1}^T \theta_k = -\alpha_{k+1} \epsilon_{k+1} \quad (66)$$

for linear systems and in [19] we have $f_k = \Phi_k$ which is independent from θ and then $\alpha_{k+1} = 1$. Substituting (66) in (65) we obtain

$$V_{k+1} = V_k + \left(\frac{\alpha_{k+1}^2 - 2\alpha_{k+1}}{\lambda_{k+1}} + \frac{1}{\lambda_{k+1}} f_{k+1}^T P_k^{-1} f_{k+1} \right) \epsilon_{k+1}^2 \quad (67)$$

thus, if the condition (54) holds, we have

$$\frac{\alpha_{k+1}^2 - 2\alpha_{k+1}}{\lambda_{k+1}} + \frac{1}{\lambda_{k+1}} \hat{f}_{k+1}^T P_{k+1} \hat{f}_{k+1} < 0 \quad (68)$$

and then

$$V_{k+1} \leq V_k \leq \dots \leq V_0. \quad (69)$$

We note

$$\lim_{k \rightarrow \infty} V_k = V.$$

From the persistently exciting conditions (52) and (53), we have

$$\frac{V_k}{\text{tr}(P_k^{-1})} \geq \frac{\lambda_{\min}[P_k^{-1}] \theta_k^T \theta_k}{n_I \lambda_{\max}[P_k^{-1}]} \geq 0 \quad (70)$$

and then

$$\lim_{k \rightarrow \infty} \frac{V_k}{\text{tr}(P_k^{-1})} = 0 \geq \lim_{k \rightarrow \infty} \frac{\lambda_{\min}[P_k^{-1}] \theta_k^T \theta_k}{n_I \lambda_{\max}[P_k^{-1}]} \geq 0 \quad (71)$$

$$\Leftrightarrow \lim_{k \rightarrow \infty} \hat{\theta}_k = 0. \quad (72)$$

End of proof.

Remarks: Hereafter, let us make some remarks.

1) Implementation of the proposed algorithm in the case of Wiener-Hammerstein model with time delay. A particular case of the realization (1)–(9) is that

$$b_{i0} = \dots = b_{i, \tau_i - 1} = 0 \quad \text{and} \quad b_{i, \tau_i} \neq 0$$

$$c_{i0} = \dots = c_{i, \tau_i - 1} = 0 \quad \text{and} \quad c_{i, \tau_i} \neq 0 \quad \text{for } i = 1, \dots, r$$

this configuration depends upon the structure selection from the input output data, where τ_i and u_i are times delay related to the i th input.

Polynomials $B_i(q^{-1})$ and $C_i(q^{-1})$ become

$$B_i(q^{-1}) = q^{-\tau_i} (b_{i, \tau_i} + b_{i, \tau_i+1} q^{-1} + \dots + b_{i, \tau_i+1} q^{-1})$$

$$C_i(q^{-1}) = q^{-\tau_i} (c_{i, \tau_i} + c_{i, \tau_i+1} q^{-1} + \dots + c_{i, \tau_i+1} q^{-1})$$

and in the proposed algorithm we replace simply Z_{ik} by $Z_{ik-\tau_i}$ and u_{ik} by $u_{ik-\tau_i}$.

2) Initialization of the algorithm, the mean of the sufficient condition (54) for convergence, and how (52)–(54) can be ensured in the practical case. Indeed, most identification methods developed in the literature are based on a linearized model around a trajectory which is generally given by the last estimation. This approach is available only if the last estimate belongs to a neighborhood of the actual parameter vector, the condition (54) represents then the validity of the linearized model. In practice, if the proposed algorithm is adequately initialized (54) is generally fulfilled. Thus, a bad initialization leads generally to various problems such as convergence to a local minimum, to a wrong estimate or instability [16], [17]. Anyway, there is no approach which can be recommended as being universal to give an analytic solution to this problem. This fact is related to the many different unexpected features that the non linear relation can introduce.

But, for the particular case of the Wiener-Hammerstein model, one way to overcome the initialization difficulty is to write the output signal as a linear parameter representation [5], [6] [11]:

$$y_k = \bar{\phi}_k^T \bar{\theta}_k \quad (73)$$

where $\bar{\phi}_k$ is the data vector which contains only input and output signals and, where $\bar{\theta}_k$ is an over parameter vector. Note that (73) is an equivalent representation of the model given by (33) with an overparameterization. Next to that the use of a least square scheme provides a consistent-like initial parameter vector which may initialize adequately the proposed algorithm, see also [3] and [19].

Fig. 2 Rate of convergence of parameter error norm. $\|\theta_k - \theta\|$

Furthermore, (52), (53) represent the persistently exciting conditions, some basic definitions are given in [17] and [19]. However, in practice we must take into account the constraints that physical limitations and safety may impose. Many strategies were developed to achieve a given input spectrum where the amplitude and variance are constrained to a certain interval. Some experiment results are given in [7] and [10].

VII. NUMERICAL EXAMPLE

The numerical example considered here is composed of two subsystems with the nonlinear static polynomials

$$V_{1t} = g_{11} Z_{1t} + g_{12} Z_{1t}^2$$

$$V_{2k} = g_{21} Z_{2k} + g_{22} Z_{2k}^2 + g_{23} Z_{2k}^3$$

and the pulse transfer functions:

$$\frac{B_1}{A_1} = \frac{1 + b_{11} q^{-1}}{1 + a_{11} q^{-1} + a_{12} q^{-2}}$$

$$\frac{C_1}{D_1} = \frac{1 + c_{11} q^{-1} + c_{12} q^{-2}}{1 + d_{11} q^{-1} + d_{12} q^{-2}}$$

$$\frac{B_2}{A_2} = \frac{1}{1 + a_{21} q^{-1}}; \quad \frac{C_2}{D_2} = \frac{1 + c_{21} q^{-1}}{1 + d_{21} q^{-1} + d_{22} q^{-2}}$$

with $a_{11} = 0.5, a_{12} = 0.35, a_{21} = 0.7, b_{11} = 0.1, c_{11} = -0.5, c_{12} = 0.6, c_{21} = 0.8, d_{11} = 0.65, d_{12} = 0.35, d_{21} = 0.45, d_{22} = 0.55, g_{11} = 1.2, g_{12} = -1.8, g_{21} = 0.95, g_{22} = 1.3, g_{23} = -1.1$.

The input signals (u_{1k}) and (u_{2k}) are zero mean white noise sequences with standard deviations $\sigma_1 = 2$ and $\sigma_2 = 2.5$, respectively. In order to show efficiency of the proposed algorithm, the sequence (λ_k) is chosen large enough to fulfill condition (54) and then to enhance convergence of the algorithm, we take

$$\lambda_{k+1} = 10 \hat{f}_k^T P_k \hat{f}_k + 1$$

where the initial estimates θ_0 and P_0 are taken as

$$\hat{\theta}_0 = 0; \quad P_0 = 10^4 I_{16}.$$

Numerical results are given in Figs. 2–4 where the true values of all parameters are reached about 1800 samples. Fig. 2 shows the rate of convergence of parameter error norm: $\|\theta_k - \theta\|$. Owing to a lack of space here, only the estimates of two parameters are given, for example: c_{21} and g_{12} which are represented by Figs. 3 and 4, respectively.

Fig. 3. Parameter estimation of c_{21} .Fig. 4. Parameter estimation of g_{12} .

VIII. CONCLUSION

A simple method for recursive identification of MISO Wiener-Hammerstein model was performed. It is shown, by means of an attractive transformation, that parameters to be estimated are those of each subsystem of the initial and unique realization. Sufficient conditions are given to assure the convergence of the algorithm where the sequence $\{\lambda_k\}$ is introduced to enlarge the interval $[1 - \sqrt{\Delta_{k+1}}, 1 + \sqrt{\Delta_{k+1}}]$ and then to enhance the convergence of the proposed procedure, this was illustrated by means of a numerical example. Finally, some important remarks to deal with the initialization problem, in order to ensure condition (54), are given.

Production Rate Control for Failure-Prone Production Systems With No Backlog Permitted

Jian-Qiang Hu

Abstract—Previously, the problem of optimal production rate control for failure-prone production systems has been studied exclusively under the assumption that backlog is permitted. It is well known that when backlog is permitted, the optimal control is usually the hedging point policy. In this note, we consider systems in which backlog is not allowed. We show that the hedging point policy is still optimal. For systems with backlog, it is usually quite straightforward to show that their optimal cost-to-go functions are convex—a key property that is needed for the hedging point policy to be optimal. With no backlog permitted, it becomes much more difficult to establish the convexity property, and the explicit formulas for the optimal hedging point and the optimal cost-to-go functions have to be obtained, based on which the convexity property can then be verified. The method we use in this note to derive these explicit formulas is mainly based on an interesting relationship between the inventory process of the system under the hedging point policy and some stochastic process which is well studied in queueing theory.

I. INTRODUCTION

In this note, we consider the problem of optimal production rate control for failure-prone production systems. This problem has been studied extensively by many researchers in the literature (for a review and a comprehensive list of references on the subject, see a recent monograph by Gershwin [4]). A key assumption used in all the previous work is that backlog of demands is allowed. This assumption usually implies that the instantaneous cost function on inventory level (negative inventory being backlog) is convex (in most cases, it is either piecewise linear or quadratic function of inventory level), which can immediately lead to convexity of optimal cost-to-go functions based on a simple sample path argument. Using the convex property and the dynamic Bellman equation for the optimal cost-to-go functions, one can then easily show that the optimal control is a hedging point policy, in which a (nonnegative) production inventory level of part types is maintained during times of excess capacity availability to hedge against future capacity shortages brought about by machine failures. Intuitively, the hedging point is safety production inventory and is carried to protect the production process from the uncertainty in future capacity availability.

Although the backlog assumption is reasonable for many systems, it may not hold for a large class of production systems in which unsatisfied demands are lost. One such example is a production line in which machines are linked in tandem. In such a system, the demand rate for each machine (except the last one) is simply equal to the production rate of its downstream machine, and obviously, in this case, production inventory level between any two machines can never become negative (i.e., backlog is not permitted). This motivates us to consider the problem of optimal production rate control for systems in which backlog is not permitted. As we shall see, for a system with no backlog permitted, it becomes much more difficult to establish convexity for its optimal cost-to-go functions. This is simply because, in this case, the instantaneous cost function on inventory level is no longer convex, hence the simple sample path argument used before when backlog is permitted cannot be applied. Instead, the explicit formulas for the optimal cost-to-go functions have to be derived.

To derive the optimal cost-to-go functions, we first focus on hedging point policies and try to obtain the optimal hedging point policy and its associated cost-to-go functions. Clearly, if the optimal control policy is a hedging point policy, then the optimal cost-to-go functions are simply equal to the cost-to-go functions associated with the optimal hedging point policy. To obtain the optimal hedging point policy, we use a method which has recently been developed by Hu and Dong [5], [6] to study the systems with backlog permitted. The basic idea of the method is to establish a relationship between the inventory processes of failure-prone production systems and some well-studied stochastic processes in queueing systems. In our case, we show that the inventory process of the system under a hedging point policy is related to the workload process of a single-node queueing system with limited workload. Based on this relationship and existing results in queueing theory, we can obtain the probability distribution function of the inventory process, from which we can then find the optimal hedging point. Finally, with the optimal hedging point policy and its cost-to-go functions, we can use the verification theorem to verify that the optimal hedging point policy is indeed optimal overall. We point out that it is also possible for one to obtain the probability distribution function of the inventory process for our system based on a different approach used in [1], [2], [8], in which a system of two differential equations needs to be solved under two boundary conditions. However, the method used in [1], [2], [8] can only be applied to Markov systems (i.e., both machine up and down times have to be exponentially distributed), while our method is applicable to non-Markov systems as well.

The remainder of the note is organized as follows. In Section II, the problem of optimal production rate control for the failure-prone production system with no backlog permitted is formulated as an optimal control problem whose optimality condition is given by a dynamic Bellman equation. In Section III, we establish an important relationship between the inventory process of the system under a hedging point policy and the workload process of a single-node queue with bounded workload. Based on this relationship, we obtain the probability distribution function for the inventory process. We then proceed in Section IV to derive the explicit formulas for the optimal hedging point, the optimal value of the cost function, and the optimal cost-to-go functions. In Section V, we present the verification theorem, based on which we prove that the optimal hedging point policy obtained in Section IV is the optimal control policy. Finally, some discussions and future research directions are presented in Section VI.

II. PROBLEM FORMULATION

We consider a production system which has a single machine and produces a single part type. The system tries to meet a constant demand rate d , and backlog is not permitted, i.e., unsatisfied demands are lost. The machine has two states: up and down. When the machine is up, it can produce at any rate between zero and a maximum rate r . We assume that $r > d$. The machine state changes in continuous time according to a homogeneous Markov process: the state changes from down to up at a rate q_0 and from up to down at a rate q_1 (i.e., both machine up and down times are exponentially distributed with rates q_1 and q_0 , respectively). We use $i \in \{1, 0\}$ to denote the state of the machine, where one corresponds to up and zero to down. Denote the production inventory at time t by $x(t) (\geq 0)$. Let $i(t)$ be the state of the machine at time t , and let $u(t)$ be the controlled production rate of the machine at time t . Then $x(t)$ is characterized by the following differential equation:

$$\frac{dx(t)}{dt} = \begin{cases} u(t) - d, & \text{if } i(t) = 1 \text{ or } x(t) > 0 \\ 0, & \text{if } i(t) = 0 \text{ and } x(t) = 0 \end{cases} \quad (1)$$

where $u(t) \in [0, r]$ when $i(t) = 1$ ($u(t) \in [d, r]$ if $x(t) = 0$), and $u(t) = 0$ when $i(t) = 0$. The objective is to find a stationary, feedback control law, $u(x, i)$, so as to minimize the following long-run expected average cost:

$$J = \lim_{T \rightarrow \infty} E \left\{ (1/T) \int_0^T (cx(t) + c_0 1(x(t) = 0, i(t) = 0)) dt \right\} \quad (2)$$

where c is the unit holding cost for inventory, c_0 is the unit shortage cost for unsatisfied demand, and $1(\cdot)$ is the indicator function. It should be pointed out that the instantaneous cost in the objective function, $g(x, i) = cx + 1(x = 0, i = 0)$, is not a convex function with respect to x .

Under suitable regularity conditions imposed on the control (e.g., [7]), the optimal feedback control of the system is stationary and characterized by the following Bellman equations:

$$\min_{u: 0 \leq u \leq r} \left\{ \frac{dV_1(x)}{dx} (u - d) \right\} - q_1 [V_1(x) - V_0(x)] + cx - J^* = 0, \quad \text{for } x \geq 0 \quad (3)$$

$$-\frac{dV_0(x)}{dx} d - q_0 [V_0(x) - V_1(r)] + cx - J^* = 0, \quad \text{for } x > 0 \quad (4)$$

where $V_i(x)$ ($i = 1, 0$) are (differential) cost-to-go functions and J^* is the minimum long-run expected average cost associated (i.e.,

$J^* = \min J$). According to (3), if $V_1(x)$ is convex with minimum point z^* , then the optimal production rate satisfies

$$u^*(x, i) = \begin{cases} 0, & \text{if } x > z^* \text{ and } i = 1 \\ d, & \text{if } x = z^* \text{ and } i = 1 \\ r, & \text{if } x < z^* \text{ and } i = 1 \end{cases} \quad (5)$$

which is hedging point policy, and z^* is the hedging point. If the instantaneous cost function were convex, then one could easily show that $V_1(x)$ is also convex based on a simple sample argument ([10]). However, as already mentioned above, the instantaneous cost function in our case is not convex, hence the explicit formula for $V_1(x)$ has to be obtained in order to establish its convexity.

III. HEDGING POINT POLICY

In this section, we focus exclusively on the hedging point policy defined by (5) with hedging point z . We want to derive the steady-state probability distribution function for the inventory process under the hedging point policy. Our method consists of two basic steps. First, we establish a relationship between the inventory process and the workload process of a single-node queueing system with bounded workload. Second, we use this relationship to derive the probability distribution function for the inventory process based on existing results in queueing theory and a level crossing technique. This method was first used by Hu and Dong [5], [6] to study systems with backlog. It is worth pointing out that a different approach proposed in [1], [2], [8] can also be used to obtain the probability distribution function in our case. The basic idea of their method is to solve a set of differential equations. However, we note that the method of [1], [2], [8] can only be applied to Markov systems, while ours is applicable to non-Markov systems as well (i.e., the machine up and down times do not have to be exponentially distributed).

To start, we take a close look at a sample path of the system under the hedging point policy. For simplicity, let us assume $x(0) = z$ and $i(0) = 0$. Denote by $t_{d,n}$ the length of the n th down time and by $t_{u,n}$ the length of the n th up time. Therefore, $t_{d,n}$'s and $t_{u,n}$'s are i.i.d. exponential random variables with rates q_0 and q_1 . Let $T_{d,n}$ be the beginning of the epoch of the n th time the machine is down and $T_{u,n}$ be the beginning of the epoch of the n th time the machine is up, i.e.,

$$T_{d,n} = \sum_{i=1}^{n-1} (t_{d,i} + t_{u,i}) \quad \text{and} \quad T_{u,n} = T_{d,n} + t_{d,n}. \quad (6)$$

To simplify notation, we denote

$$x_{d,n} \triangleq x(T_{d,n}) \quad \text{and} \quad x_{u,n} \triangleq x(T_{u,n}).$$

We then have the following recursive equations for $x_{d,n}$ and $x_{u,n}$:

$$x_{d,n} = \max(x_{d,n-1} - t_{d,n}d, 0) \quad (7)$$

$$x_{u,n+1} = \min(z, x_{u,n} + t_{u,n}(r-d)) \quad (8)$$

with $x_{d,1} = z$. Equation (7) represents the unique dynamics when the machine is down, where "max" means that the inventory level cannot fall below zero (i.e., backlog is not permitted). The "min" in (8) represents the hedging point policy, namely, when the machine is up, the inventory level increases at rate $r-d$ until either it hits the level z where it remains until the machine breaks down, or the machine breaks down before it hits the level z . The trajectory of $x(t)$ is illustrated in Fig. 1.

Define the following two random time transformations:

$$\omega_d(t) = \int_0^t 1(i(s) = 0) ds$$

Fig. 1. The trajectory of $x(t)$.

Fig. 2. The trajectory of $x_d(t)$.

$$\phi_d(t) = \int_0^t 1(i(s) = 1) ds$$

and their inverse functions

$$\tau_d(t) = \phi_d^{-1}(t) = \inf \{ \tau : \phi_d(\tau) > t \}$$

$$\tau_u(t) = \phi_u^{-1}(t) = \inf \{ \tau : \phi_u(\tau) > t \}.$$

Define also two processes $\{x_d(t); t \geq 0\}$ and $\{x_u(t); t \geq 0\}$ as

$$x_d(t) = x(\tau_d(t)) \quad \text{and} \quad x_u(t) = x(\tau_u(t)).$$

Intuitively, $\phi_d(t)$ [respectively, $\phi_u(t)$] is the total down (respectively, up) time of the machine during the time interval $[0, t]$. The process $\{x_d(t); t \geq 0\}$ (respectively, $\{x_u(t); t \geq 0\}$) corresponds to the part of the process $\{x(t); t \geq 0\}$ when the machine is down (respectively, up). The process $\{x_d(t); t \geq 0\}$ is illustrated in Fig. 2.

It is not too difficult to verify that $x_d(t)$ is in fact the same as the workload process of an $M/M/1$ queue with bounded workload, in which the interarrival times are $\{t_{d,n}; n = 1, 2, \dots\}$, the service requirements are $\{t_{u,n}(r-d); n = 1, 2, \dots\}$, the service rate is d , and the upper bound on the workload process is z . Hence, the steady-state probability distribution function of the process $\{x_d(t); t \geq 0\}$ is given by

$$F_{x_d}(x) = \begin{cases} 1, & x \geq z \\ \frac{1-\rho - \mu(1-\rho)^x}{1-\rho - \mu(1-\rho)^z}, & 0 \leq x < z \\ 0, & x < 0 \end{cases} \quad (9)$$

where

$$\mu = \frac{q_1}{r-d} \quad \text{and} \quad \rho = \frac{q_0(r-d)}{q_1 d}.$$

(See Takács [9].) Next we use $F_{x_d}(x)$ to calculate $F_{x_d}(x)$, the steady-state probability distribution function of the process $\{x_d(t); t \geq 0\}$. We use $f_{x_d}(x)$ and $f_{x_u}(x)$ to denote the density functions of $F_{x_d}(x)$ and $F_{x_u}(x)$, respectively.

Define $D_x(t)$ to be the downcrossing counting process of $x(t)$ at level x during the interval $[0, t]$, and $U_x(t)$ the upcrossing counting process. Define $t_0 = 0$, and

$$t_n = \inf \{ t : x(t) = z, i(t) = 0, t > t_{n-1} \} \quad \text{for } n \geq 1.$$

By definition, it is clear that $\{x(t), t \geq 0\}$ is a regenerative process with regenerative points $\{t_n, n \geq 0\}$. Based on the regenerative theorem, we have

$$F_{\lambda}(x) = \frac{E\left[\int_0^{t_1} 1(x(s) < x) ds\right]}{E[t_1]}.$$

Note that

$$\int_0^{t_1} 1(x(s) < x + \delta x) ds - \int_0^{t_1} 1(x(s) < x) ds$$

is the total time that the process $x(t)$ takes value between the interval $[x, x + \delta x)$ during $[0, t_1]$, which is also equal to

$$\frac{U_r(t_1)\delta x}{r-d} + \frac{D_r(t_1)\delta x}{d} \quad \text{for } 0 < x < z.$$

We further note that $U_r(t_1) = D_r(t_1)$ for $0 < x < z$. Therefore, we have

$$\frac{d}{dx} E\left[\int_0^{t_1} 1(x(s) < x) ds\right] = \frac{r}{(r-d)d} E[D_r(t_1)].$$

This gives us

$$\begin{aligned} f_{\lambda}(x) &= \frac{dF_{\lambda}(x)}{dx} = \frac{r}{(r-d)d} \frac{E[D_r(t_1)]}{E[t_1]} \\ &= \frac{r}{r-d} \frac{E[\phi_d(t_1)]}{E[t_1]} \frac{E[D_r(t_1)]}{dE[\phi_d(t_1)]} \\ &= \frac{r}{r-d} \frac{q_1}{q_0 + q_1} \frac{E[D_r(t_1)]}{dE[\phi_d(t_1)]} \quad \text{for } 0 < x < z. \end{aligned} \quad (10)$$

The above method, which we used to derive (10), is the standard analysis of level crossings (e.g., see Cohen [3, p. 363-373]). Using the same method, we can also show that the most right-hand side of (10) is equal to $f_{\lambda,d}(x)$. Therefore, we have

$$f_{\lambda}(x) = \frac{r}{r-d} \frac{q_1}{q_0 + q_1} \frac{\rho\mu(1-\rho)e^{-\mu(1-\rho)z}}{1-\rho} \quad \text{for } 0 < x < z. \quad (11)$$

We now calculate $F_{\lambda}(0)$ and $F_{\lambda}(z)$. Again, using the regenerative theorem, we have

$$\begin{aligned} F_{\lambda}(0) &= \frac{E\left[\int_0^{t_1} 1(x(s) = 0) ds\right]}{E[t_1]} \\ &= \frac{E[\phi_d(t_1)]}{E[t_1]} \frac{E\left[\int_0^{\phi_d(t_1)} 1(x_d(\phi_d(s)) = 0) d\phi_d(s)\right]}{E[\phi_d(t_1)]} \\ &= \frac{q_1}{q_0 + q_1} F_{\lambda,d}(0) = \frac{q_1}{q_0 + q_1} \frac{1-\rho}{1-\rho e^{-\mu(1-\rho)z}} \end{aligned}$$

and

$$F_{\lambda}(z) = 1 - F_{\lambda}(0) - \int_0^z f_{\lambda}(x) dx = \frac{q_0}{q_0 + q_1} \frac{(1-\rho)e^{-\mu(1-\rho)z}}{1-\rho e^{-\mu(1-\rho)z}}.$$

Finally, we calculate the long-run expected average cost J , associated with the hedging point policy. Based on (2), it is quite clear that

$$\begin{aligned} J &= c \int_0^z x f_{\lambda}(x) dx + c_0 F_{\lambda}(0) \\ &= \frac{1}{(q_0 + q_1)(1-\rho e^{-\mu(1-\rho)z})} \left[c_0 q_1 (1-\rho) \right. \\ &\quad \left. + c\rho \left[\frac{r(1-e^{-\mu(1-\rho)z})}{1-\rho} - (q_0 + q_1)ze^{-\mu(1-\rho)z} \right] \right]. \end{aligned} \quad (12)$$

IV. OPTIMAL COST-TO-GO FUNCTIONS

To obtain the optimal cost-to-go functions, let us assume throughout this section that the optimal control is the hedging point policy. This will be verified later in the next section. Let z^* be the optimal hedging point, then (12) tells us that it must satisfy the following equation:

$$h(z) \triangleq \frac{c(q_0 + q_1)z}{1-\rho} + \frac{c}{(1-\rho)^2} [d - (r+d)\rho + \rho(r-d+\rho d)e^{-\mu(1-\rho)z}] - c_0 q_1 = 0 \quad (13)$$

(this is simply due to $dJ/dz = 0$), and furthermore,

$$Jz^* = cz^* + \frac{cd}{q_1 + q_1}. \quad (14)$$

It is worth noting that z^* is the unique solution of $h(z) = 0$ (because $dh(z)/dz > 0$). However, $z^* = 0$ if the unique solution of $h(z) = 0$ is negative (which is the case if $h(0) = cd - c_0 q_1 > 0$). Since we have assumed that the optimal control is the hedging point policy, we have $J^* = J_{z^*}$, and furthermore, the Bellman equations (3) and (4) reduce to

$$\frac{dV(x)}{dx} = \begin{cases} A_1 V(x) - b_1(J^* - cx), & \text{for } 0 < x \leq z^* \\ A_2 V(x) - b_2(J^* - cx), & \text{for } x \geq z^* \end{cases} \quad (15)$$

where

$$A_1 = \begin{pmatrix} \frac{q_1}{r-d} & -\frac{q_1}{r-d} \\ \frac{q_0}{d} & -\frac{q_0}{d} \end{pmatrix}, \quad A_2 = \begin{pmatrix} -\frac{q_1}{d} & \frac{q_1}{d} \\ \frac{q_0}{d} & -\frac{q_0}{d} \end{pmatrix}.$$

$$V(x) = \begin{pmatrix} V_1(x) \\ V_0(x) \end{pmatrix}, \quad b_1 = \begin{pmatrix} -\frac{1}{r-d} \\ \frac{1}{d} \end{pmatrix}, \quad b_2 = \begin{pmatrix} \frac{1}{d} \\ \frac{1}{d} \end{pmatrix}$$

with boundary conditions

$$c_0 - J^* + q_0(V_1(0) - V_0(0)) = 0 \quad (16)$$

$$cz^* - J^* - q_1(V_1(z^*) - V_0(z^*)) = 0. \quad (17)$$

Solving (15), we have, for $0 \leq x \leq z^*$,

$$\begin{aligned} V(x) &= \left(I - \frac{A_1}{k_1} + \frac{A_1}{k_1} e^{k_1 x} \right) V(0) + \left(\frac{A_1}{k_1} - I \right) b_1 \left(J^* x - \frac{1}{2} cx^2 \right) \\ &\quad + \frac{A_1 b_1}{k_1^2} \left[J^* (1 - e^{k_1 x}) - cx + \frac{c}{k_1} (e^{k_1 x} - 1) \right] \end{aligned} \quad (18)$$

where $k_1 = \mu(1-\rho)$, and for $x \geq z^*$,

$$\begin{aligned} V(x) &= \left(I - \frac{A_2}{k_2} + \frac{A_2}{k_2} e^{k_2(x-z^*)} \right) V(z^*) \\ &\quad - \left(J^*(x-z^*) - \frac{1}{2} c(x-z^*)^2 \right) b_2 \end{aligned} \quad (19)$$

where $k_2 = -(q_0 + q_1)/d$.

Based on (18) and also using (16), we have for $0 \leq x \leq z^*$

$$\begin{aligned} V_1(x) &= V_1(0) + \frac{q_1}{k_1(r-d)q_0} (J^* - c_0)(e^{k_1 x} - 1) \\ &\quad - \frac{q_0 + q_1}{k_1 d(r-d)} \left(J^* x - \frac{1}{2} cx^2 \right) \\ &\quad - \frac{q_1 r}{k_1^2 d(r-d)^2} \left[J^* (1 - e^{k_1 x}) - cx + \frac{c}{k_1} (e^{k_1 x} - 1) \right] \end{aligned} \quad (20)$$

and

$$\frac{dV_1(i)}{di} = \frac{q_1(q_0 + q_1)}{k_1 q_0 (i - d)^2} J^* e^{k_1 i} - \frac{c_0 q_1}{(i - d) q_0} e^{k_1 i} - \frac{q_0 + q_1}{k_1 d (i - d)} (J^* - c_1) + \frac{c_1 q_1}{k_1 d (i - d)^2} (1 - e^{k_1 i}) \quad (21)$$

Substituting c_0 and J^* from (13) and (14) into (21), we obtain

$$\frac{dV_1(i)}{di} = \frac{c(q_0 + q_1)(i - d)}{q_1^2 d (1 - \rho)^2} (1 - e^{-k_1(i - i^*)}) - \frac{c(q_0 + q_1)}{k_1 d (i - d)} (J^* - c_1) \quad \text{for } 0 \leq i \leq i^* \quad (22)$$

Similarly, by combining (19), (17), and (14), we obtain for $i \geq i^*$

$$V_1(i) = V_1(i^*) + \frac{J^* - c_1}{k_1 d} (e^{k_1(i - i^*)} - 1) + \frac{1}{d} \left[\frac{1}{2} (e^{k_1(i - i^*)} - e^{k_1(i^* - i^*)}) - J^* (i - i^*) \right] \quad (23)$$

and

$$\frac{dV_1(i)}{di} = -\frac{c}{q_0 + q_1} (e^{k_1(i - i^*)} - 1) + \frac{c}{d} (i - i^*) \quad (24)$$

V THE VERIFICATION THEOREM

In this section we verify that the optimal hedging point policy we obtained in the previous section is the optimal control. We first need the following verification theorem.

Verification Theorem For the system under consideration suppose the control $u^*(i, i)$ is defined by (5) where i^* is given by (13). If there exist continuously differentiable functions $V(i)$ on $i \in (0, \infty)$ and a constant J^* such that the Bellman equations (3) and (4) are satisfied and $V(i) < ai^* + b$ (where a and b are two constants) then $u^*(i, i)$ is the optimal control which minimizes the long run expected average cost defined by (2).

The proof of the verification theorem is essentially the same as the one given in [2] which uses the Dynkin formula. Hence we will not repeat it here. For the optimal cost-to-go function $V_1(i)$ which we obtained in the previous section we can easily verify [based on (22) and (24)] that it is a convex function with minimum J^* and also it is continuously differentiable. Hence based on the above verification theorem the optimal hedging point policy is indeed optimal.

VI CONCLUSION

We proved that even when backlog is not permitted, the optimal control for the failure-prone production system remains to be a hedging point policy. We demonstrated that the traditional sample path argument is no longer valid in proving that the optimal cost-to-go functions are convex functions. Instead the explicit formulas have to be obtained. To obtain the optimal hedging point policy and the optimal cost to go functions, we first established a relationship between the inventory process of the system under a hedging point policy and the workload process of a single-node queueing system with limited workload, and then used it to obtain the probability distribution function of the inventory process based on some existing results in queueing theory and the level crossing technique.

An immediate application of our results in this note is to failure-prone production systems with many machines connected in network. One way to study the optimal control problem for these complex

systems is to decompose them into many simple subsystems systems with only one machine. The interaction among these simple subsystems can be formulated through the total demand rate to each subsystem. Clearly, for some subsystems backlog of demands will not be permitted, especially if they are suppliers to other subsystems. One example is a production line in which machines are linked together in tandem. In such a system the demand rate for each machine (except the last one) is simply equal to the production rate of its downstream machine hence backlog will not be permitted. Our results can give optimal instantaneous production rates for those subsystems in which backlog is not permitted. Hence, they can be used to develop optimal or near-optimal designs on production rate control for complex systems when combined with other methods.

ACKNOWLEDGMENT

Relative Stability of a Linear Time-Varying Process with First-Order Nonlinear Time-Varying Feedback

J. S. Ansari

Abstract—A method of establishing sufficient conditions for the stability of a system consisting of a time-varying linear process and a first-order nonlinear time-varying feedback is presented. Rate of decay of unforced response and BIBO stability can also be determined. The governing equation of the system is represented in the form of an integro-differential equation, so that a modified form of the Lyapunov–Razumikhin-type condition can be applied. The first part of the note deals with stability of vector functional equations. The results obtained are applied to feedback systems. An example is worked out to show the applicability of the results obtained.

1. INTRODUCTION

Methods such as circle criterion and Popov's criterion are available for establishing sufficient condition for the stability of systems consisting of a linear process and zero-order nonlinear feedback [1], [2]. No general results are available for linear time-varying process with first-order nonlinear, time-varying feedback systems. The method presented here is applicable to such systems. In particular, linear processes with an arbitrarily varying parameter can also be considered. As such, the results may be useful for studying stability of adaptive control systems.

The note is in two parts. The first part presents a method of establishing an upper bound on the norm of the solution of a vector functional differential equation. The results obtained are then applied to a linear time-varying process with a first-order nonlinear, time-varying feedback.

The note presents two points. It shows that the Lyapunov–Razumikhin theorem, which is essentially applicable to functional equations, can be applied to feedback systems governed by ordinary differential equations. This is done by rewriting the system equations in integro-differential form. Some systems which cannot be analyzed by other methods can be studied by this method. The other contribution is that the Lyapunov–Razumikhin theorem has been extended to included inputs and, furthermore, a method of establishing the rate of decay of solutions is also included.

II. LYAPUNOV–RAZUMIKHIN-TYPE THEOREM

Let

$$\dot{y}(t) = f(y_t, t) \quad (1)$$

represent a vector functional differential equation of the retarded type [3], where $y(t)$ is an $(n \times 1)$ vector, and y_t in the argument of f implies dependence of f on $y(s)$, $t - T(t) \leq s \leq t$. Function $[t - T(t)]$ is nondecreasing. Interval $[t - T(t), t]$ is represented by $I(t)$. $\|y\|$ represents Euclidian norm in R^n . Equation (1) is such that $y = 0$ is a solution. If $y(s)$ is given in the initial interval, $I(t_0)$, then $y(t)$ for $t > t_0$ is determined by equation (1). It can be shown that the solution is continuous. A scalar function $V(t, y)$ is chosen such that $w(\|y\|) \leq V(t, y) \leq v(\|y\|)$, where w and v are increasing functions, and $w(0)$ and $v(0)$ are zero. If V tends to zero with time, then it follows that $\|y\|$ also tends to zero.

Lyapunov–Razumikhin sufficient conditions for stability require that [4]

$$\dot{V}(t, p(t)) \leq -\alpha < 0$$

for all continuous test functions, p , that satisfy the inequality

$$V(s, p(s)) < V(t, p(t)) + \delta, \quad s \in I(t).$$

A modified form of a Lyapunov–Razumikhin-type condition is presented here in the form of a theorem. The theorem gives sufficient conditions under which $V(t, y(t)) < H(t)$, for all $t > t_0$; where $H(t)$ is a function of our choice. By choosing H as an exponentially decaying function, we can establish the rate of decay of the response, which is not possible through the original condition. Moreover, the Lyapunov–Razumikhin theorem had not been used to study stability of finite-order linear processes with nonlinear feedback, because it is not applicable to ordinary differential equations. In order to apply a Lyapunov–Razumikhin-type condition, we shall use convolution to represent the governing equation in an integro-differential equation form.

Let $y(t)$ be a solution of equation (1), and $V(t, y(t))$ be a scalar function fulfilling the following conditions.

i)

$$w(\|y\|) \leq V(t, y) \leq v(\|y\|) \quad (2)$$

for $\|y\| \leq Y_0$, $t > -T(t_0)$ where $w(s)$ and $v(s)$ are increasing functions of s for $0 \leq s \leq Y_0$, and $w(0) = v(0) = 0$.

ii) $V(t, y)$ is differentiable with respect to t and by all elements y_i of the vector y . We denote

$$\left(\frac{\partial V}{\partial y_1} + \frac{\partial V}{\partial y_2} + \cdots + \frac{\partial V}{\partial y_n} \right) T = \frac{\partial V}{\partial y}.$$

iii) $\partial V / \partial t$ and all $\partial V / \partial y_i$ are continuous with respect to t and y_i , for $t > t_0$ and $\|y\| \leq Y_0$.

Theorem. If for a continuous function $H(t) \leq v(\|y_0\|)$, with continuous derivative,

$$\lim_{s \rightarrow t} \left[\frac{\partial V(s, p)}{\partial s} + \frac{\partial V}{\partial p} \cdot f(p, s) \right] < \dot{H}(t) \quad \forall t > t_0 \quad (3)$$

For all test functions p , belonging to set $P(t)$, where $P(t)$ is the set of all vector continuous functions for which the following conditions are satisfied:

$$V(t, p(t)) = H(t) \quad (4)$$

$$V(s, p(s)) < H(s), \quad \text{for } t - T(t) \leq s < t \quad (5)$$

then

$$V(t, y(t)) < H(t), \quad \text{for all } t > t_0 \quad (6)$$

provided the initial conditions are such that

$$V(s, y(s)) < H(t_0), \quad \text{for } s \in I(t_0). \quad (7)$$

Proof: It is given that initially

$$V(t_0, y(t_0)) < H(t_0). \quad (8)$$

Suppose there exists a t_1 , such that t_1 is the smallest value of $t > t_0$ for which

$$V(t_1, y(t_1)) = H(t_1). \quad (9)$$

It follows that

$$V(t, y(t)) < H(t), \quad t_0 - T(t_0) \leq t < t_1 \quad (10)$$

Manuscript received May 4, 1993; revised October 20, 1993.

IEEE Log Number 9406989.

and that $y(t)$ belongs to the set $P(t_1)$, where P is defined by conditions (4) and (5). Hence, we can substitute y in place of p in condition (3) to get

$$\lim_{s \rightarrow t_1} \left[\frac{\partial V(s, y)}{\partial s} + \frac{\partial V}{\partial y} f(y, s) \right] < H(t_1) \quad (11)$$

According to (1), $f(y, s)$ is equal to $q(s)$. Hence the left hand side of inequality (11) is equal to V and inequality (11) can be written as

$$\lim_{s \rightarrow t_1} V(s, y(s)) < H(t_1) \quad (12)$$

At the same time it follows from relations (9) and (10) that

$$\lim_{s \rightarrow t_1} V(s, y(s)) \geq H(t_1) \quad (13)$$

which contradicts inequality (12). Hence assumption (9) is not true and V is bounded by H .

III. APPLICATION TO FEEDBACK SYSTEMS

Consider a system consisting of a time varying linear n th order asymptotically stable plant coupled with nonlinear time varying feedback. Let the plant be governed by

$$\dot{y}(t) = \int_0^t q(t-t')u(t')dt' + \phi(t, Y) \quad (14)$$

where q is the impulse response function and $\phi(t, Y)$ is the initial condition response and Y is the $(n \times 1)$ vector representing the initial state. For convenience we shall write (14) as

$$\dot{y} = q(u, Y) \quad (14a)$$

Let the feedback be given by

$$u + F(t, u) = \lambda(t, (r - y)) \quad (15)$$

where r is the reference input. Functions $F(t, u)$ and $\lambda(t, v)$ are nondecreasing with respect to u and $\lambda(t, 0)$ and $F(t, 0)$ are identically zero.

Combining (14a) and (15) gives

$$\dot{u} = -F(t, u) + \lambda(t, (r - y(u, Y))) \quad (16)$$

Let us choose

$$V(t, u) = u^2 \quad (17)$$

and

$$H(t) = B e^{-\lambda t} \quad (18)$$

Since the linear plant is asymptotically stable we can find a $\Phi(t)$ such that the initial condition response

$$|\phi(t, Y)| < \epsilon \Phi(t) \quad t \geq 0 \quad (19)$$

if

$$\|Y\| < \epsilon \quad (20)$$

Let the input be bounded by

$$|r(t)| < \delta \quad t \geq t_0 \quad (21)$$

Application of the above theorem to (16) shows the following

Corollary 1 If

$$\begin{aligned} \pm B e^{-\lambda t} \lambda \left[t \pm \left(\delta + \epsilon \Phi(t) + B \int_0^t |q(t-t')| e^{-\lambda t'} dt' \right) \right] \\ < -\lambda + \frac{F(t \pm B e^{-\lambda t})}{\pm B e^{-\lambda t}} \end{aligned} \quad (22)$$

then

$$|u(t)| < B e^{-\lambda t} \quad t < T$$

where T can be infinity provided

$$\|Y\| < \epsilon, |r(t)| < \delta \quad \text{and} \quad |u(t)| < B \quad \text{for } t \in I(t_0)$$

Corollary 2 If for any $B > 0$ and $\delta = 0$ we can find positive λ and ϵ to satisfy condition (22) for all $t > t_0$ then the unforced solution $y = u = 0$ is asymptotically stable.

Corollary 3 If for any $B > 0$ and $\lambda = 0$ we can find positive δ and ϵ to satisfy condition (22) for all $t > t_0$ then the system is stable in the sense of bounded input bounded output (BIBO).

Remark Corollaries follow immediately and obviously from the theorem. Therefore proofs are not included.

A Example

Let

$$\dot{y} + (a + b)y + ab y = cu \quad (23)$$

and

$$u + F(t, u) = \lambda(t, (r - y)) \quad (24)$$

where $b > a > 0$, $c > 0$, $\lambda(t, 0) = F(t, 0) = 0$, $F(t, u)$ and $\lambda(t, v)$ are nondecreasing with respect to u . Let initial conditions be such that

$$|u(0)| < B, \quad \|\lambda(0)\| \leq \epsilon$$

where $\lambda(0) = (y(0) - y(0)/b)e^{-t}$. Let $|r(t)| \leq \delta$, $t \geq 0$.

Evaluating q and Φ and substituting in inequality (22) we get

$$\begin{aligned} \pm B e^{-\lambda t} \lambda \left[t \pm \left(\delta + \frac{B e^{-\lambda t} \exp(-\lambda t)}{(a - \lambda)(b - \lambda)} \right) \right. \\ \left. - \left(\frac{B e^{-\lambda t}}{a - \lambda} - \sqrt{2b\epsilon} \right) \frac{\exp(-\lambda t)}{b - a} \right. \\ \left. + \left(\frac{B e^{-\lambda t}}{b - \lambda} - \sqrt{2a\epsilon} \right) \frac{\exp(-\lambda t)}{b - a} \right] < -\lambda + \frac{F(t \pm B e^{-\lambda t})}{\pm B e^{-\lambda t}} \end{aligned} \quad (25)$$

If $a = 2$, $b = 3$, $c = 1$ and

$$\frac{F(t \pm u)}{u} \geq 10.5 \quad t \geq 0$$

and we choose $\lambda = 0.5$, $\delta = 0$, $\epsilon = B/6\sqrt{2}$ then inequality (25) becomes

$$\frac{F(t \pm u)}{\pm u} < \frac{37.5}{1 - 0.625e^{-t} + 2.75e^{-t}} \quad (26)$$

where

$$u = 0.266B e^{-0.5t} - 0.1625B e^{-t} + 0.75B e^{-1.5t}$$

If inequality (26) is satisfied for all $t > 0$ then

$$|u(t)| < B e^{-0.5t} \quad t \geq 0$$

BIBO Stability: If the values of a , b , c , and F are as chosen above, and we choose $\lambda = 0$, $\delta = B/2$, then inequality (25) yields

$$\frac{N(t, \pm x)}{\pm x} < \frac{15}{1 + e^{-3t/4}} \quad (27)$$

where

$$x = \delta + (B/6) + (2Be^{-3t/4}/3).$$

If condition (27) is satisfied, then

$$|u(t)| < B \quad t \geq 0$$

provided

$$|r(t)| \leq B/2 \quad t \geq 0.$$

B. Comparison to the Result Obtained Through the Original Lyapunov–Razumikhin Theorem

It is of interest to note that the application of the original Lyapunov–Razumikhin condition to (23) and (24) gives the following sufficient condition for asymptotic stability of the unforced solution:

$$\pm B^{-1} N \left[\frac{\pm c B}{b-a} \left(\frac{b-a}{ab} - \frac{e^{-at}}{a} - \frac{e^{-bt}}{b} \right) \right] < \frac{F(\pm B, t)}{\pm B} - \alpha \quad \times \forall B, B_0 \geq B > 0 \quad (28)$$

where α is positive and as small as we like.

For asymptotic stability with infinitesimal rate of decay, λ in condition (25) can be taken as infinitesimally small, and δ is zero. It can be seen that as λ and α tend to zero, conditions (25) and (28) approach each other. Thus, the result obtained through the original Lyapunov–Razumikhin theorem is a special case of the result obtained through the modified theorem.

IV. CONCLUSIONS

A method of applying the Lyapunov–Razumikhin sufficient condition for stability to feedback systems governed by ordinary nonlinear differential equations is presented. The results obtained show that the method is useful in that it is applicable to some systems which cannot be analyzed by other known methods.

A modified form of the Lyapunov–Razumikhin condition is presented, which establishes rate of decay of unforced response. Inputs can also be considered and BIBO stability studied.

Properties of Optimal Weighted Sensitivity Designs

Kathryn E. Lenz

Abstract—Weighted sensitivity designs for a class of single-input/single-output, linear, time-invariant systems are shown to have the property that the optimal controller has fewer right-half plane poles than the plant has right-half plane zeros. Weighted complementary sensitivity designs are shown to have the property that the optimal controller has fewer right-half plane zeros than the plant has right-half plane poles. Effects of various choices of weighting functions on the optimal solutions are described.

1. INTRODUCTION

Using a result due to Poreda [7], we derive basic frequency domain qualitative properties of the optimal solutions to weighted sensitivity minimization and weighted complementary sensitivity minimization problems for single-input/single-output, linear, time-invariant systems. We show that under certain continuity assumptions applied to the plant and weighting function, weighted sensitivity optimal controllers have fewer right-half plane poles than the plant has right-half plane zeros. Conversely, if a given stabilizing controller has fewer right-half plane poles than the plant has right-half plane zeros and makes the magnitude of the weighted sensitivity function flat across frequencies, then the controller is optimal.

The analogous result for weighted complementary sensitivity designs is that the optimal controller has fewer right-half plane zeros than the plant has right-half plane poles. Conversely, if a given stabilizing controller has fewer right-half plane zeros than the plant has right-half plane poles and makes the magnitude of the weighted complementary sensitivity function flat across frequencies, then the controller is optimal.

Certain weighted sensitivity and weighted complementary sensitivity problems are not optimized by a stabilizing controller, even though the optimization is done over the set of all stabilizing controllers. We describe situations in which this can happen for plants with $j\mathbb{R}$ poles or zeros. We also show that if one wishes to obtain a stabilizing controller as the optimal solution to a weighted sensitivity or weighted complementary sensitivity optimization problem, one should not use a weighting function with a $j\mathbb{R}$ zero.

II. NOTATION, DEFINITIONS, AND ASSUMPTIONS

Denote the imaginary axis of the complex plane \mathbb{C} by $j\mathbb{R}$ and the imaginary axis together with infinity by $j\overline{\mathbb{R}}$. We say that s is in the right-half plane, \mathbb{C}^+ , if $\text{Re}(s) > 0$. Correspondingly, s is in the left-half plane, \mathbb{C}^- , if $\text{Re}(s) < 0$. The subset of functions in L^∞ on $j\mathbb{R}$ that are also continuous on $j\overline{\mathbb{R}}$ will be denoted by L_c^∞ . The space of functions that are analytic in \mathbb{C}^+ and extend to functions in L^∞ on $j\mathbb{R}$ will be denoted by H^∞ . The functions in H^∞ having continuous extensions from \mathbb{C}^+ to $\mathbb{C}^+ \cup j\overline{\mathbb{R}}$ will be denoted by A_∞ .

For M a function of the complex variable s , M^* will denote $\overline{M(-\bar{s})}$. A function $M \in H^\infty$ is inner if $M^*M = 1$ a.e. on $j\mathbb{R}$. A Blaschke product $B(s)$ of degree m is an inner function of the form $B(s) = k \prod_{j=1}^m (1 - \bar{z}_j s)/(1 + z_j s)$, where $|k| = 1$ and $z_j \in \mathbb{C}^+$ for $j = 1, 2, \dots, m$. For B a finite Blaschke product, $B^* = B^{-1}$.

IEEE Log Number 9407261.

A function $N \in H^\infty$ is outer if the closure of NH^2 is H^2 , where H^2 is the space of functions that are square integrable on $j\mathbb{R}$ and analytic in \mathbb{C}^+ . A function $F \in H^\infty$ is a unit in H^∞ if $F^{-1} \in H^\infty$.

If there exist functions $X, U, V, D \in H^\infty$ such that $P = XD^{-1}$, and $U^*X + V^*D = I$, then we call XD^{-1} a coprime factorization of P . We say that K stabilizes P under negative feedback if the functions $(1 + PK)^{-1}$, $PK(1 + PK)^{-1}$, $K(1 + PK)^{-1}$, and $P(1 + PK)^{-1}$ are in H^∞ . If such a K exists for P , we say that P is stabilizable.

Suppose that C has a coprime factorization $C = U^*V^{-1}$ such that $U^*X + V^*D = I$, where $P = XD^{-1}$, and $X, U, V, D \in H^\infty$. Then C stabilizes P under negative feedback. The Youla parameterization of the set of functions that stabilize P under negative feedback, parameterized in terms of $C = U^*V^{-1}$, is given by

$$\Sigma(P) := \{K: K = (U - D\hat{Q})(V + X\hat{Q})^{-1}, \hat{Q} \in H^\infty \text{ and } \hat{Q} \neq -V^*X^{-1}\}.$$

Assumption 1: The plant $P(s)$ is stabilizable and has a coprime factorization $P = XD^{-1} = X_0X_\infty D^{-1}$, where X_0 is a finite Blaschke product, X_∞ is an outer function, and D is a rational function with inner/outer factorization $D = D_1D_\infty$.

Let a generalized zero of a Lebesgue measurable function f on a Lebesgue measurable subset of $j\mathbb{R}$ be, as defined in [3], a point on $j\mathbb{R}$ for which the magnitude of f is not essentially bounded from zero on any neighborhood of the point. If f is continuous at a generalized zero, the generalized zero is a zero of f . Denote the set of generalized zeros of f on $j\mathbb{R}$ by $Z(f)$.

For a function f continuous and nonvanishing on $j\mathbb{R}$ and meromorphic in \mathbb{C}^+ , the winding number (or index) of $f(j\omega)$ may be computed as $\text{wno}(f) = \gamma_f - p_f$, where γ_f and p_f denote the number of \mathbb{C}^+ zeros and \mathbb{C}^+ poles of f respectively, counted according to their multiplicities.

For a given controller C and plant P , denote the number of \mathbb{C}^+ poles of C by p_c , the number of \mathbb{C}^+ zeros of C by z_c , the number of \mathbb{C}^+ poles of P by p_p , and the number of \mathbb{C}^+ zeros of P by z_p , counted according to their multiplicities. We show in Section III that the optimality, as described in (3.3) and (3.5), of $C \in \Sigma(P)$ depends in part on the number of \mathbb{C}^+ poles and \mathbb{C}^+ zeros of P and C .

Lemma 2.1. If $g(s) \in A_\infty$ and is nonvanishing on $j\mathbb{R}$, then $g(s)$ has at most a finite number of \mathbb{C}^+ zeros.

Proof. Suppose that $g(s) \in A_\infty$ and is nonvanishing on $j\mathbb{R}$. Since $g(s)$ is analytic and not identically zero in \mathbb{C}^+ , each \mathbb{C}^+ zero of $g(s)$ has a finite order and the set of all zeros of $g(s)$ has no limit point in \mathbb{C}^+ . Suppose that $g(s)$ has an infinite number of \mathbb{C}^+ zeros. Let $\phi(s) = (s-1)/(s+1) = z$. The function $\phi(s)$ conformally maps \mathbb{C}^+ onto the open unit disk. The function $g\phi\omega^{-1}$ is analytic in the open unit disk and continuous and nonvanishing on the unit circle. Since g has an infinite number of zeros in \mathbb{C}^+ , $g\phi\omega^{-1}$ has an infinite number of zeros in the open unit disk. But this set of zeros has no limit point in the open unit disk. There must be a sequence of these zeros with a limit point on the unit circle. Therefore $g\phi\omega^{-1}$ has a zero on the unit circle. This implies that $g(s)$ has a zero on $j\mathbb{R}$, which is a contradiction.

III. QUALITATIVE PROPERTIES OF OPTIMAL SOLUTIONS

Both weighted sensitivity and weighted complementary sensitivity optimization problems can be transformed into the one-block general distance problem of finding an optimal norm γ and if possible an optimal $\hat{Q} \in H^\infty$ such that

$$\gamma = \inf_{Q \in H^\infty} \|R - Q\|_\infty = \|R - \hat{Q}\|_\infty. \quad (3.1)$$

When $R \in L^\infty$ the infimum in (3.1) is achieved for some $Q \in H^\infty$ [4, p. 135]. If $R \in L^\infty$, then the optimal \hat{Q} is unique and $|R - \hat{Q}|$ is constant a.e. on $j\mathbb{R}$ [5, p. 196].

From Poreda's Theorem 1 [7, p. 250] we have that for R continuous and nonvanishing on $j\mathbb{R}$

$$\inf_{Q \in H^\infty} \|R - Q\|_\infty = \|R\|_\infty \quad (3.2)$$

if and only if $|R|$ is constant on $j\mathbb{R}$ and $\text{wno}(R) < 0$. From Poreda's Corollary ([7, p. 250] see also [1, p. 52]), if R is also meromorphic in \mathbb{C}^+ , (3.2) holds if and only if $R = \gamma B_1^* B_2$, where B_1 and B_2 are Blaschke products with $\deg(B_1) > \deg(B_2)$ and γ is a constant.

Throughout this section, suppose that $P = XD^{-1}$ satisfies Assumption 1 and a controller C is given such that $C = U^*V^{-1}$ for $U, V \in H^\infty$, and $U^*X + V^*D = I$. Also assume that neither P nor C is the zero function.

Define the weighted sensitivity transfer function $\Lambda(s, K)$ to be $\Lambda(K) = [W_1/(1 + PK)]$. Assume that the weighting function W_1 is analytic in \mathbb{C}^+ and has no zeros in \mathbb{C}^+ . Assume that $W_1 D_0 X_\infty \in H^\infty$ has at most finitely many generalized zeros on $j\mathbb{R}$ and is continuous at each point of $Z(W_1 D_0 X_\infty)$. Further assume that $W_1 D_0 V \in A_\infty$.

Parameterize the set of all stabilizing controllers $\Sigma(P)$ in terms of C . Then the weighted sensitivity optimization problem associated with Λ consists of finding γ_1 and \hat{K} such that

$$\begin{aligned} \gamma_1 = \|\Lambda(K)\|_\infty &= \inf_{K \in \Sigma(P)} \left\| \frac{W_1}{1 + PK} \right\|_\infty \\ &= \inf_{Q \in H^\infty} \|W_1 D V + W_1 X \hat{Q}\|_\infty. \end{aligned} \quad (3.3)$$

Define

$$\gamma_2 = \inf_{Q \in H^\infty} \|X_0^* W_1 D_0 V - Q\|_\infty. \quad (3.4)$$

To equate the optimization problem (3.3) with the one block general distance problem (3.4) we rule out the possibility that $\gamma_2 < \gamma_1$. To do this assume that $\gamma_2 \geq |W_1 D_0 V(j\omega)|$ for every $j\omega \in Z(W_1 D_0 X_\infty)$. Then, [2, p. 12], $\gamma_2 = \gamma_1$. This assumption need only be checked when P has a generalized zero on $j\mathbb{R}$. With this assumption C is optimal for (3.3) if and only if $Q = 0$ optimizes the right-hand side of (3.4).

Let W_2 be analytic in \mathbb{C}^+ and have no zeros in \mathbb{C}^+ . Assume that $W_2 X_\infty D_0 \in A_\infty$ has at most finitely many zeros on $j\mathbb{R}$. Also assume that $W_2 X_0 U \in A_\infty$. Define the weighted complementary sensitivity transfer function $\Theta(s, K)$ to be $\Theta(K) = [W_2 PK/(1 + PK)]$.

The weighted complementary sensitivity optimization problem associated with Θ consists of finding γ_3 and \hat{K} such that

$$\begin{aligned} \gamma_3 = \|\Theta(K)\|_\infty &= \inf_{K \in \Sigma(P)} \left\| \frac{W_2 PK}{1 + PK} \right\|_\infty \\ &= \inf_{Q \in H^\infty} \|W_2 X U - W_2 X D Q\|_\infty. \end{aligned} \quad (3.5)$$

Define

$$\gamma_4 = \inf_{Q \in H^\infty} \|D_0^* W_2 X_0 U - Q\|_\infty. \quad (3.6)$$

To equate the optimization problem (3.5) with (3.6), assume that $\gamma_4 \geq |W_2 X_0 U(j\omega)|$ for every $j\omega \in Z(W_2 X_\infty D_0)$. Then, [2, p. 12], $\gamma_4 = \gamma_3$. This assumption need only be checked when P has a pole on $j\mathbb{R}$. With this assumption C is optimal for (3.5) if and only if $Q = 0$ optimizes the right-hand side of (3.6).

Theorem 3.7. A controller $C \in \Sigma(P)$ is uniquely optimal for the weighted sensitivity problem if and only if $|\Lambda(C)|$ is constant a.e. on $j\mathbb{R}$ and $p_c < z_p$.

Proof: Parameterizing $\Sigma(P)$ in terms of $C = U^*V^{-1}$ we have that C is uniquely optimal for (3.3) if and only if $Q = 0$ is uniquely optimal for (3.4). Assume that $Q = 0$ is optimal for (3.4). Then since $X_i^*W_1D_oV \in L^\infty$, $Q = 0$ is uniquely optimal and $|\Lambda(C)| = |X_i^*W_1D_oV|$ is constant on $j\bar{\mathbb{R}}$. Therefore $X_i^*W_1D_oV$ does not vanish anywhere on $j\bar{\mathbb{R}}$ and [7, p. 250], $\text{wno}(X_i^*W_1D_oV) < 0$. The product $X_i^*W_1D_oV$ is meromorphic in \mathcal{C}^+ since it can be expressed as the quotient of analytic functions in \mathcal{C}^+ . Since X_i is a finite Blaschke product and $X_i^*W_1D_oV$ does not vanish on $j\bar{\mathbb{R}}$, W_1D_oV does not vanish on $j\bar{\mathbb{R}}$. Then by Lemma 2.1, W_1D_oV has a finite number of \mathcal{C}^+ zeros. The \mathcal{C}^+ zeros of W_1D_oV are the \mathcal{C}^+ poles of C and the \mathcal{C}^+ zeros of X_i are the \mathcal{C}^+ zeros of P . Therefore $\text{wno}(X_i^*W_1D_oV) = p_i - z_p$. Thus $z_p > p_i$.

Conversely, suppose that $z_p > p_i$ and $|\Lambda(C)|$ is constant a.e. on $j\bar{\mathbb{R}}$. Then $|X_i^*W_1D_oV|$ is constant on $j\bar{\mathbb{R}}$. Since $X_i^*W_1D_oV$ is continuous and not identically zero on $j\bar{\mathbb{R}}$, it does not vanish anywhere on $j\bar{\mathbb{R}}$. Then $\text{wno}(X_i^*W_1D_oV) = p_i - z_p < 0$. Therefore [7, p. 250], $Q = 0$ is uniquely optimal.

Theorem 3.8: A controller $C \in \Sigma(P)$ is uniquely optimal for the weighted complementary sensitivity problem if and only if $|\Theta(C)|$ is constant a.e. on $j\bar{\mathbb{R}}$ and $z_i < p_p$.

Proof: Parameterizing $\Sigma(P)$ in terms of $C = U^*V^{-1}$, we have that C is uniquely optimal for (3.5) if and only if $Q = 0$ is uniquely optimal for (3.6). Assume that $Q = 0$ is optimal for (3.6). Since $D_i^*W_2X_oU \in L^\infty$, $Q = 0$ is uniquely optimal and $|\Theta(C)| = |D_i^*W_2X_oU|$ is constant on $j\bar{\mathbb{R}}$. Therefore $D_i^*W_2X_oU$ does not vanish anywhere on $j\bar{\mathbb{R}}$ and $\text{wno}(D_i^*W_2X_oU) < 0$. The product $D_i^*W_2X_oU$ is meromorphic in \mathcal{C}^+ since it can be expressed as the quotient of analytic functions in \mathcal{C}^+ . Since D_i is a finite Blaschke product and $D_i^*W_2X_oU$ does not vanish on $j\bar{\mathbb{R}}$, W_2X_oU does not vanish on $j\bar{\mathbb{R}}$. Then by Lemma 2.1, W_2X_oU has a finite number of \mathcal{C}^+ zeros. The \mathcal{C}^+ zeros of W_2X_oU are the \mathcal{C}^+ zeros of U and the \mathcal{C}^+ zeros of D_i are the \mathcal{C}^+ poles of P . Therefore $\text{wno}(D_i^*W_2X_oU) = z_i - p_p$. Thus $p_p > z_i$.

Conversely, suppose that $p_p > z_i$ and $|\Theta(C)|$ is constant a.e. on $j\bar{\mathbb{R}}$. Then $|D_i^*W_2X_oU|$ is constant on $j\bar{\mathbb{R}}$. Since $D_i^*W_2X_oU$ is assumed continuous and not identically zero on $j\bar{\mathbb{R}}$, it is nonzero on $j\bar{\mathbb{R}}$. Then $\text{wno}(D_i^*W_2X_oU) = z_i - p_p < 0$. Therefore $Q = 0$ is uniquely optimal.

Example 3.9: Let sequences $\{\gamma_n\}$ and $\{\phi_n\}$ consist of the positive numbers satisfying $\cos \gamma_n \sinh \gamma_n = \sin \gamma_n \cosh \gamma_n$, and $\cos \phi_n \cosh \phi_n = 1$. Assume the ordering $\phi_j < \phi_k$ and $\gamma_j < \gamma_k$ for $j < k$. Let $P = X_o D_i^{-1}$, where $D_i = (s - 1)/(s + 1)$, and

$$X_o = \frac{1}{(s+1)} \prod_{n=1}^{\infty} \frac{1 + \epsilon s + s^2 \gamma_n^{-1}}{1 + \epsilon s + s^2 \phi_n^{-1}}.$$

One can show that X_o belongs to A_∞ and is outer [6]. Let $U(s)$ be the constant $X_o(1)^{-1}$. Then $V = (1 - U^*X_o)D_i^{-1}$ belongs to H^∞ and $U^*X_o + V^*D_i = 1$. So $C = U^*V^{-1} \in \Sigma(P)$. Define the weighting function $W_2 = (U^*X_o)^{-1}$. Since U^*X_o has no poles or zeros in \mathcal{C}^+ , W_2 is analytic in \mathcal{C}^+ and has no zeros in \mathcal{C}^+ . Also $|\Theta(C)| = |W_2X_oU| = 1$ a.e. on $j\bar{\mathbb{R}}$. Since $p_p = 1$, and $z_i = 0$, by Theorem 3.8 $C = U^*V^{-1}$ is optimal for (3.5).

Remark 3.10: Theorem 3.7 requires that P have at least one \mathcal{C}^+ zero. Suppose that $z_p = 0$ and that $P = X_o D_i^{-1}$ with D_i inner and X_o a unit in H^∞ . Let $C_k = kX_o^{-1}$. For $k > 1$, $C_k \in \Sigma(P)$ and $W_1/(1 + PC_k) = W_1 D_i/(D_i + k)$. For each $j\omega \in j\bar{\mathbb{R}}$

$$\lim_{k \rightarrow \infty} \left| \frac{W_1}{1 + PC_k} \right|^2 = \lim_{k \rightarrow \infty} \frac{W_1^* W_1}{1 + k D_i + k D_i^* + k^2} = 0.$$

Thus $\inf_{K \in \Sigma(P)} \|\Lambda(K)\|_\infty = 0$. No $K \in \Sigma(P)$ achieves this minimum.

Remark 3.11: Theorem 3.8 requires that P have at least one \mathcal{C}^+ pole. When $p_p = 0$ and P has no poles on $j\bar{\mathbb{R}}$, $K = 0$ is optimal for the weighted complementary sensitivity problem. One can check that $0 \in \Sigma(P)$ and that $\|\Theta(0)\|_\infty = 0$.

IV. WEIGHTING FUNCTIONS

In Section III we observed that the optimal controller makes the weighted sensitivity or weighted complementary sensitivity function flat across frequencies. In this section we explore the implications of this for various choices of weighting functions. Suppose throughout this section that the plant P and given controller C satisfy the same assumptions as in Section III. Let $U = U^*U_o$ and $V = V^*V_o$ be inner/outer factorizations.

One might expect that a controller that optimizes a weighted sensitivity problem would have poor complementary sensitivity properties. This is not necessarily the case.

Corollary 4.1: Suppose that $C' \in \Sigma(P)$ is the unique optimal controller for a weighted sensitivity problem. Suppose that C' has no generalized zeros on $j\bar{\mathbb{R}}$. Then C' is also uniquely optimal for the weighted complementary sensitivity problem with $W_2 = \alpha(X_o U_o)^{-1}$, where α is any nonzero constant, if and only if $z_i < p_p$.

Proof: This result follows from Theorem 3.8 after we observe that for $W_2 = \alpha(X_o U_o)^{-1}$, $|\Theta(C')| = |D_i^*W_2X_oU| = |\alpha|$ on $j\bar{\mathbb{R}}$.

Corollary 4.2: Suppose that $C' \in \Sigma(P)$ is the unique optimal controller for a weighted complementary sensitivity problem. Suppose that V_o has no generalized zeros on $j\bar{\mathbb{R}}$. Then C' is also uniquely optimal for the weighted sensitivity problem with $W_1 = \nu(D_o V_o)^{-1}$, where ν is any nonzero constant, if and only if $p_i < z_p$.

Proof: Observe that $|\Lambda(C')| = |X_i^*W_1D_oV| = |\nu|$ on $j\bar{\mathbb{R}}$. Apply Theorem 3.7.

In weighted sensitivity optimization the weighting function and the plant determine the optimal Nyquist plot of $PC'(j\omega)$ versus ω . In the case of a constant weight we can say precisely what the optimal Nyquist plot is.

Corollary 4.3: Suppose that $W_1 = \nu$, for some constant $\nu > 0$, $C' \in \Sigma(P)$, and $p_i < z_p$. Then C' is optimal for the weighted sensitivity problem if and only if for each $\omega \in j\bar{\mathbb{R}}$, $PC'(j\omega)$ satisfies the equation of a circle with center $c_r = (-1, 0)$ and radius $r = \nu/z_i$, where γ is the optimal norm in (3.3). Furthermore, $r < 1$.

Proof: By Theorem 3.7, C' is optimal for (3.4) if and only if $|\Lambda(C')|$ is constant on $j\bar{\mathbb{R}}$. Let $PC'(j\omega) = x + jy$. Then for each $j\omega \in j\bar{\mathbb{R}}$, $|\Lambda(C')| = \gamma$ if and only if $\nu^2/(1/(1+x)^2 + y^2)) = \gamma^2$. Equivalently, $y^2 + (1+x)^2 = \nu^2/\gamma^2$. From the Maximum Modulus Theorem, since $\Lambda(C')$ is analytic in \mathcal{C}^+ and $\Lambda(C') = \nu$ at every \mathcal{C}^+ zero of P , $\|\Lambda(C')\|_\infty \geq \nu$. Since $\Lambda(C')$ is nonconstant in \mathcal{C}^+ , $\|\Lambda(C')\|_\infty > \nu$.

Corollary 4.4: Suppose that $W_2 = \mu$, for some constant $\mu > 0$, $C' \in \Sigma(P)$, and $z_i < p_p$. Then C' is optimal for the weighted complementary sensitivity problem if and only if for each $\omega \in j\bar{\mathbb{R}}$, $PC'(j\omega)$ satisfies the equation of a circle with center $c_r = (c_{rx}, 0)$ and radius $r = \gamma\mu/(\gamma^2 - \mu^2)$, where $c_{rx} = -\gamma^2/(\gamma^2 - \mu^2)$, where $\gamma > \mu$ is the optimal norm in (3.5).

Proof: By Theorem 3.8, C' is uniquely optimal for (3.5) if and only if $|\Theta(C')| = \gamma$ a.e. on $j\bar{\mathbb{R}}$ for some constant γ . From the Maximum Modulus Theorem, since $\Theta(C')$ is analytic in \mathcal{C}^+ and $\Theta(C') = \mu$ at every \mathcal{C}^+ pole of P , $\gamma \geq \mu$. Since $\Theta(C')$ is nonconstant in \mathcal{C}^+ , $\gamma > \mu$. Let $PC'(j\omega) = x + jy$. Then for each $j\omega \in j\bar{\mathbb{R}}$, $|\Lambda(C')| = \gamma$ if and only if $\mu^2((x^2 + y^2)/(1+x)^2 + y^2)) = \gamma^2$. Equivalently, $y^2 + (x + \gamma^2/(\gamma^2 - \mu^2))^2 = \gamma^2\mu^2/(\gamma^2 - \mu^2)^2$.

Certain weighted sensitivity and weighted complementary sensitivity problems are not optimized by a stabilizing controller, even though the optimization is done over the set of all stabilizing controllers.

We describe situations in which this happens in Corollary 4.5 and Corollary 4.6

Corollary 4.5 Suppose that $W_1 D$ has a zero on $j\bar{\mathbb{R}}$. Then $C \in \Sigma(P)$ is not optimal for the weighted sensitivity problem.

Proof Suppose that $C \in \Sigma(P)$ is optimal for (3.3). Then by Theorem 3.7 $|\Lambda(C)|$ is constant a.e. on $j\bar{\mathbb{R}}$. Since $W_1 D$ has a zero at $j\omega_c \in j\bar{\mathbb{R}}$, then $|\Lambda(C)| = 0$ a.e. on $j\bar{\mathbb{R}}$. But no $K \in \Sigma(P)$ can achieve this.

Thus when a plant P has a $j\bar{\mathbb{R}}$ pole with multiplicity n , no stabilizing controller will minimize the weighted sensitivity function if W_1 does not also have the pole with multiplicity at least n . For example consider $P = (s+1)/s$. For $\Lambda = 1$ and $D = s/(s+1)$, ΛD^{-1} is a coprime factorization of P . For any W_1 that does not have a pole at $s = 0$, problem (3.3) will not be optimized by a stabilizing controller.

Also, Corollary 4.5 shows that if one wishes to obtain a stabilizing controller as the optimal solution to a weighted sensitivity problem, one should not choose W_1 strictly proper or with a $j\bar{\mathbb{R}}$ zero.

Corollary 4.6 Suppose that $p_1 > 0$ and $W_1 \Lambda$ has a zero on $j\bar{\mathbb{R}}$. Then $C \in \Sigma(P)$ is not optimal for the weighted complementary sensitivity problem.

Proof Suppose that $C \in \Sigma(P)$ is optimal for (3.5). By Theorem 3.8 $|\Theta(C)|$ is constant a.e. on $j\bar{\mathbb{R}}$. Since $W_1 \Lambda$ has a zero at $j\omega_c \in j\bar{\mathbb{R}}$, $|\Theta(C)| = 0$ a.e. on $j\bar{\mathbb{R}}$. But this contradicts the fact that since $p_1 > 0$ by the Maximum Modulus theorem $\|\Theta(K)\|_\infty > 0$ for all $K \in \Sigma(P)$.

Thus when an unstable plant P has a $j\bar{\mathbb{R}}$ zero, no stabilizing controller will minimize the weighted complementary sensitivity function if $W_1 P$ also has the zero. Corollary 4.6 also shows that if one wishes to obtain a stabilizing controller as the optimal solution to a weighted complementary sensitivity optimization problem with an unstable plant, one should not use a weighting function with a $j\bar{\mathbb{R}}$ zero.

A Periodic Fixed-Structure Approach to Multirate Control

Wassim M. Haddad and Vikram Kapila

Abstract—In this note we develop an approach to designing reduced-order multirate controllers. A discrete-time model that accounts for the multirate timing sequence of measurements is presented and is shown to have periodically time-varying dynamics. Using discrete-time stability theory, the optimal projection approach to fixed-order (i.e., full- and reduced-order) dynamic compensation is generalized to obtain reduced-order periodic controllers that account for the multirate architecture. It is shown that the optimal reduced-order controller is characterized by means of a periodically time-varying system of equations consisting of coupled Riccati and Lyapunov equations. In addition, the multirate static output-feedback control problem is considered. For both problems, the design equations are presented in a concise, unified manner to facilitate their accessibility for developing numerical algorithms for practical applications.

I. INTRODUCTION

Many applications of feedback control involve continuous time systems subject to digital (discrete time) control. Furthermore, in practical applications, the control system actuators and sensors have differing bandwidths. For example, in flexible structure control, it is not unusual to attenuate the low frequency high amplitude modes by means of low bandwidth actuators that are relatively heavy and hence able to exert high force/torque to control the higher frequency modes. Obviously, the high bandwidth actuators would require sensors that are sampled at high rates, while low bandwidth actuators require only sensors sampled at low data rates. As a consequence, the use of various sensor data rates leads to a multirate control problem. To properly use such data, a multirate controller must carefully account for the timing sequence of incoming data. The purpose of this note is to develop a general approach to full- and reduced order steady state multirate dynamic compensation.

Multirate control problems have been of interest for many years with increased emphasis in recent years [1]-[3], [9]-[11], [15]. A common feature of these papers is the realization that the multirate sampling process leads to periodically time varying dynamics. Hence, with a suitable reinterpretation, results on multirate control can also be applied to single rate or multirate problems involving systems with periodically time varying dynamics. The principal challenge of these problems is to arrive at a tractable control design formulation in spite of the extreme complexity of such systems. In order to account for the periodic time varying dynamics of multirate systems, a periodically time varying control law architecture was proposed in [10] and [11] which appears promising in this regard. An alternative approach which has been proposed for the multirate control problem is the use of an expanded state space formulation [2]. However, this approach results in very high order systems and is often numerically intractable. Finally, a cost translation and a lifting approach to the multirate LQG problem has been proposed in [15] which does not lead to an increase in the state dimension. Specifically, [15] shows how to translate a multirate sampled data LQG problem into an equivalent modified single rate shift invariant problem via a lifted isomorphism.

However, this approach results in an equivalent system involving more inputs and outputs than the original system. The interested reader is referred to [7], [8], [10], and [14] for further discussions on multirate and periodic control.

For generality in our development, we consider both full- and reduced-order dynamic compensators as well as static output-feedback controllers. In the discrete-time case, this problem was considered in [4], while single rate sampled-data aspects were addressed in [5]. The approach of the present note is the fixed-structure Riccati equation technique developed in [4]. Essentially, this approach addresses controller complexity by explicitly imposing implementation constraints on the controller structure, and optimizing over that class of controllers. Specifically, in addressing the problem of reduced-order dynamic compensation, it is shown in [4] that optimal reduced-order steady-state dynamic compensators can be characterized by means of an algebraic system of Riccati/Lyapunov equations coupled by a projection matrix which arises as a direct consequence of optimality and which represents a breakdown of the separation between the operations of state estimation and state estimate feedback; that is, the certainty equivalence principle is no longer valid. The proof is based on expressing the closed-loop quadratic cost functional as a function of the design parameters, i.e., the compensator gains, and the utilization of Lagrange multipliers for optimization over the parameter space. Thus, this approach provides a constrained optimal control methodology in which we do not seek to optimize a performance measure per se, but rather a performance measure within a class of *a priori* fixed-structure controllers.

In the present note, analog-to-digital conversions are employed within a multirate setting to obtain periodically time-varying dynamics. The compensator is thus assigned a corresponding discrete-time periodic structure to account for the multirate measurements. It is shown that the optimal reduced-order multirate dynamic compensator is characterized by a periodically time-varying system of four equations consisting of two modified Riccati equations and two modified Lyapunov equations corresponding to each intermediate point of the periodicity interval. Because of the time-varying nature of the problem, the necessary conditions for optimality now involve multiple projections corresponding to each intermediate point of the periodic interval and whose rank along the periodic interval is equal to the order of the compensator. Similar extensions to reduced-order multirate estimation are addressed in [12].

Nomenclature

$I_r, 0, \infty, 0,$	$r \times r$ identity matrix, $r \times s$ zero matrix, $0, \infty,$
$(\cdot)^T, (\cdot)^{-1}, \text{tr}(\cdot), \mathcal{E}$	transpose, inverse, trace, expected value
$\mathcal{R}, \mathcal{R}^{*s}, \mathcal{R}^t$	real numbers, $r \times s$ real matrices, $\mathcal{R}^{t \times t}$
k, α	discrete-time indices
n, m, l_k, n_c, \hat{n}	positive integers; $1 \leq n_c \leq n; \hat{n} = n + n_c$
x, y, x_c, u	$n-, l_k-, n_c-, m$ -dimensional vectors
$A, B, C(k)$	$n \times n, n \times m, l_k \times n$ matrices
$A_c(k), B_c(k), C_c(k), D_c(k)$	$n_c \times n_c, n_c \times l_k, m \times n_c, m \times l_k$ matrices
R_1, R_2	$n \times n, m \times m$ state and control weightings; $R_1 \geq 0, R_2 > 0$
R_{12}	$n \times m$ cross weighting; $R_1 - R_{12}R_2^{-1}R_{12}^T \geq 0$

II. THE FIXED-STRUCTURE MULTIRATE STATIC AND DYNAMIC CONTROL PROBLEMS

In this section, we state the fixed-structure static and dynamic, sampled-data, multirate output-feedback control problems. In the problem formulation, the sample intervals h_k and dynamic compensator order n_c are fixed, and the optimization is performed over the compensator parameters $[A_c(\cdot), B_c(\cdot), C_c(\cdot), D_c(\cdot)]$. For design trade-off studies, h_k and n_c can be varied and the problem can be solved for each pair of values of interest.

Fixed-Structure Multirate Static Output-Feedback Control Problem: Consider the n th-order continuous-time system with multirate sampled-data measurements

$$\dot{x}(t) = Ax(t) + Bu(t) + w_1(t), \quad t \in [0, \infty), \quad (2.1)$$

$$y(t_k) = C(t_k)x(t_k) + w_2(t_k), \quad k = 1, 2, \dots \quad (2.2)$$

Then design a static output-feedback multirate sampled-data control law

$$u(t_k) = D_c(t_k)y(t_k) \quad (2.3)$$

which, with D/A zero-order-hold controls $u(t) = u(t_k), t \in [t_k, t_{k+1})$, minimizes the quadratic performance criterion

$$\mathcal{J}_s(D_c(\cdot)) \triangleq \lim_{t \rightarrow \infty} \mathcal{E} \frac{1}{t} \int_0^t [x^T(s)R_1x(s) + 2x^T(s)R_{12}u(s) + u^T(s)R_2u(s)] ds. \quad (2.4)$$

Fixed-Structure Multirate Dynamic Output-Feedback Control Problem: Given the n th-order continuous-time system (2.1) with multirate sampled-data measurements (2.2), design an n_c th-order ($1 \leq n_c \leq n$) multirate sampled-data dynamic compensator

$$x_c(t_{k+1}) = A_c(t_k)x_c(t_k) + B_c(t_k)y(t_k) \quad (2.5)$$

$$u(t_k) = C_c(t_k)x_c(t_k) + D_c(t_k)y(t_k) \quad (2.6)$$

which, with D/A zero-order-hold controls $u(t) = u(t_k), t \in [t_k, t_{k+1})$, minimizes the quadratic performance criterion (2.4) with $\mathcal{J}_s(D_c(\cdot))$ denoted by $\mathcal{J}_d(A_c(\cdot), B_c(\cdot), C_c(\cdot), D_c(\cdot))$.

The key feature of both problems is the time-varying nature of the output equation (2.2) which represents sensor measurements available at different rates. Fig. 1 provides a typical multirate timing diagram for a three-sensor model. For generality, we do not assume that the sample intervals $h_k \triangleq t_{k+1} - t_k$ are uniform (note the sample times for sensor #3 in Fig. 1). However, we do assume that the overall timing sequence of intervals $[t_k, t_{k+N}]$, $k = 1, 2, \dots$, is periodic over $[0, \infty)$, where N represents the periodic interval. Note that $h_{k+N} = h_k, k = 1, 2, \dots$. Since different sensor measurements are available at different times t_k , the dimension l_k of the measurements $y(t_k)$ may also vary periodically. Finally, in subsequent analysis, the static output-feedback law (2.3) and dynamic compensator (2.5) and (2.6) are assigned periodic gains corresponding to the periodic timing sequence of the multirate measurements.

In the above problem formulation, $w_1(t)$ denotes a continuous-time stationary white noise process with nonnegative-definite intensity $V_1 \in \mathcal{R}^{n \times n}$, while $w_2(t_k)$ denotes a variable-dimension discrete-time white noise process with positive-definite covariance $V_2(t_k) \in \mathcal{R}^{l_k \times l_k}$. We assume $w_2(t_k)$ is cyclostationary, that is, $V_2(t_{k+N}) = V_2(t_k), k = 1, 2, \dots$.

In what follows, we shall simplify the notation considerably by replacing the continuous-time sample instant t_k by the discrete-time index k . With this minor abuse of notation, we replace $x(t_k)$ by $x(k)$, $x_c(t_k)$ by $x_c(k)$, $y(t_k)$ by $y(k)$, $u(t_k)$ by $u(k)$, $w_2(t_k)$ by $w_2(k)$, $A_c(t_k)$ by $A_c(k)$ [and similarly for $B_c(\cdot), C_c(\cdot)$, and

$D_c(\cdot)$, $C(t_k)$ by $C(k)$, and $V_2(t_k)$ by $V_2(k)$. The context should clarify whether the argument is " k " or " t_k ." With this notation, our periodicity assumption on the compensator implies $A_c(k+N) = A_c(k)$, $k = 1, 2, \dots$, and similarly for $B_c(\cdot)$, $C_c(\cdot)$, and $D_c(\cdot)$. Also, by assumption, $C(k+N) = C(k)$, for $k = 1, 2, \dots$.

Next, we model the propagation of the plant over one time step. For notational convenience, define $H(k) \triangleq \int_0^{h_k} e^{A_s} ds$.

Theorem 2.1: For the fixed-order multirate sampled-data control problem, the plant dynamics (2.1) and quadratic performance criterion (2.4) have the equivalent discrete-time representation

$$x(k+1) = A(k)x(k) + B(k)u(k) + w_1'(k), \quad (2.7)$$

$$y(k) = C(k)x(k) + w_2(k), \quad (2.8)$$

$$\begin{aligned} J = \delta_\infty + \lim_{K \rightarrow \infty} \frac{1}{K} \mathcal{E} \sum_{k=1}^K [x^T(k) R_1(k) x(k) \\ + 2x^T(k) R_{12}(k) u(k) + u^T(k) R_2(k) u(k)] \end{aligned} \quad (2.9)$$

where

$$A(k) \triangleq e^{A h_k}, \quad B(k) \triangleq H(k) B,$$

$$w_1'(k) \triangleq \int_0^{h_k} e^{A(h_k-s)} w_1(k+s) ds,$$

$$\delta_\infty \triangleq \lim_{K \rightarrow \infty} \frac{1}{K} \text{tr} \sum_{k=1}^K \frac{1}{h_k} \int_0^{h_k} \int_0^s e^{A^T V_1} e^{A^T r} R_1 dr ds,$$

$$R_1(k) \triangleq \frac{1}{h_k} \int_0^{h_k} e^{A^T s} R_1 e^{A s} ds,$$

$$R_{12}(k) \triangleq \frac{1}{h_k} \int_0^{h_k} e^{A^T s} R_1 H(s) B ds + \frac{1}{h_k} H^T(k) R_{12},$$

$$\begin{aligned} R_2(k) \triangleq R_2 + \frac{1}{h_k} \int_0^{h_k} [B^T H^T(s) R_1 H(s) B \\ + R_{12}^T H(s) B + B^T H^T(s) R_{12}] ds \end{aligned}$$

and $w_1'(k)$ is a zero-mean discrete-time white noise process with

$$\mathcal{E}\{w_1'(k) w_1'^T(k)\} = V_1(k) \triangleq \int_0^{h_k} e^{A^T s} V_1 e^{A^T s} ds.$$

The proof of this theorem is a straightforward calculation involving integrals of white noise signals, and hence is omitted. Note that by the sampling periodicity assumption, $A(k+N) = A(k)$, $k = 1, 2, \dots$.

The above formulation assumes that a discrete-time multirate measurement model is available. One can assume, alternatively, that analog measurements corrupted by continuous-time white noise are available instead, that is, $y(t) = Cx(t) + w_2(t)$. In this case, one can develop an equivalent discrete-time model that employs an averaging-type A/D device [5] $\hat{y}(k) = (1/h_k) \int_{t_k}^{t_{k+1}} y(t) dt$. It can be shown that the resulting averaged measurements depend upon delayed samples of the state. In this case, the equivalent discrete-time model can be captured by a suitably augmented system. For details see [5].

Remark 2.1: The equivalent discrete-time quadratic performance criterion (2.9) involves a constant offset δ_∞ ¹ which is a function of sampling rates, and effectively imposes a lower bound on sampled-data performance due to the discretization process.

¹As will be shown by Lemma 3.1, due to the periodicity of h_k , δ_∞ is a constant.

Fig. 1. Multirate timing diagram for sampled-data control

III. THE FIXED-STRUCTURE MULTIRATE SAMPLED-DATA STATIC OUTPUT-FEEDBACK PROBLEM

In this section, we obtain necessary conditions that characterize solutions to the multirate sampled-data static output-feedback control problem. First, we form the closed-loop system for (2.7), (2.8), and (2.3) to obtain

$$x(k+1) = \hat{A}(k)x(k) + \hat{w}(k) \quad (3.1)$$

where $\hat{A}(k) \triangleq A(k) + B(k)D_c(k)C(k)$. The closed-loop disturbance $\hat{w}(k) \triangleq w_1'(k) + B(k)D_c(k)w_2(k)$, $k = 1, 2, \dots$, has nonnegative-definite covariance $\hat{V}(k) \triangleq V_1(k) + B(k)D_c(k)V_2(k)D_c^T(k)B^T(k)$, where we assume that the noise correlation $V_{12}(k) \triangleq \mathcal{E}\{w_1'(k)w_2^T(k)\} = 0$, that is, the continuous-time plant noise and the discrete-time measurement noise are uncorrelated. The cost functional (2.9) can now be expressed in terms of the closed-loop second-moment matrix. The following result is immediate.

Proposition 3.1: For given $D_c(\cdot)$, the second-moment matrix $Q(k) \triangleq \mathcal{E}[x(k)x^T(k)]$, satisfies

$$Q(k+1) = \hat{A}(k)Q(k)\hat{A}^T(k) + \hat{V}(k). \quad (3.2)$$

Furthermore,

$$\begin{aligned} J_s(D_c(\cdot)) = \delta_\infty + \lim_{K \rightarrow \infty} \frac{1}{K} \text{tr} \\ \sum_{k=1}^K [Q(k)\hat{R}(k) + D_c^T(k)R_2(k)D_c(k)V_2(k)] \end{aligned} \quad (3.3)$$

where $\hat{R}(k) \triangleq R_1(k) + R_{12}(k)D_c(k)C(k) + C^T(k)D_c^T(k)R_{12}^T(k) + C^T(k)D_c^T(k)R_2(k)D_c(k)C(k)$.

Remark 3.1: Equation (3.2) is a periodic Lyapunov equation which has been extensively studied in [7] and [8].

We now show that the covariance Lyapunov equation (3.2) reaches a steady-state periodic trajectory as $K \rightarrow \infty$. For the next result, we introduce the parameterization, $k = \alpha + \beta N$, where the index α satisfies $1 \leq \alpha \leq N$, and $\beta = 1, 2, \dots$. We now restrict our

attention to output-feedback controllers having the property that the closed-loop transition matrix over one period $\hat{\Phi}_p(\alpha) \triangleq \hat{A}(\alpha + N - 1)\hat{A}(\alpha + N - 2) \cdots \hat{A}(\alpha)$, is stable for $\alpha = 1, \dots, N$. Note that since $\hat{A}(\cdot)$ is periodic, the eigenvalues of $\hat{\Phi}_p(\alpha)$ are actually independent of α . Hence, it suffices to require that $\hat{\Phi}_p(1) = \hat{A}(N)\hat{A}(N-1) \cdots \hat{A}(1)$ is stable.

Lemma 3.1 [12]: Suppose $\hat{\Phi}_p(1)$ is stable. Then for given $D_c(k)$, the covariance Lyapunov equation (3.2) reaches a steady-state periodic trajectory as $k \rightarrow \infty$, that is,

$$\lim_{k \rightarrow \infty} [Q(k), Q(k+1), \dots, Q(k+N-1)] \\ = [Q(\alpha), Q(\alpha+1), \dots, Q(\alpha+N-1)]. \quad (3.4)$$

In this case, the covariance $Q(k)$ satisfies

$$Q(\alpha+1) = \hat{A}(\alpha)Q(\alpha)\hat{A}^T(\alpha) + \hat{V}(\alpha), \quad \alpha = 1, \dots, N \quad (3.5)$$

where $Q(N+1) = Q(1)$. Furthermore, the quadratic performance criterion (3.3) is given by

$$\mathcal{J}_s(D_c(\cdot)) = \delta + \frac{1}{N} \text{tr} \sum_{\alpha=1}^N [Q(\alpha)\hat{R}(\alpha) + D_c^T(\alpha)R_2(\alpha)D_c(\alpha)V_2(\alpha)] \quad (3.6)$$

where

$$\delta \triangleq \frac{1}{N} \text{tr} \sum_{\alpha=1}^N \frac{1}{h_\alpha} \int_0^{h_\alpha} \int_0^s e^{A_1 \tau} V_1 \tau^{-1/2} R_1 d\tau ds.$$

For the statement of the main result of this section, define the set

$$S_s \triangleq \{D_c(\cdot) : \hat{\Phi}_p(\alpha) \text{ is stable, for } \alpha = 1, \dots, N\}. \quad (3.7)$$

In addition to ensuring that the covariance Lyapunov equation (3.2) reaches a steady-state periodic trajectory as $k \rightarrow \infty$, the set S_s constitutes sufficient conditions under which the Lagrange multiplier technique is applicable to the fixed-order multirate sampled-data static output-feedback control problem. The asymptotic stability of the transition matrix $\hat{\Phi}_p(\alpha)$ serves as a normality condition which further implies that the dual $P(\alpha)$ of $Q(\alpha)$ is nonnegative-definite.

For notational convenience in stating the multirate sampled-data static output-feedback result, define the notation

$$R_{2a}(\alpha) \triangleq B^T(\alpha)P(\alpha+1)B(\alpha) + \frac{1}{N}R_2(\alpha),$$

$$V_{2a}(\alpha) \triangleq C^T(\alpha)Q(\alpha)C^T(\alpha) + V_2(\alpha),$$

$$P_a(\alpha) \triangleq B^T(\alpha)P(\alpha+1)A(\alpha) + \frac{1}{N}R_{12}^T(\alpha),$$

$$Q_a(\alpha) \triangleq A(\alpha)Q(\alpha)C^T(\alpha)$$

for arbitrary $Q(\alpha)$ and $P(\alpha) \in \mathcal{R}^{n \times n}$ and $\alpha = 1, \dots, N$.

Theorem 3.1: Suppose $D_c(\cdot) \in S_s$ solves the multirate sampled-data static output-feedback control problem. Then there exist $n \times n$ nonnegative-definite matrices $Q(\alpha)$ and $P(\alpha)$ such that, for $\alpha = 1, \dots, N$, $D_c(\alpha)$ is given by

$$D_c(\alpha) = R_{2a}^{-1}(\alpha)P_a(\alpha)Q(\alpha)C^T(\alpha)V_{2a}^{-1}(\alpha) \quad (3.8)$$

and such that $Q(\alpha)$ and $P(\alpha)$ satisfy

$$Q(\alpha+1) = A(\alpha)Q(\alpha)A^T(\alpha) + V_1(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)Q_a^T(\alpha) \\ + [Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)] \\ \cdot V_{2a}^{-1}(\alpha)[Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)]^T, \quad (3.9)$$

$$P(\alpha) = A^T(\alpha)P(\alpha+1)A(\alpha) \\ + \frac{1}{N}R_1(\alpha) - P_a^T(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha) \\ + [P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C^T(\alpha)]^T \\ \cdot R_{2a}^{-1}(\alpha)[P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C^T(\alpha)]. \quad (3.10)$$

Furthermore, the minimal cost is given by

$$\mathcal{J}_s(D_c(\cdot)) = \delta + \frac{1}{N} \text{tr} \sum_{\alpha=1}^N Q(\alpha)[R_1(\alpha) - 2R_{12}(\alpha)R_{2a}^{-1}(\alpha) \\ \cdot P_a(\alpha)Q(\alpha)C^T(\alpha)V_{2a}^{-1}(\alpha)C^T(\alpha) \\ + P_a^T(\alpha)R_{2a}^{-1}(\alpha)R_{2a}(\alpha)R_{2a}^{-1}(\alpha) \\ \cdot P_a(\alpha)Q(\alpha)C^T(\alpha)V_{2a}^{-1}(\alpha)C^T(\alpha)]. \quad (3.11)$$

Proof. The necessary conditions for optimality follow from standard Lagrange multiplier arguments. See [14] for a similar proof. \square

Remark 3.2. In the full-state feedback case, we take $C^T(\alpha) = I$, $V_2(\alpha) = 0$, and $R_{12}(\alpha) = 0$ for $\alpha = 1, \dots, N$. In this case, (3.8) becomes $D_c(\alpha) = -R_{2a}^{-1}(\alpha)B^T(\alpha)P(\alpha+1)A(\alpha)$, and (3.10) specializes to

$$P(\alpha) = A^T(\alpha)P(\alpha+1)A(\alpha) + \frac{1}{N}R_1(\alpha) \\ - A^T(\alpha)P(\alpha+1)B(\alpha)R_{2a}^{-1}(\alpha)B^T(\alpha)P(\alpha+1)A(\alpha) \quad (3.12)$$

while (3.9) is superfluous and can be omitted. Finally, we note that if we assume a single rate architecture, the plant dynamics are constant and (3.12) collapses to the standard discrete-time regulator Riccati equation.

IV. THE FIXED-STRUCTURE MULTIRATE SAMPLED-DATA DYNAMIC OUTPUT-FEEDBACK CONTROL PROBLEM

In this section, we consider the fixed order multirate sampled-data dynamic compensation problem. As in Section III, we first form the closed-loop system for (2.7), (2.8), (2.5), and (2.6) to obtain

$$x(k+1) = A(k)\bar{x}(k) + w(k) \quad (4.1)$$

where

$$\bar{x}(k) \triangleq \begin{bmatrix} x(k) \\ x_c(k) \end{bmatrix},$$

$$\bar{A}(k) \triangleq \begin{bmatrix} A(k) + B(k)D_c(k)C^T(k) & B(k)C^T(k) \\ B_c(k)C^T(k) & A_c(k) \end{bmatrix},$$

$$\bar{A}(k+N) = \bar{A}(k), \quad k = 1, 2, \dots$$

The closed-loop disturbance

$$w(k) \triangleq \begin{bmatrix} w_1^T(k) + B(k)D_c(k)w_2(k) \\ B_c(k)w_2(k) \end{bmatrix}, \quad k = 1, 2, \dots$$

has nonnegative-definite covariance shown by (x) at the bottom of the next page, where once again we assume that the continuous-time plant noise and the discrete-time measurement noise are uncorrelated, i.e., $V_{12}(k) \triangleq \mathcal{E}[w_1^T(k)w_2^T(k)] = 0$. As for the static output-feedback case, the cost functional (2.9) can now be expressed in terms of the closed-loop second-moment matrix. Specifically, Proposition 3.1 and Lemma 3.1 hold for the dynamic-output feedback problem with $x(k)$, $\bar{A}(k)$, $\bar{V}(k)$, and $\bar{R}(k)$ replaced by $x(k)$, $\bar{A}(k)$, $\bar{V}(k)$, and $\bar{R}(k)$, respectively, where $\bar{R}(k)$ is shown in (y) at the bottom of the next page.

For the next result, define the closed-loop transition matrix and the compensator transition matrix over one period by $\hat{\Phi}_p(\alpha) \triangleq \bar{A}(\alpha +$

$N-1) \bar{A}(\alpha+N-2) \cdots \bar{A}(\alpha)$ and $\Phi_{cp}(\alpha) \triangleq A_c(\alpha+N-1)A_c(\alpha+N-2) \cdots A_c(\alpha)$, respectively. Note that since $A_c(\alpha)$ is required to be periodic, the eigenvalues of $\Phi_{cp}(\alpha)$ are actually independent of α .

In the following, we obtain necessary conditions that characterize solutions to the fixed-order multirate sampled-data dynamic compensation problem. Derivation of these conditions requires additional technical assumptions. Specifically, we further restrict $[A_c(\cdot), B_c(\cdot), C_c(\cdot), D_c(\cdot)]$ to the set

$$S_c \triangleq \{(A_c(\alpha), B_c(\alpha), C_c(\alpha), D_c(\alpha)) : \Phi_p(\alpha) \text{ is stable and } (\Phi_{cp}(\alpha), B_{cp}(\alpha), C_{cp}(\alpha)) \text{ is controllable and observable, } \alpha = 1, \dots, N\} \quad (4.2)$$

where

$$B_{cp}(\alpha) \triangleq [A_c(\alpha+N-1)A_c(\alpha+N-2) \cdots A_c(\alpha+1)B_c(\alpha), A_c(\alpha+N-1)A_c(\alpha+N-2) \cdots A_c(\alpha+2)B_c(\alpha+1), \dots, B_c(\alpha+N-1)]. \quad (4.3)$$

$$C_{cp}(\alpha) \triangleq \begin{bmatrix} C_c(\alpha+N-1)A_c(\alpha+N-2) \cdots A_c(\alpha) \\ C_c(\alpha+N-2)A_c(\alpha+N-3) \cdots A_c(\alpha) \\ \vdots \\ C_c(\alpha) \end{bmatrix}. \quad (4.4)$$

The set S_c constitutes sufficient conditions under which the Lagrange multiplier technique is applicable to the fixed-order multirate sampled-data control problem. This is similar to concepts involving *moving equilibrium* for periodic Lyapunov/Riccati equations discussed in [7] and [8]. Specifically, the formulas for the lifted isomorphism (4.3) and (4.4) are equivalent to assuming the stability of $\bar{A}(\cdot)$ along with the reachability and observability of $[A_c(\cdot), B_c(\cdot), C_c(\cdot)]$ [8], [10]. The asymptotic stability of the transition matrix $\Phi_p(\alpha)$ serves as a normality condition which further implies that the dual $\hat{P}(\alpha)$ of $\hat{Q}(\alpha) \triangleq \mathcal{E}[\tilde{x}(\alpha)\tilde{x}^T(\alpha)]$ is nonnegative-definite. Furthermore, the assumption that $[\Phi_{cp}(\alpha), B_{cp}(\alpha), C_{cp}(\alpha)]$ is controllable and observable is a nondegeneracy condition which implies that the lower right $n_c \times n_c$ subblocks of $\hat{Q}(\alpha)$ and $\hat{P}(\alpha)$ are positive definite, thus yielding explicit gain expressions for $A_c(\alpha)$, $B_c(\alpha)$, $C_c(\alpha)$, and $D_c(\alpha)$.

In order to state the main result, we require some additional notation and a lemma concerning pairs of nonnegative-definite matrices. For details see [6].

Lemma 4.1: Let \hat{Q} , \hat{P} be $n \times n$ nonnegative-definite matrices and assume $\text{rank } \hat{Q}\hat{P} = n_c$. Then there exist $n_c \times n$ matrices G , Γ and an $n_c \times n_c$ invertible matrix M , unique except for a change of basis in \mathbb{R}^{n_c} , such that $\hat{Q}\hat{P} = G^T M \Gamma$, $\Gamma G^T = I_{n_c}$. Furthermore, the $n \times n$ matrices $\tau \triangleq G^T \Gamma$, $\tau_\perp \triangleq I_n - \tau$, are idempotent and have $\text{rank } n_c$ and $n - n_c$, respectively.

The following result gives necessary conditions that characterize solutions to the fixed-order multirate sampled-data control problem. For convenience in stating this result, recall the definitions of $R_{2a}(\cdot)$, $V_{2a}(\cdot)$, $P_a(\cdot)$, and $Q_a(\cdot)$ and define the additional notation

$$M(\alpha) \triangleq \begin{bmatrix} I_n \\ D_c(\alpha)C_c(\alpha) \end{bmatrix}, \quad \hat{M}(\alpha) \triangleq \begin{bmatrix} I_n \\ -R_{2a}^{-1}(\alpha)P_a(\alpha) \end{bmatrix}.$$

$$\hat{R}(\alpha) \triangleq \begin{bmatrix} R_1(\alpha) & R_{12}(\alpha) \\ R_{12}^T(\alpha) & R_2(\alpha) \end{bmatrix}$$

for arbitrary $P(\alpha) \in \mathbb{R}^{n \times n}$ and $\alpha = 1, \dots, N$.

Theorem 4.1: Suppose $[A_c(\cdot), B_c(\cdot), C_c(\cdot), D_c(\cdot)] \in S_c$ solves the fixed-order multirate sampled-data dynamic output-feedback control problem. Then there exist $n \times n$ nonnegative-definite matrices $\hat{Q}(\alpha)$, $\hat{P}(\alpha)$, $\hat{Q}(\alpha)$, and $\hat{P}(\alpha)$ such that, for $\alpha = 1, \dots, N$, $A_c(\alpha)$, $B_c(\alpha)$, $C_c(\alpha)$, and $D_c(\alpha)$ are given by

$$A_c(\alpha) = \Gamma(\alpha+1)[A(\alpha) - B(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)C_c(\alpha) - B(\alpha)D_c(\alpha)C_c(\alpha)]G^T(\alpha), \quad (4.5)$$

$$B_c(\alpha) = \Gamma(\alpha+1)[Q_a(\alpha)V_{2a}^{-1}(\alpha) + B(\alpha)D_c(\alpha)], \quad (4.6)$$

$$C_c(\alpha) = -[R_{2a}^{-1}(\alpha)P_a(\alpha) + D_c(\alpha)C_c(\alpha)]G^T(\alpha), \quad (4.7)$$

$$D_c(\alpha) = -R_{2a}^{-1}(\alpha)P_a(\alpha)Q_c(\alpha)C_c^T(\alpha)V_{2a}^{-1}(\alpha) \quad (4.8)$$

and such that $\hat{Q}(\alpha)$, $\hat{P}(\alpha)$, $\hat{Q}(\alpha)$, and $\hat{P}(\alpha)$ satisfy

$$\begin{aligned} \hat{Q}(\alpha+1) = & A(\alpha)Q(\alpha)A^T(\alpha) + V_1(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)Q_a^T(\alpha) \\ & + \tau_\perp(\alpha+1)\{[A(\alpha) - B(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha)] \\ & \cdot \hat{Q}(\alpha)\{A(\alpha) - B(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha)\}^T \\ & + \{Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)\}V_{2a}^{-1}(\alpha) \\ & \cdot \{Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)\}^T\}\tau_\perp(\alpha+1), \end{aligned} \quad (4.9)$$

$$\begin{aligned} P(\alpha) = & A^T(\alpha)P(\alpha+1)A(\alpha) + \frac{1}{N}R_1(\alpha) \\ & - P_a^T(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha) \\ & + \tau_\perp^T(\alpha)\{[A(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)C_c(\alpha)]^T \hat{P}(\alpha+1) \\ & \cdot \{A(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)C_c(\alpha)\} \\ & + \{P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C_c(\alpha)\}^T R_{2a}^{-1}(\alpha) \\ & \cdot \{P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C_c(\alpha)\}\}\tau_\perp(\alpha), \end{aligned} \quad (4.10)$$

$$\begin{aligned} \hat{Q}(\alpha+1) = & \tau(\alpha+1)\{[A(\alpha) - B(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha)]\hat{Q}(\alpha) \\ & \cdot \{A(\alpha) - B(\alpha)R_{2a}^{-1}(\alpha)P_a(\alpha)\}^T \\ & + \{Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)\}V_{2a}^{-1}(\alpha) \\ & \cdot \{Q_a(\alpha) + B(\alpha)D_c(\alpha)V_{2a}(\alpha)\}^T\}\tau^T(\alpha+1), \end{aligned} \quad (4.11)$$

$$\begin{aligned} \hat{P}(\alpha) = & \tau^T(\alpha)\{[A(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)C_c(\alpha)]^T \hat{P}(\alpha+1) \\ & \cdot \{A(\alpha) - Q_a(\alpha)V_{2a}^{-1}(\alpha)C_c(\alpha)\} \\ & + \{P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C_c(\alpha)\}^T R_{2a}^{-1}(\alpha) \\ & \cdot \{P_a(\alpha) + R_{2a}(\alpha)D_c(\alpha)C_c(\alpha)\}\}\tau(\alpha) \end{aligned} \quad (4.12)$$

$$\text{rank } \hat{Q}(\alpha) = \text{rank } \hat{P}(\alpha) = \text{rank } \hat{Q}(\alpha)\hat{P}(\alpha) = n_c. \quad (4.13)$$

$$\hat{V}(k) \triangleq \begin{bmatrix} V_1(k) + B(k)D_c(k)V_2(k)D_c^T(k)B^T(k) & B(k)D_c(k)V_2(k)B_c^T(k) \\ B_c(k)V_2(k)D_c^T(k)B^T(k) & B_c(k)V_2(k)B_c^T(k) \end{bmatrix} \quad (x)$$

$$\hat{R}(k) \triangleq \begin{bmatrix} R_1(k) + R_{12}(k)D_c(k)C_c(k) + C_c^T(k)D_c^T(k)R_{12}^T(k) & R_{12}(k)C_c(k) + C_c^T(k)D_c^T(k)R_2(k)C_c(k) \\ + C_c^T(k)D_c^T(k)R_2(k)D_c(k)C_c(k) & C_c^T(k)R_{12}^T(k) + C_c^T(k)R_2(k)D_c(k)C_c(k) \\ C_c^T(k)R_{12}^T(k) + C_c^T(k)R_2(k)D_c(k)C_c(k) & C_c^T(k)R_2(k)C_c(k) \end{bmatrix}. \quad (y)$$

Furthermore, the minimal cost is given by

$$\mathcal{J}_c(A_c(\cdot), B_c(\cdot), C_c(\cdot), D_c(\cdot)) = \delta + \frac{1}{N} \text{tr} \sum_{\alpha=1}^N [\{M(\alpha)Q(\alpha)M^T(\alpha) + \hat{M}(\alpha)\hat{Q}(\alpha)\hat{M}^T(\alpha)\}\hat{R}(\alpha)]. \quad (4.14)$$

Proof: The proof is identical to the proof of Theorem 3.3 of [14] concerning reduced-order control of discrete-time linear periodic systems with suitable reinterpretations for capturing the equivalent multirate sampled-data model. \square

Theorem 4.1 provides necessary conditions for the fixed-order multirate sampled-data control problem. These necessary conditions consist of a system of two modified periodic difference Lyapunov equations and two modified periodic difference Riccati equations coupled by projection matrices $\tau(\alpha)$, $\alpha = 1, \dots, N$. As expected, these equations are periodically time-varying over the period $1 \leq \alpha \leq N$ in accordance with the multirate nature of the measurements. As discussed in [4], the fixed-order constraint on the compensator gives rise to the projection τ which characterizes the optimal reduced-order compensator gains. In the multirate case, however, it is interesting to note that the time-varying nature of the problem gives rise to multiple projections corresponding to each of the intermediate points of the periodicity interval, and whose rank along the periodic interval is equal to the order of the compensator.

Remark 4.3: As in the linear time-invariant case [4] to obtain the full-order multirate LQG controller, set $n_c = n$. In this case, the projections $\tau(\alpha)$, and $\Gamma(\alpha)$ and $G(\alpha)$, for $\alpha = 1, \dots, N$, become the identity. Consequently, (4.11) and (4.12) play no role and hence can be omitted. In order to draw connections with existing full-order multirate results, set $D_c(\alpha) = 0$ and $R_{12}(\alpha) = 0$, $\alpha = 1, \dots, N$, so that

$$A_c(\alpha) = A(\alpha) - B(\alpha)R_{2\alpha}^{-1}(\alpha)B^T(\alpha)P(\alpha+1)A(\alpha) - A(\alpha)Q(\alpha)C^T(\alpha)V_{2\alpha}^{-1}(\alpha)C^T(\alpha), \quad (4.15)$$

$$B_c(\alpha) = A(\alpha)Q(\alpha)C^T(\alpha)V_{2\alpha}^{-1}(\alpha), \quad (4.16)$$

$$C_c(\alpha) = -R_{2\alpha}^{-1}(\alpha)B^T(\alpha)P(\alpha+1)A(\alpha) \quad (4.17)$$

where $Q(\alpha)$ and $P(\alpha)$ satisfy

$$Q(\alpha+1) = A(\alpha)Q(\alpha)A^T(\alpha) + V_1(\alpha) - A(\alpha)Q(\alpha)C^T(\alpha)V_{2\alpha}^{-1}(\alpha)C^T(\alpha)Q(\alpha)A^T(\alpha), \quad (4.18)$$

$$P(\alpha) = A^T(\alpha)P(\alpha+1)A(\alpha) + \frac{1}{N}R_1(\alpha) - A^T(\alpha)P(\alpha+1)B(\alpha)R_{2\alpha}^{-1}(\alpha)B^T(\alpha)P(\alpha+1)A(\alpha). \quad (4.19)$$

Thus, the full-order multirate sampled-data controller is characterized by two decoupled periodic difference Riccati equations (observer and regulator Riccati equations) over the period $\alpha = 1, \dots, N$. This corresponds to the results obtained in [10]. Next, assuming a single rate architecture yields time-invariant plant dynamics, while (4.18) and (4.19) specialize to the discrete-time observer and regulator Riccati equations. Alternatively, retaining the reduced-order constraint and assuming single rate sampling, Theorem 4.1 yields the sampled-data optimal projection equations for reduced-order dynamic compensation given in [5].

V. NUMERICAL EVALUATION OF INTEGRALS INVOLVING MATRIX EXPONENTIALS

To evaluate the integrals involving matrix exponentials appearing in Theorem 2.1, we utilize the approach of [16]. The idea is to eliminate the need for integration by computing the matrix exponential of appropriate block matrices.

Proposition 5.1: For $\alpha = 1, \dots, N$, consider the following partitioned matrix exponentials

$$\begin{bmatrix} E_1 & E_2 & E_3 & E_4 \\ 0_n & E_5 & E_6 & E_7 \\ 0_n & 0_n & E_8 & E_9 \\ 0_{m \times n} & 0_{m \times n} & 0_{m \times n} & I_m \end{bmatrix} \triangleq \exp \begin{bmatrix} -A^T & I_n & 0_n & 0_{n \times m} \\ 0_n & -A^T & R_1 & 0_{n \times m} \\ 0_n & 0_n & A & B \\ 0_{m \times n} & 0_{m \times n} & 0_{m \times n} & 0_m \end{bmatrix} h_\alpha$$

$$\begin{bmatrix} E_{10} & E_{11} & E_{12} & E_{13} \\ 0_n & E_{14} & E_{15} & E_{16} \\ 0_n & 0_n & E_{17} & E_{18} \\ 0_{m \times n} & 0_{m \times n} & 0_{m \times n} & I_m \end{bmatrix} \triangleq \exp \begin{bmatrix} -A^T & I_n & 0_n & 0_{n \times m} \\ 0_n & -A^T & R_1 & R_{12} \\ 0_n & 0_n & A & B \\ 0_{m \times n} & 0_{m \times n} & 0_{m \times n} & 0_m \end{bmatrix} h_\alpha$$

$$\begin{bmatrix} E_{19} & E_{20} & E_{21} \\ 0_n & E_{22} & E_{23} \\ 0_n & 0_n & E_{24} \end{bmatrix} \triangleq \exp \begin{bmatrix} -A & I_n & 0_n \\ 0_n & -A & V_1 \\ 0_n & 0_n & A^T \end{bmatrix} h_\alpha$$

of orders $(3n+m) \times (3n+m)$, $(3n+m) \times (3n+m)$, and $3n \times 3n$, respectively. Then, for $\alpha = 1, \dots, N$,

$$A(\alpha) = E_{21}^T, \quad B(\alpha) = E_{18}, \quad V_1(\alpha) = E_{21}^T E_{21},$$

$$R_1(\alpha) = \frac{1}{h_\alpha} E_{17}^T E_{15}, \quad R_{12}(\alpha) = \frac{1}{h_\alpha} E_{17}^T E_{16},$$

$$R_2(\alpha) = R_2 + \frac{1}{h_\alpha} [B^T E_{17}^T E_{15} + E_{15}^T E_{17} B - B^T E_{17}^T E_{15}].$$

$$\delta = \frac{1}{N} \sum_{\alpha=1}^N \frac{1}{h_\alpha} \text{tr} R_1 E_{21}^T E_{21}.$$

The proof of the above proposition involves straightforward manipulations of matrix exponentials.

VI. ILLUSTRATIVE NUMERICAL EXAMPLE

For illustrative purposes, we consider a numerical example involving a rigid body with a flexible appendage. This example is reminiscent of a single-axis spacecraft involving unstable dynamics and sensor fusion of slow, accurate spacecraft attitude sensors (such as horizon sensors or star trackers) with fast, less accurate rate gyroscopes. The motivation for slow/fast sensor configuration is that rate information can be used to improve the attitude control between attitude measurements. Hence define

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & -0.01 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}.$$

$$C = \begin{bmatrix} 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{bmatrix}, \quad D = \begin{bmatrix} 0.1 & 0 & 0.1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}^T.$$

$$V_1 = DD^T, \quad V_2 = I_2, \quad E = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix},$$

$$R_1 = E^T E, \quad R_2 = 1.$$

Note that the dynamic model involves one rigid body mode along with one flexible mode at a frequency of 1 rad/s with 0.5% damping. The matrix C captures the fact that the rigid body angular position and tip velocity of the flexible appendage are measured. Also, note that the rigid body position measurement is corrupted by the flexible mode (i.e., observation spillover). To reflect a plausible mission, we assume that the rigid body angular position is measured by an attitude sensor sampling at 1 Hz, while the tip appendage velocity is measured by a rate gyro sensor sampling at 5 Hz. The matrix R_1 expresses the desire to regulate the rigid body and tip appendage positions, and the matrix V_1 was chosen to capture the type of noise correlation that arises when the dynamics are transformed into a modal basis.

Using the homotopy algorithm based on a prediction and a Newton correction scheme for periodic difference Riccati equations reported in [13], the following designs were obtained. For $n_c = 4$ discrete-time single rate and multirate controllers were obtained from (4.15)–(4.19) using Theorem 2.1 for continuous-time to discrete-time conversions. These designs were compared using the performance criterion (4.14). The results are summarized as follows

Measurement Scheme	Optimal Cost
Two 1 Hz sensors	65.6922
Two 5 Hz sensors	53.9930
Multirate scheme (1 Hz and 5 Hz sensors)	54.8061

Note that the improvement in the cost of the two 5 Hz sensor scheme over the multirate scheme is minimal, which clearly demonstrates that the multirate scheme provides sensor complexity reduction over the two 5 Hz sensor scheme.

Pursuing a Maneuvering Target Which Uses a Random Process for Its Control

V. E. Beneš, K. L. Helmes, and R. W. Rishel

Abstract—Since a pursuer pursuing a maneuvering target does not know what maneuvers an evading target will make, the maneuvers (the target's control law) appear as a random process to the pursuer. However, he has opinions about what the evader will do. From these, he can assign a prior probability distribution to the evader's maneuvers.

For a linear pursuit evasion problem in which the evader's control law is modeled as a random process, in which the pursuer has partial noisy linear measurements of his own and the evader's relative position, and a quadratic optimality criterion is used, past results of the authors imply that the optimal control is a linear function of the "predicted miss." Determining the predicted miss involves estimating the evader's terminal position from past system measurements. Nonlinear filtering techniques are used to give expressions for computing the conditional expectation of the evader's terminal position even in the presence of the random unknown maneuvers of the evader.

1. INTRODUCTION

Recently, Helmes and Rishel [5], [6], and Beneš [1] have shown, for a linear system,

$$dx_t = (Ax_t + Bu_t)dt + dz_t \quad (1)$$

whose driving noises z_t may not be Gaussian, and for an optimality criteria which is a quadratic function of the terminal state plus a quadratic running cost in the control, that the optimal control is a linear function of a quantity called the "predicted miss."

The purpose of this note is to apply these results, and results from optimal nonlinear filtering and extrapolation, to describe the optimal control for a linear pursuit-evasion problem in which the evader's control is modeled as an unknown random process.

The main problem in computing the predicted miss is to compute the conditional expectation of the evader's terminal position given

IEEE Log Number 9406992.

where

$$\alpha_t \triangleq e^{\int_0^t (H y_s^\#)' dm_s - (1/2) \int_0^t |H y_s^\#|^2 ds} \quad (45)$$

and

$$\beta_t = e^{\int_0^t (H y_s^\nu)' (dm_s - H y_s^\# ds) - (1/2) \int_0^t |H y_s^\nu|^2 ds}. \quad (46)$$

Thus, from (36),

$$E[y_t | \mathcal{M}_t] = \frac{E_0[\hat{y}_t | \mathcal{M}_t]}{E_0[\hat{\Lambda}_t | \mathcal{M}_t]} = \frac{E_0[y_s^\# \alpha_t \beta_t | \mathcal{M}_t]}{E_0[\alpha_t \beta_t | \mathcal{M}_t]} + \frac{E_0[y_t^\nu \alpha_t \beta_t | \mathcal{M}_t]}{E_0[\alpha_t \beta_t | \mathcal{M}_t]}. \quad (47)$$

Now, from (40) and (45), we see that $y_t^\#$ and α_t are \mathcal{M}_t measurable. Thus, they may be taken out of the conditional expectations in (47) giving

$$E[y_t | \mathcal{M}_t] = y_t^\# + \frac{E_0[y_t^\nu \beta_t | \mathcal{M}_t]}{E_0[\beta_t | \mathcal{M}_t]}. \quad (48)$$

Now, again, since under P_0 , v_t and m_t are independent processes, the conditional expectations in (48) may be replaced by ordinary expectations with respect to the distribution of v_t giving (38). A similar argument gives (39). That β_t is a solution of (42) follows by differentiating (46) using Ito's rule.

Remark 1: Formulas (21) and (22) [or (38) and (39)] express the conditional expectations we are interested in, in terms of the expected value with respect to the distribution of the process v_t of quantities which are solutions of stochastic differential equations driven by the measurements m_t . It is not surprising since we do not know v_t that we should have to take an expected value with respect to its distribution. However, evaluating this expected value in the general case could be prohibitively complex. For instance, to determine the quantities whose expected value is to be taken in (38) and (39), equations (40)–(42) must be solved. There is one equation—(41)—for each control path and the solution of this equation is a coefficient in (42) for β_t . Thus, (42) could be an infinite system of equations, one for each control path, which are driven by the incoming measurements m_t .

The difficulties mentioned in Remark 1 disappear in the following case.

Finiteness Assumption: The probability distribution of the control v_t is concentrated on a finite number of paths

$$v_t^1, v_t^2, \dots, v_t^n \quad (49)$$

and is given by

$$P[v_t = v_t^i] = P^i, \quad i = 1, \dots, n. \quad (50)$$

Theorem II, in this case, is easily seen to reduce to the following theorem.

Theorem 3: If the finiteness assumption holds, then

$$E[y_t | \mathcal{M}_t] = y_t^\# + \frac{\sum_{i=1}^n P^i y_t^i \beta_t^i}{\sum_{i=1}^n P^i \beta_t^i} \quad (51)$$

and

$$E[v_t | \mathcal{M}_t] = \frac{\sum_{i=1}^n P^i v_t^i \beta_t^i}{\sum_{i=1}^n P^i \beta_t^i} \quad (52)$$

where $y_t^\#$ is the solution of (40), y_t^i is the solution of

$$dy_t^i = [(C' - R(t)H'H)y_t^i + Dv_t^i] dt; \quad y_0^i = 0 \quad (53)$$

and β_t^i is the solution of

$$d\beta_t^i = \beta_t^i (H y_t^i)' (dm_t - H y_t^\# dt); \quad \beta_0^i = 1. \quad (54)$$

Remark 2: In Theorem 3, the solutions of the linear system (53) driven by the n known paths v_t^i could be precomputed to give the n functions y_t^i . Thus, (40) for $y_t^\#$ and (54) for the n functions β_t^i are a system of $n+1$ equations driven by the measurements m_t which must be solved to determine the quantities in (51) and (52). This is an implementable method for computing these conditional expectations.

Remark 3: In the case of a general distribution for the paths of the control process v_t , the following could be considered as a numerical method for determining the conditional distributions in Theorem 2. Choose a finite partition of the path space of v_t into sets S_1, \dots, S_n . Choose a representative element v_t^i in each set S_i . Then form an approximate distribution \hat{P} on the path space concentrated on the representative elements, by

$$P[v_t = v_t^i] = P(S_i). \quad (55)$$

The sets S_i should be chosen so that if y_t^i and $y_t^{i'}$ are, respectively, solutions of (53) corresponding to an arbitrary element v_t^i of S_i and the representative element $v_t^{i'}$ of $S_{i'}$, the probability that y_t^i and $y_t^{i'}$ are far apart is small. Then for this finite approximate distribution, use the quantities (51) and (52) of Theorem 3 as approximations for (38) and (39) of Theorem 2.

How, in practice, could the previous results be used to give a control law for the pursuit-evasion problem? First, a finite representative family of control paths that the evader might use or nearly use should be selected and probabilities assigned to them. Then the formulas (51) and (52) of Theorem 3 would give the conditional expectations

$$E[y_t | \mathcal{M}_t] \quad \text{and} \quad E[v_t | \mathcal{M}_t]. \quad (56)$$

Then the conditional expectation of the evader's terminal position is given in terms of the conditional expectations of (56) by (20), the predicted miss by (17), and the control by (7). This gives a computationally feasible procedure for computing (7).

V. CONCLUSIONS

Previous work [1] implied that the optimal control for the pursuit-evasion problem could be given in terms of a formula involving the conditional expectation of the evader's terminal position. The Kallianpur–Striebel formula, a double conditioning with respect to both the past measurements and the values of the evader's unknown control law, and Kalman filtering were used to express this conditional expectation in terms of expected values of given functions of past measurements with respect to the distribution of the unknown control law. When the unknown control law has only a finite number of paths, this gives a computationally feasible procedure for computing the optimal control law. In other cases it gives an approximation to the optimal control law.

A Subspace Fitting Method for Identification of Linear State-Space Models

A. Swindlehurst, R. Roy, B. Ottersten, and T. Kailath

Abstract—A new method is presented for the identification of systems parameterized by linear state-space models. The method relies on the concept of *subspace fitting*, wherein an input/output data model parameterized by the state matrices is found that best fits, in the least-squares sense, the dominant subspace of the measured data. Some empirical results are included to illustrate the performance advantage of the algorithm compared to standard techniques.

I. INTRODUCTION

Research in the identification of discrete time linear systems has focused in recent years on prediction error methods (PEMs) based on autoregressive and autoregressive moving average (ARMA) data models and their various derivatives (e.g., [1], [2]). Although linear state space models are common in estimation and control, they have not been widely used in identification. Implicitly, of course, a given input/output model can be associated with various canonical state space realizations, and thus a PEM might be thought of as finding a state space model for the system. One of the goals of this note is to demonstrate, however, that there are some important advantages in explicitly considering more general state space forms in identification.

Several early approaches to the general state space identification problem were based on examining the structure of a Hankel matrix composed of samples of the impulse response of the system [3], [5]. More recently, De Moor [6], [7] has developed a total least squares algorithm that exploits the same shift structure present in a certain input/output data model, and that allows arbitrary input excitations.

Manuscript received May 21, 1993; revised February 1, 1994. This work was supported by the National Science Foundation under Grant MIP 9110112.

Related methods have also been recently proposed by Moonen [8] and Verhaegen et al. [9].

The method presented in this note also exploits the inherent shift structure in the data, but in a different way. The motivation for this new algorithm comes from some recent results in sensor array signal processing. In particular, it is shown how the identification problem can be cast in the *subspace fitting* framework, where the goal is to find the input/output model which best fits (in the least squares sense) the dominant subspace of the data. This approach has been successfully applied by Ottersten and Viberg in the context of narrowband direction-of-arrival estimation [10]. Of special interest is the fact that a weighting can be applied to the dominant subspace to emphasize certain directions where the signal to noise ratio is high. This weighting can provide an advantage in cases involving nearly unobservable systems or an insufficiently excited state space.

II. DATA MODEL AND ASSUMPTIONS

Consider the following multiple input multiple output (MIMO) time invariant linear system in state space form:

$$x_{k+1} = Ax_k + Bu_k$$

$$y_k = Cx_k + Du_k + v_k \quad (1)$$

where $x_k \in \mathbb{R}$, $u_k \in \mathbb{R}$, $y_k \in \mathbb{R}^l$, $v_k \in \mathbb{R}^l$ and the system matrices A , B , C , and D are of consistent dimension. The system input u_k is assumed known and the output y_k is corrupted by additive measurement noise v_k . If several observations of the input and output vectors are available, they may be grouped together into the single equation (e.g., see [6] and [11])

$$Y = GX + HU + V \quad (2)$$

where

$$Y = \begin{bmatrix} y_k & y_{k+1} & \dots & y_{k+j-1} \\ y_{k+1} & y_{k+2} & \dots & y_{k+j} \\ \vdots & \vdots & \ddots & \vdots \\ y_{k+j-1} & y_{k+j} & \dots & y_{k+j+j-1} \end{bmatrix}$$

$$G = \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{j-1} \end{bmatrix}$$

$$H = \begin{bmatrix} D & 0 & 0 & 0 \\ CB & D & 0 & 0 \\ CAB & CB & D & 0 \\ CA^2B & CA^3B & CA^4B & D \end{bmatrix}$$

$x = [x_k x_{k+1} \dots x_{k+j-1}]$ and where $U(m \times j)$ and $V(l \times j)$ are block Hankel matrices constructed exactly as Y but containing samples of the input and disturbance sequences, respectively.

We will make the following assumptions concerning the data model of (2):

- The system is observable, and the block dimension l is chosen to be large enough so that $\text{rank}(G) = n$. This implies $li \geq n$.
- The input sequence u_k has sufficiently excited the system and $j \geq n$, so that $\text{rank}(X) = n$.

- The input is uncorrelated with the measurement noise (open-loop operation).
- A nontrivial matrix U^\perp can be found to satisfy $UU^\perp = 0$. This requires $j > mi$, and leads to

$$YU^\perp = \Gamma XU^\perp + VU^\perp. \quad (3)$$

- $\text{rank}(XU^\perp) = n$, so that $j \geq mi + n$. This rank condition is satisfied for most choices of the input (e.g., with probability one if the input is zero-mean white noise) [6], [11].

With these assumptions, YU^\perp is an $li \times p$ matrix, with $n \leq p \leq j - mi$. In most situations, $p = j - mi > n$, so that YU^\perp is composed of a (low) rank n "signal" term ΓXU^\perp that depends on the parameters of interest, and a "noise" term VU^\perp that is (with probability one) full rank.

It is convenient for us to also define here the "sample covariance" matrix

$$\hat{R}_{YU^\perp} = \frac{1}{j} (YU^\perp)(YU^\perp)^T$$

and note that it converges to its limiting expected value with probability one

$$R_{YU^\perp} = \lim_{j \rightarrow \infty} \mathcal{E} \{ \hat{R}_{YU^\perp} \} = \Gamma R_{XU^\perp} \Gamma^T + \sigma^2 \Sigma$$

where

$$R_{XU^\perp} = \frac{1}{j} (XU^\perp)(XU^\perp)^T, \quad \sigma^2 \Sigma = \frac{1}{j} \mathcal{E} \{ (VU^\perp)(VU^\perp)^T \}$$

and Σ is normalized so that $\det(\Sigma) = 1$. It is easy to show that the generalized eigenvalues $\{\lambda_k\}$ of the pair (R_{YU^\perp}, Σ) satisfy $\lambda_1 \geq \dots \geq \lambda_n > \lambda_{n+1} = \dots = \lambda_l = \sigma^2$. Furthermore, the eigenvectors $E = [e_1 \dots e_n]$ associated with $\lambda_1, \dots, \lambda_n$ satisfy

$$\Sigma E = \Gamma(\eta)T \quad (4)$$

for some $n \times n$ matrix T . We have written Γ as a function of a vector η , which contains the elements of the parameterization chosen for A and C . Just as there are many realizations or coordinate systems that can be used to describe the state space, there are many identifiable parameterizations η that can be chosen, each yielding a different T that satisfies (4). The subspace fitting method presented in this note is based on the relationship of (4).

Note that with no measurement noise or infinite data, the model order n is revealed by simply counting how many of the smallest generalized eigenvalues are equal. With a finite collection of noisy data, a statistical test is required to estimate this quantity. This problem has been extensively studied in very general contexts, and many such tests have been developed (e.g., see [12]–[14]). We will thus assume throughout the remainder of the note that n has been correctly determined.

III. A SUBSPACE FITTING APPROACH

Because of the effects of noise, only an estimate of the generalized eigenvectors \hat{E} can be obtained from \hat{R}_{YU^\perp} (or equivalently from an SVD of YU^\perp). Consequently, assuming an appropriate identifiable parameterization η has been chosen, we propose the following two-step identification procedure based on (4).

1) Estimate η by means of the following weighted least-squares problem:

$$\begin{aligned} \hat{\eta} &= \arg \min_{\eta} \| \Sigma \hat{E} W^{1/2} - \Gamma(\eta)T \|^2_F \\ &= \arg \min_{\eta} \text{Tr}(P_{\hat{\eta}}^\perp \Sigma \hat{E} W \hat{E}^T \Sigma^T) \end{aligned} \quad (5)$$

where $P_{\hat{\eta}}^\perp = I - \Gamma(\hat{\eta})[\Gamma(\hat{\eta})^T \Gamma(\hat{\eta})]^{-1} \Gamma(\hat{\eta})^T$. The estimates of the system matrices are thus given by $A(\hat{\eta}), C(\hat{\eta})$.

2) Estimate B and C using a noise-free version of (2) and the estimates $A(\hat{\eta}), C(\hat{\eta})$.

Some comments are in order concerning the two steps of the Weighted Subspace Fitting (WSF) algorithm described above.

Step 1: The choice of the weighting matrix W will be discussed below in Subsection A. A variety of possible parameterizations for η exist, depending on what (if any) prior information about the system is available. For example, if the system is multiple-input single-output, a particularly appropriate choice is to assume that the system is in observer form, and hence that A is left-companion and $C = [1 \ 0 \dots 0]$. Alternatively, A could be assumed to be diagonalizable, in which case C is solved for directly, and the minimization of (5) can be simplified to involve only a search over the n pole locations.

One of the advantages of the problem formulation considered herein is that any *a priori* information about the structure of A and C can be directly incorporated into the problem. In some instances, the dynamical model underlying the system may be well understood, but may depend on certain parameters that are imprecisely known. These parameters appear as unknown constants in the matrices A and C of the system model, and could serve as the parameters in the minimization of (5) just as easily as the poles or the coefficients of the characteristic polynomial. Whether or not the set of unknown parameters can be uniquely identified is then problem dependent, and must be determined on a case-by-case basis.

The minimization of (5) is identical in form to a problem in antenna array signal processing considered in [15]. In fact, once an appropriate parameter vector has been identified, an algorithm essentially identical to that described in [15] may be used to estimate A and C . Additional information on the connection between state-space system identification and array signal processing can be found in [16] and [17].

We note here that, even though $\Sigma \neq I$, consistent parameter estimates can be obtained by setting $\Sigma = I$ if the noise is white and independent with equal variance among the l outputs, and if j is sufficiently large.¹ In other cases, however, ignoring Σ when $\Sigma \neq I$ (as is done in [6], [7], [9]) can lead to biased parameter estimates.

Step 2: This step is also used by De Moor in his identification method [6], [7]. A description of the mechanics required to solve for B and D can also be found in [19], and will not be given here.

A. Subspace Weighting

In simple terms, the presence of the weighting matrix W in the minimization of (5) allows certain directions or dimensions of the low rank subspace to be emphasized over others. For example, the generalized eigenvector e_1 corresponding to the largest eigenvalue represents the component of the measured data where the signal energy is the strongest. The eigenvector e_n gives the direction where the signal energy is weakest but still nonzero. A measure of how "strong" or "weak" the signal energy is in a given direction can be based on how much bigger than σ^2 the eigenvalues $\lambda_1, \dots, \lambda_n$ are. The difference $\lambda_n - \sigma^2$ can be quite small in cases where Γ or X are ill-conditioned (e.g., because the system is nearly unobservable or the input is not sufficiently exciting), and in such cases one would probably wish to give much less weight to e_n in (5) than e_1 .

The following "optimal" weighting has been derived for subspace fitting problems of the form (5) in [10]:

$$W_{\text{WSF}} = (\hat{\Lambda}_n - \sigma^2 I)^2 \hat{\Lambda}_n^{-1} \quad (6)$$

¹How large j has to be for this to hold depends on the magnitude of the noise.

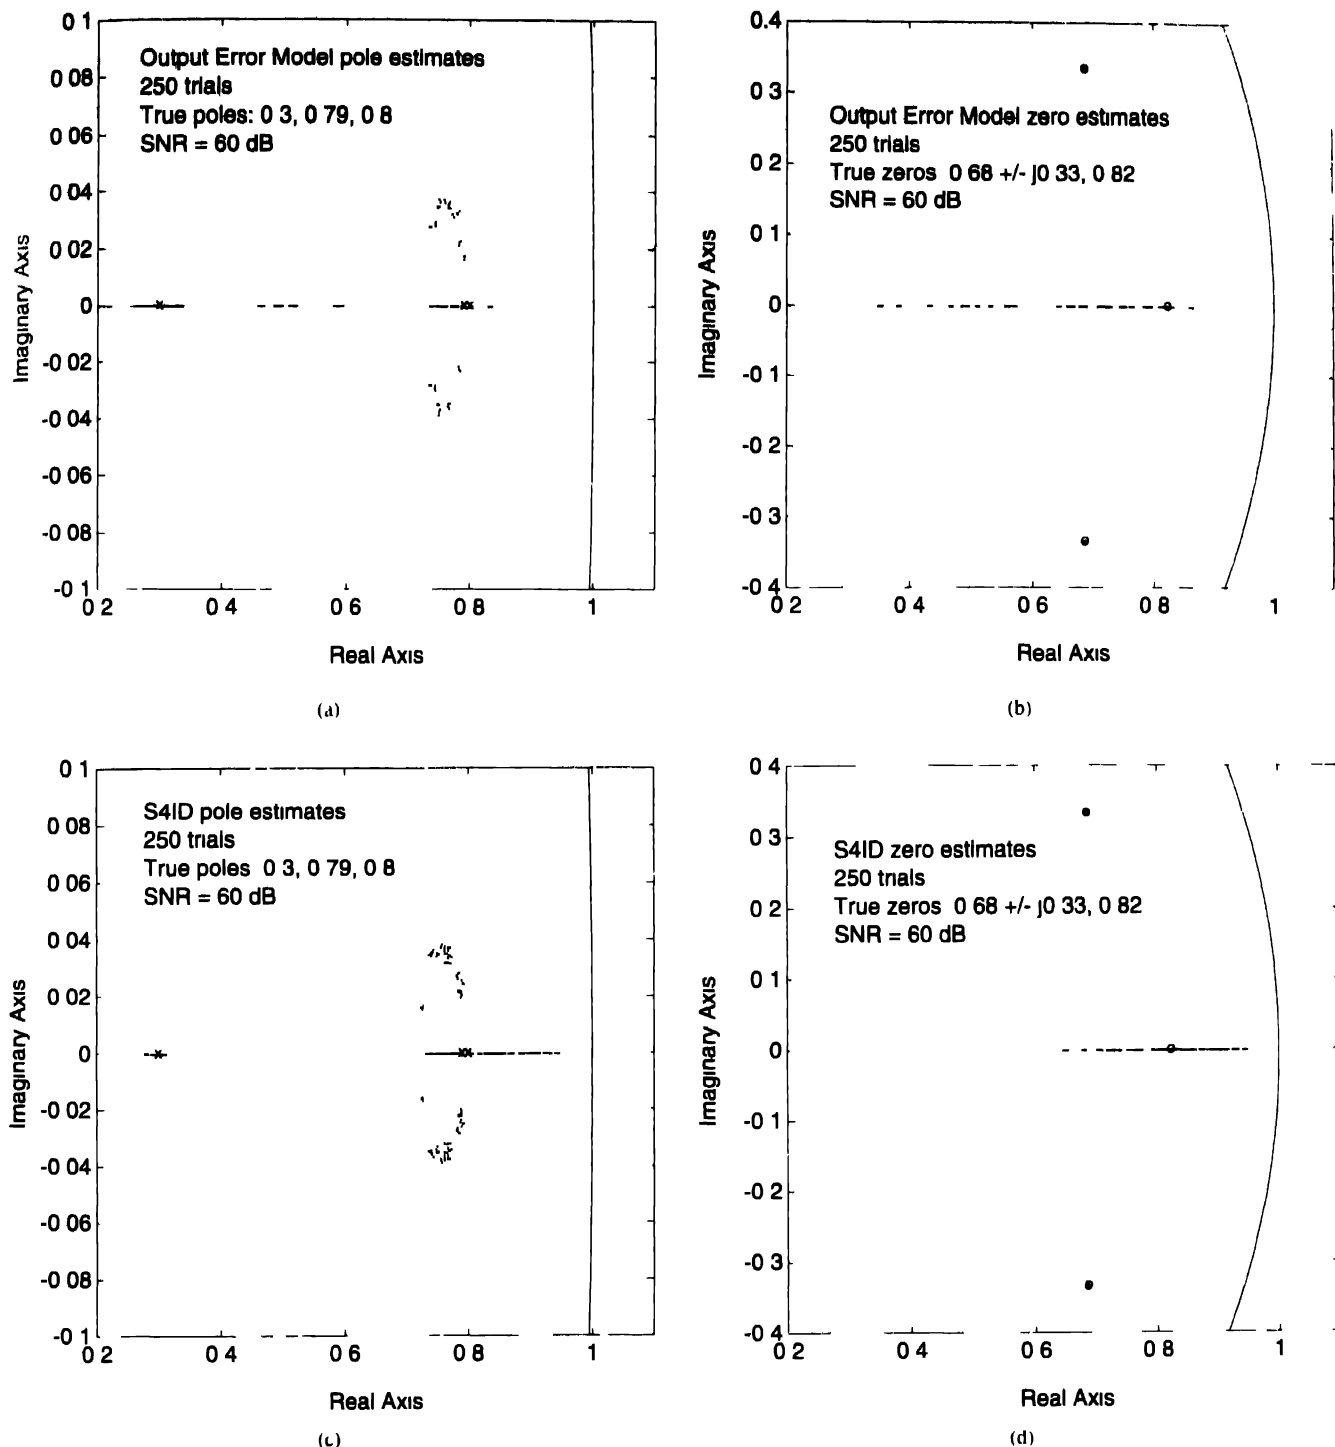

Fig 1 Pole and zero estimates for simulation example 1

where the diagonal matrix \mathbf{A} contains $\lambda_1, \dots, \lambda_n$ as its diagonal elements, and σ^2 is an appropriate estimate of σ^2 (obtained, for example as an average of the $l-n$ smallest generalized eigenvalues). The term "optimal" here means that, under certain conditions, the weighting of (6) will lead to minimum variance parameter estimates. The Hankel structure of \mathbf{Y} and \mathbf{V} in our problem violates one of these conditions, namely, that the columns of the data matrix be independent. However, using \mathbf{W}_{WSF} in (5) has been empirically shown to yield better results than using no weighting at all ($\mathbf{W} = \mathbf{I}$).

B Comparison to Other Techniques

The principle difference between the WSF algorithm presented above and the methods described in [6], [7], and [9] is that the WSF approach can exploit the complete structure of \mathbf{F} rather than just a single "shift-invariance." This advantage is especially evident in situations where *a priori* information is available about the structure of \mathbf{A} and \mathbf{C} . On the other hand, the methods of [6], [7], and [9] admit a simple "closed-form" solution, whereas (5) can only be solved by means of a multidimensional search.

Fig. 1 Continued

Unlike standard ARMA-based PEM approaches, the WSF algorithm is just as easily applied to MIMO systems as in the single-input single-output case, has a built-in mechanism for model order determination, and can exploit structured system models with more compact parameterizations. Even in the unstructured case, WSF tends to yield pole and zero estimates with much lower variance than PEM's, as illustrated by the simulation examples of the next section. Recent work in identification and controller design for rapid thermal processing of semiconductor wafers [19], [20] has also borne out some of the advantages of using subspace-based identification methods over PEM's.

IV. SIMULATION EXAMPLES

In this section we consider two simple simulation examples that illustrate the advantage of the subspace fitting approach. In the first example, the parameters of the following three state SISO discrete time system will be estimated:

$$A = \begin{bmatrix} 0.30 & -0.40 & 0.60 \\ 0.00 & 0.80 & 0.00 \\ 0.00 & 0.00 & 0.79 \end{bmatrix}$$

$$B = \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix}$$

$$C = [1.30 \quad 0.40 \quad -0.80]$$

$$D = 1$$

The poles of this system are located at 0.3, 0.79, and 0.8, and the zeros at 0.82, and $0.68 \pm j0.33$. Note that for this system, X will be ill-conditioned since the lower right 2×2 block of A is diagonal, with nearly equal diagonal elements, and the last two elements of B are identical. This is also evidenced by the fact that there is a near pole-zero cancellation in the transfer function.

This system was simulated using a zero mean unit power white Gaussian process as its input, and assuming a zero initial state.² White Gaussian measurement noise with a standard deviation of 0.001 was added to the system output. Using the noise free input and the noisy system output, three methods were used to estimate the system poles and zeros. These were the method of De Moor [6], [7] (which, for brevity, we refer to as the S4ID technique), the WSF algorithm, and a PEM based on an *output error* model [1]. The correct model order was assumed to be known in each case.

We conducted 250 Monte Carlo experiments with an independent measurement noise and input sequence generated for each trial. The block dimensions of the Hankel matrices were chosen as $i = 12$ and $j = 50$, corresponding to a total of 61 output samples for each trial. The WSF method was implemented using the weighting of (6) and assuming a diagonal parameterization for the system matrix A . Both WSF and PEM used the true parameter vectors to initialize their respective search routines. The results of the simulations are displayed in Fig. 1. The solid line at the right of each plot represents the unit circle, and the true pole and zero locations are indicated by the symbols \times and \circ , respectively.

The variance of the poles and zeros estimated by WSF is clearly much smaller than that of the other algorithms. This is especially true for the pole at 0.3, in fact, all 250 estimates are so closely bunched together that they are almost indistinguishable from the \times marking the true pole. All three algorithms estimated the complex zeros very accurately, the individual trials are again indistinguishable from the true zero locations. However, the variance of the real valued zero is much smaller for WSF than for either PEM or S4ID. In addition, both PEM and S4ID estimated complex poles on about 20% of the simulations, while the WSF poles were always purely real (although they were not constrained to be so). One drawback of the subspace based methods is that, on a few occasions (5 for WSF and 11 for S4ID), they produced unstable pole estimates.

²The effects of a nonzero initial state can be handled by assuming the presence of an additional input that is a unit Dirac impulse [6].

Fig. 2. Pole estimates for output error model, example 2.

Fig. 3. Pole estimates for WSF, example 2.

In the second example, we consider the following system used in the simulation studies of [9]

$$A = \begin{bmatrix} 1.92 & -0.9316 \\ 1 & 0 \end{bmatrix}$$

$$B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

$$C = [0.05 \quad 0.025]$$

$$D = 0.$$

The poles of this system are at $0.96 \pm j0.01$, and there is a single zero at -0.5 . The same type of input and measurement disturbance as above were used in this case, except the variance of the disturbance was increased to one. This resulted in an average effective output SNR of only 4.4 dB. The dimensions of the block Hankel matrices were chosen as $i = 40$ and $j = 161$, for a total of 200 samples per trial. As before, both WSF and the output error PEM were initialized with the true parameters, and 250 independent trials were conducted. The results of the simulation are plotted in Figs. 2 and 3.

Fig. 2 shows the pole estimates for the output error model, with the true pole locations indicated by the crosshairs, and Fig. 3 shows

the same for the WSF algorithm. No separate plot is shown for S4ID, since it gave results essentially equivalent to WSF in this case (with the exception of one outlier). The WSF approach again yields pole estimates with a much smaller variance than the corresponding PEM. The average mean-square prediction error for WSF in this case was 0.985, compared to 1.403 for the output error PEM.

Because of the various optimality properties of PEM's in general [1], one may be surprised by the superior performance of WSF in the above two examples. Since both algorithms used essentially the same minimization procedure (Gauss-Newton iterations with identical initial conditions and termination criteria) the relatively poor performance of the output error PEM in these examples may be attributed to a propensity for convergence to local minima.

V CONCLUSIONS

We have presented a new method for identification of linear systems parameterized by state-space models. The method is based on the notion of weighted subspace-fitting (WSF), a problem-solving philosophy most recently applied to parameter estimation problems in sensor array signal processing. Like other state space identification schemes, WSF is easily applied in the MIMO case, allows for direct incorporation of *a priori* physical constraints into the problem, and appears to have better numerical properties than methods based on input/output models. In addition, the ability to appropriately weight the signal subspace vectors used in the WSF minimization provides a degree of robustness over previous subspace-based methods when the system is nearly unobservable or not sufficiently excited. Although implementation of WSF requires a multidimensional parameter search, accurate initial conditions for the search are readily obtained.

Consistency of Modified LS Estimation Method for Identifying 2-D Noncausal SAR Model Parameters

Ping Ya Zhao and John Litva

Abstract—Least squares (LS) and maximum likelihood (ML) are the two main methods for parameter estimation of two-dimensional (2-D) noncausal simultaneous autoregressive (SAR) models. ML is asymptotically consistent and unbiased but computationally unattractive. On the other hand, conventional LS is computationally efficient but does not produce accurate parameter estimates for noncausal models. Recently, in [17], a modified LS estimation method was proposed and shown to be unbiased. In this note we prove that, under certain assumptions, the method introduced in [17] is also consistent.

I INTRODUCTION

Two dimensional (2-D) signal and system modeling and parameter estimation have many applications such as 2-D Kalman filtering [1], image estimation and identification [2]–[4], image restoration [5], [6], multidimensional spectrum estimation [7], [8], direction finding [9], texture analysis and synthesis [10], [11], multidimensional system identification [12], [13], etc. Several kinds of models are used to cite a few: Gauss-Markov random field (GMRF) models which are sometimes called conditional Markov (CM) models [14]–[16], simultaneous autoregressive (SAR) models [16], [17], autoregressive moving average (ARMA) models [18], [19], etc. In this note we will concentrate on the problem of estimating the parameters $\{q_k\}$ of the 2-D noncausal SAR model in the form of

$$y(i, j) = - \sum_{(k, l) \in N} q_k y(i-k, j-l) + e(i, j) \quad (1)$$

Manuscript received June 18, 1993; revised February 20, 1994. The authors are with Communications Research Laboratory, McMaster University, Hamilton, Ontario, Canada L8S 4K1. IEEE Log Number 9406994.

where $\{\epsilon(t, j)\}$ is a field of independent and identically distributed random variables with zero mean and constant variance. Λ is called the neighbor set of the model whose shape determines the causality of the model. According to [20] the model is a noncausal one if Λ is the form

$$\Lambda \subseteq \{(k, l) : -p \leq k \leq p, -q \leq l \leq q\} \setminus \{(0, 0)\} \quad (2)$$

This is the most general of all the models and is known to provide the best performance. For the same specific problem using the noncausal model will lead to simpler model form and more efficient computational schemes.

If the model is noncausal however $\epsilon(t, j)$ will correlate with $\{q(t-k, j-l) : (k, l) \in \Lambda\}$ and the conventional least squares (LS) will not be an unbiased and consistent parameter estimator. One is then forced to use the computationally inefficient maximum likelihood (ML) estimator to determine the noncausal SAR model parameters accurately. To avoid excessive computation of the ML an iterative scheme was developed in [16] which gives approximate ML estimates of the SAR model parameters. As a means of overcoming inaccuracy in the conventional LS a modified LS estimator was proposed in [17]. The modified LS has been proved mathematically to be an unbiased estimator under some mild conditions and the experiments in [17] show that the modified LS and the approximate ML have the same estimation accuracy. On the other hand the modified LS is superior to the approximate ML from a computational point of view. If the modified LS estimate is calculated directly from (14) it requires fewer operations than for one iteration of the approximate ML whose implementation usually requires several iterations. More importantly the modified LS possesses some shift invariance properties [21] which can be used to develop a fast implementation based on recursion. An order recursive algorithm with the computational complexity of $O(m^2)$ where m is the number of the estimated parameters is given in [17] and a spatially recursive algorithm with the computational complexity of $16m^{1/2} + O(m)$ multiplications and divisions per recursion (MADPR) is given in [22]. The spatially recursive algorithm uses only the local observations appearing in a sliding data window so it can be used to estimate 2-D nonstationary and noncausal SAR model parameters. It is believed that the computational efficiency is an important issue and recursive algorithms usually lead to reduction in computational burden [23] [24].

When further comparisons are made to the conventional LS estimator the modified LS estimator is favored to have another significant advantage. The conventional LS normal equations are sometimes ill conditioned which leads to numerical instabilities. However the coefficient matrix of the modified LS normal equation has a different structure with a lower probability of being singular. It thus can effectively avoid the instability problem which is very important in real implementations of the parameter estimators.

Yet consistency is an extremely essential characteristic for an estimator which can serve as a very important criterion for selecting an estimator for a particular application. The mathematical proof of the consistency of the above mentioned modified LS estimator has not been presented anywhere in the literature. The purpose of this note is to present a proof for the consistency of the unbiased modified LS estimator. This proof corroborates computer simulation results that the mean square errors of the modified LS decrease at their greatest rate when the sizes of the data sample windows increase and that the mean square error of the modified LS estimator has a rate of decrease which is much greater than the approximate ML.

II THE MODIFIED LS ESTIMATION METHOD

When the model is a causal one the conventional LS is an unbiased and consistent estimator. The basic idea of the modified LS is the translation of the noncausal SAR model parameter estimation problem into a problem based on a causal model and an anticausal model. This is achieved by translating (1) into

$$q_{0,0}y(t, j) = - \sum_{(k,l) \in \Lambda} q_{k,l}y(t-k, j-l) + \epsilon(t, j) \quad (3)$$

$$q_{0,0}y(t, j) = - \sum_{(k,l) \in \Lambda} q_{k,l}y(t-k, j-l) + \epsilon(t, j) \quad (4)$$

where

$$q_{0,1} + q_{0,-1} - q_{0,0} = 1 \quad (5)$$

$$\epsilon(t, j) + \epsilon(t, j) = \epsilon(t, j) \quad (6)$$

$$\Lambda \subseteq \{(k, l) : 1 \leq k \leq p, -q < l \leq q\} \cup \{(0, l) : 1 < l \leq q\} \quad (7)$$

$$\Lambda \subseteq \{(k, l) : -p \leq k < -1, -q < l \leq q\} \cup \{(0, l) : -q < l \leq -1\} \quad (8)$$

provided that such a decomposition exists. Minimization of the modified LS objective function

$$\begin{aligned} F(\mathbf{g}_i) &= \sum_{(t,j) \in G} \{[\epsilon(t, j)]^2 + [\epsilon(t, j)]^2\} + 2D(q_{0,1} + q_{0,-1} - 1) \\ &= \sum_{(t,j) \in G} \{[\epsilon(t, j)]^2 + [\epsilon(t, j)]^2\} + 2n_G d(q_{0,1} + q_{0,-1} - 1) \end{aligned} \quad (9)$$

with respect to \mathbf{g}_i results in the modified LS estimator where G is a 2-D data window, n_G is a number of data points contained in G and

$$\mathbf{g}_i = [\mathbf{g}_i^T \text{ ml } d \mathbf{g}_i^T]^T \quad (10)$$

$$\mathbf{g}_i = \left[\text{column} \{q_{k,l} : (k,l) \in \Lambda\} \right] \quad (11)$$

$$\mathbf{g}_i = \left[\text{column} \{q_{k,l} : (k,l) \in \Lambda\} \right] \quad (12)$$

$$D = n_G d = - \frac{\sum_{(t,j) \in G} [\epsilon(t, j)]}{q_{0,0}} = - \frac{\sum_{(t,j) \in G} [\epsilon(t, j)]}{I_0} \quad (13)$$

The resulting modified LS estimator is

$$\mathbf{g}_i(G) = \mathbf{R}_i^{-1}(G) \mathbf{z}_i \quad (14)$$

where

$$\mathbf{R}_i(G) = \begin{bmatrix} \mathbf{J} \mathbf{R}_i(G) \mathbf{J} & \mathbf{0} & \mathbf{0} \\ & n_G & \\ \mathbf{0} & n_G & \mathbf{0} \\ & n_G & \\ \mathbf{0} & \mathbf{0} & \mathbf{R}_i(G) \end{bmatrix} \quad (15)$$

$$\mathbf{R}_p^c(G) = \sum_{(i,j) \in G} \mathbf{x}_p^c(i,j) \mathbf{x}_p^{cT}(i,j) \quad (16)$$

$$\mathbf{R}_p^a(G) = \sum_{(i,j) \in G} \mathbf{x}_p^a(i,j) \mathbf{x}_p^{aT}(i,j) \quad (17)$$

$$\mathbf{x}_p^c(i,j) = \begin{bmatrix} y(i,j) \\ \mathbf{y}_p^c(i,j) \end{bmatrix} \quad (18)$$

$$\mathbf{x}_p^a(i,j) = \begin{bmatrix} y(i,j) \\ \mathbf{y}_p^a(i,j) \end{bmatrix} \quad (19)$$

$$\mathbf{y}_p^c(i,j) = \text{column}\{y(i-k, j-l) : (k,l) \in N^c\} \quad (20)$$

$$\mathbf{y}_p^a(i,j) = \text{column}\{y(i-k, j-l) : (k,l) \in N^a\} \quad (21)$$

$$\mathbf{x}(i,j) = [y(i,j+q) \cdots y(i,j) \cdots y(i,j-q)]^T \quad (22)$$

$$\mathbf{z}_p = [0 \cdots 0 n_G 0 \cdots 0]^T. \quad (23)$$

Boldface $\mathbf{0}$ stands for a matrix or vector with all zero entries, \mathbf{J} is a variable dimension square exchange matrix with ones along the antidiagonal and zeros everywhere else, and $\mathbf{g}_p(G)$ denotes the estimate of \mathbf{g}_p based on the use of the data $\{y(i,j) : (i,j) \in B\}$, and $B \supset G$ is another data window, such that for $(i_1, j_1) \in G$, the elements of vectors $\mathbf{x}_p^c(i_1, j_1)$ and $\mathbf{x}_p^a(i_1, j_1)$ are defined on B , i.e., if $y(i,j)$ is an element of $\mathbf{x}_p^c(i_1, j_1)$ or $\mathbf{x}_p^a(i_1, j_1)$, then $(i,j) \in B$.

Using the same procedure as that in [17], we can prove that $\mathbf{g}_p(G)$ is an unbiased estimate of \mathbf{g}_p if

- 1) $\mathbf{R}_p(G)$, defined by (15), is a positive matrix and independent of $\mathbf{g}_p - \mathbf{g}_p(G)$;
- 2) the decomposition of (1) into (3) and (4) and $e(i,j)$ into $e^c(i,j)$ and $e^a(i,j)$ which are independent and have zero means and constant variances exists, and (13) is valid for sufficiently large G ; and
- 3) $e^c(i,j)$ and $e^a(i,j)$ are uncorrelated with $\{y(i-k, j-l) : (k,l) \in N^c\}$ and $\{y(i-k, j-l) : (k,l) \in N^a\}$, respectively.

Because the same modified LS objective function (9) is used, $\mathbf{g}_p(G)$ is actually the same estimate as that in [17] except that D is factored into $n_G d$ and d , instead of D , is used as the central element of $\mathbf{g}_p(G)$. From (13), we see that d is approximately a constant and D is proportional to n_G if $\{e^c(i,j)\}$ and $\{e^a(i,j)\}$ are stationary.

III. CONSISTENCY OF THE MODIFIED LS ESTIMATOR

Lemma: Given a stationary image $\{y(i,j) : (i,j) \in B\}$, the absolute value of any element of $E\{\mathbf{R}_p(G)[\mathbf{g}_p - \mathbf{g}_p(G)][\mathbf{g}_p - \mathbf{g}_p(G)]^T \mathbf{R}_p^T(G)\}$ does not exceed $O(n_G)$ as $n_G \rightarrow \infty$, where n_G is a number of data points contained in G , if the conditions 2) and 3) are valid, and

- 4) there is a positive number M such that for (i_1, j_1) , (i_2, j_2) , $(i_3, j_3) \in B$ and $k_1 + k_2 + k_3 = 4$,

$$|E\{[y(i_1, j_1)]^{k_1} [e^c(i_2, j_2)]^{k_2} [e^a(i_3, j_3)]^{k_3}\}| \leq M; \quad (24)$$

and

- 5) $e^c(i,j)$ and $e^a(i,j)$ are uncorrelated with $y(i-k, j-l)$ for $(k,l) \notin N \cup \{(0,0)\}$, where N is the neighbor set used in (1).

Proof: By the same procedure as that in [17], it can be shown that

$$\mathbf{R}_p(G)[\mathbf{g}_p - \mathbf{g}_p(G)] = \begin{bmatrix} \sum_{(i,j) \in G} \mathbf{J} \mathbf{y}_p^a(i,j) e^a(i,j) \\ \sum_{(i,j) \in G} y(i,j) e^a(i,j) + D \\ 0 \\ \sum_{(i,j) \in G} y(i,j) e^c(i,j) + D \\ \sum_{(i,j) \in G} \mathbf{y}_p^c(i,j) e^c(i,j) \end{bmatrix}. \quad (25)$$

Let

$$\mathbf{R}_p(G)[\mathbf{g}_p - \mathbf{g}_p(G)][\mathbf{g}_p - \mathbf{g}_p(G)]^T \mathbf{R}_p^T(G) = \mathbf{S} \quad (26)$$

where

$$\mathbf{S} = \begin{bmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} & \mathbf{0} & \mathbf{S}_{14} & \mathbf{S}_{15} \\ \mathbf{S}_{12}^T & \mathbf{S}_{22} & \mathbf{0} & \mathbf{S}_{24} & \mathbf{S}_{25} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{S}_{14}^T & \mathbf{S}_{24} & \mathbf{0} & \mathbf{S}_{44} & \mathbf{S}_{45} \\ \mathbf{S}_{15}^T & \mathbf{S}_{25} & \mathbf{0} & \mathbf{S}_{45}^T & \mathbf{S}_{55} \end{bmatrix}. \quad (27)$$

The purpose of the proof is to show that the absolute values of all elements of matrices $E\{\mathbf{S}_{11}\}$, $E\{\mathbf{S}_{15}\}$, and $E\{\mathbf{S}_{55}\}$, vectors $E\{\mathbf{S}_{12}\}$, $E\{\mathbf{S}_{14}\}$, $E\{\mathbf{S}_{25}\}$, and $E\{\mathbf{S}_{45}\}$, as well as scales $E\{\mathbf{S}_{22}\}$, $E\{\mathbf{S}_{24}\}$, and $E\{\mathbf{S}_{44}\}$, do not exceed $O(n_G)$ as $n_G \rightarrow \infty$. Let us begin by studying $E\{\mathbf{S}_{11}\}$.

From condition 2), we conclude that $e^a(i,j)$ has zero mean, and from condition 3) that $e^a(i,j)$ is uncorrelated with $\mathbf{y}_p^a(i,j)$. Further, from condition 5), we conclude that $e^a(i,j)$ is uncorrelated with $y(i-k, j-l)$ for $(k,l) \notin N \cup \{(0,0)\}$. It follows, by using condition 4) for (k_1, l_1) , $(k_2, l_2) \in N^a$ that

$$|E\{y(i_1 - k_1, j_1 - l_1) e^a(i_1, j_1) y(i_2 - k_2, j_2 - l_2) e^a(i_2, j_2)\}| \leq M \quad (28)$$

if $(i_1, j_1) = (i_2, j_2)$, $(i_1 - i_2 + k_2, j_1 - j_2 + l_2) \in N^c \cup \{(0,0)\}$, or $(i_2 - i_1 + k_1, j_2 - j_1 + l_1) \in N^c \cup \{(0,0)\}$; otherwise, the left-hand side of (28) equals zero. Thus, the absolute value of the $(m_N - |k_1(2q+1) + l_1| + 1, m_N - |k_2(2q+1) + l_2| + 1)$ th element of $E\{\mathbf{S}_{11}\}$ can be expressed in the following form:

$$\begin{aligned} & \left| E \left\{ \sum_{(i_1, j_1) \in G} y(i_1 - k_1, j_1 - l_1) e^a(i_1, j_1) \right. \right. \\ & \quad \cdot \left. \sum_{(i_2, j_2) \in G} y(i_2 - k_2, j_2 - l_2) e^a(i_2, j_2) \right\} \Big| \\ & \leq \sum_{\substack{(i_1, j_1), (i_2, j_2) \in G \\ (i_1 - i_2 + k_2, j_1 - j_2 + l_2) \in N^c \cup \{(0,0)\}}} |E\{y(i_1 - k_1, j_1 - l_1) \\ & \quad \cdot e^a(i_1, j_1) y(i_2 - k_2, j_2 - l_2) e^a(i_2, j_2)\}| \\ & + \sum_{\substack{(i_1, j_1), (i_2, j_2) \in G \\ (i_2 - i_1 + k_1, j_2 - j_1 + l_1) \in N^c \cup \{(0,0)\}}} |E\{y(i_1 - k_1, j_1 - l_1) \\ & \quad \cdot e^a(i_1, j_1) y(i_2 - k_2, j_2 - l_2) e^a(i_2, j_2)\}| \\ & + \sum_{(i_1, j_1) \in G} |E\{y(i_1 - k_1, j_1 - l_1) \\ & \quad \cdot y(i_1 - k_2, j_1 - l_2) [e^a(i_1, j_1)]^2\}| \\ & = S \leq 2(m_N + 1)n_G M + n_G M \end{aligned} \quad (29)$$

where m_N is the number of the parameters contained in N^a or N^c .

Similarly, the absolute value of the $(m_N - |k_1(2q+1) + l_1| + 1)$ th element of $E\{S_{12}\}$ is

$$\begin{aligned} & \left| F \left\{ \sum_{(i_1, j_1) \in \mathcal{C}} y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \right. \right. \\ & \quad \left. \left. \left[\sum_{(i_2, j_2) \in \mathcal{C}} y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)} + D \right] \right\} \right| \\ & \leq \sum_{\substack{(i_1 - k_1 - j_1 - l_1) \in \mathcal{C} \\ (i_2 - k_2 - j_2 - l_2) \in \mathcal{C}}} |F\{y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \\ & \quad + y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)} + D)\}| \\ & \leq 2(m_N + 1)n_c M \end{aligned} \quad (30)$$

Since $e^{j\omega(i_1 - j_1)}$ and $e^{j\omega(i_2 - j_2)}$ have zero means and are uncorrelated with $y(i - k - j - l)$ for $(k, l) \notin \mathcal{N} \cup \{(0, 0)\}$, $e^{j\omega(i_1 - j_1)}$ is uncorrelated with $y(i_2 - k_2 - j_2 - l_2)$ and $e^{j\omega(i_2 - j_2)}$ is uncorrelated with $y(i_1 - k_1 - j_1 - l_1)$ for $(k_1, l_1) \in \mathcal{N}$ and $(k_2, l_2) \in \mathcal{N}$ respectively then

$$|F\{y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)}\}| \leq M \quad (31)$$

if $(i_1 - i_2 + k_2 - j_1 - j_2 + l_1) \in \mathcal{N} \cup \{(0, 0)\}$ or $(i_1 - i_2 + k_1 - j_1 - j_2 + l_2) \in \mathcal{N} \cup \{(0, 0)\}$ otherwise the left hand side of (31) equals zero. Thus the absolute value of the $(m_N - |k_1(2q+1) + l_1| + 1 - |k_2(2q+1) + l_2|)$ th element of $F\{S_1\}$ can be expressed as

$$\begin{aligned} & \left| F \left\{ \sum_{(i_1, j_1) \in \mathcal{C}} y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \right. \right. \\ & \quad \left. \left. \sum_{(i_2, j_2) \in \mathcal{C}} y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)} \right\} \right| \\ & \leq \sum_{\substack{(i_1 - k_1 - j_1 - l_1) \in \mathcal{C} \\ (i_2 - k_2 - j_2 - l_2) \in \mathcal{C}}} |F\{y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \\ & \quad + y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)}\}| \\ & \leq 2(m_N + 1)n_c M \end{aligned} \quad (32)$$

and the absolute value of the $(m_N - |k_1(2q+1) + l_1| + 1)$ th element

$$\begin{aligned} & \left| E \left\{ \sum_{(i_1, j_1) \in \mathcal{C}} y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \right. \right. \\ & \quad \left. \left. \left[\sum_{(i_2, j_2) \in \mathcal{C}} y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)} + D \right] \right\} \right| \\ & \leq \sum_{\substack{(i_1 - k_1 - j_1 - l_1) \in \mathcal{C} \\ (i_2 - k_2 - j_2 - l_2) \in \mathcal{C}}} |E\{y(i_1 - k_1 - j_1 - l_1) e^{j\omega(i_1 - j_1)} \\ & \quad + y(i_2 - k_2 - j_2 - l_2) e^{j\omega(i_2 - j_2)} + D)\}| \\ & \leq 2(m_N + 1)n_c M \end{aligned} \quad (33)$$

By a similar procedure we can prove that for $(k_1, l_1), (k_2, l_2) \in \mathcal{N}$ the following statements are true

- 1) the absolute value of $(|k_1(2q+1) + l_1|)$ th element of $F\{S_2\} \leq 2(m_N + 1)n_c M$
- 2) the absolute value of $(|k_2(2q+1) + l_2|)$ th element of $F\{S_1\} \leq 2(m_N + 1)n_c M$
- 3) the absolute value of $(|k_1(2q+1) + l_1| - |k_2(2q+1) + l_2|)$ th element of $E\{S_1\} \leq 2(m_N + 1)n_c M + n_c M$
- 4) $|L\{S_1\}| \leq 2(m_N + 1)n_c M + n_c M$
- 5) $|F\{S_{11}\}| \leq 2(m_N + 1)n_c M + n_c M$ and
- 6) $|F\{S_{41}\}| \leq 2(m_N + 1)n_c M + n_c M$

To summarize the absolute value of any element of $F\{S\}$ does not exceed $O(n_c)$ as $n_c \rightarrow \infty$.

Because the maximum absolute value of all elements of a matrix is a norm of the matrix under the conditions of the above lemma the norm of $F\{R_i(\zeta)[g_i - g_j(\zeta)][g_i - g_j(\zeta)]^T R_i^T(\zeta)\}$ does not exceed $O(n_c)$ as $n_c \rightarrow \infty$.

Theorem Given a stationary image $\{y(i, j) | (i, j) \in B\}$ the modified LS estimator defined by (14) is a consistent estimator if the conditions in the lemma are valid and (34) (found at the bottom of the page) is a positive definite matrix.

Proof For large value of n_c

$$R_i(\zeta) = n_c Q + \Theta(n_c) \quad (35)$$

where Q is defined by (34) and $\Theta(n_c) = R_i(\zeta) - n_c Q$ is a matrix satisfying the condition that

$$F\{\Theta^2(n_c)\} = O(n_c) \quad (36)$$

$$Q = \begin{bmatrix} JF\{x_i^T(i, j)x_i^T(i, j)\}J & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & F\{x_i^T(i, j)x_i^T(i, j)\} \end{bmatrix} \quad (34)$$

Therefore

$$\begin{aligned} & E\{R_p(G)[g_p - g_p(G)][g_p - g_p(G)]^T R_p^T(G)\} \\ &= E\{[n_G Q + \Theta(n_G)][g_p - g_p(G)][g_p - g_p(G)]^T [n_G Q + \Theta(n_G)]^T\} \\ &\simeq n_G^2 Q E\{[g_p - g_p(G)][g_p - g_p(G)]^T\} Q + O(n_G^{1/2}). \end{aligned} \quad (37)$$

The application of the lemma, which says $\|E\{R_p(G)[g_p - g_p(G)][g_p - g_p(G)]^T R_p^T(G)\}\|$ does not exceed $O(n_G)$ as $n_G \rightarrow \infty$, leads to

$$Q E\{[g_p - g_p(G)][g_p - g_p(G)]^T\} Q \rightarrow 0 \quad \text{as } n_G \rightarrow \infty \quad (38)$$

and thus the consistency of the estimate $g_p(G)$ follows because of the positive definiteness of Q .

IV. CONCLUDING REMARKS

In this note, we have proven analytically the consistency of the modified LS estimator recently introduced in [17], which can serve as a very important basis for choosing the best estimator. The conditions for the consistency are 2)–5). There have been some discussions on conditions 1)–3) in [17]. Condition 4) can be valid in practical applications where $\{y(i, j)\}$ is bounded, and therefore $\{e'(i, j)\}$ and $\{e''(i, j)\}$ are bounded. Condition 5) means $e'(i, j)$ and $e''(i, j)$ are uncorrelated with $y(k, l)$ far away from the point (i, j) , which is also very natural in real applications.

Extensive computer simulations with changing size data sample windows have been done. The results of the computer simulations show the following:

- 1) The mean square errors for the modified LS estimator decrease, and the modified LS parameter estimates converge to their corresponding true parameter values with the greatest rate when the sizes of the data sample windows increase.
- 2) The rate of decrease in the mean square error for the modified LS estimator is about seven times greater than that for the approximate ML.
- 3) The conventional LS estimator has the least rate of decrease in its mean square errors because, in this case, the conventional LS is not theoretically a consistent estimator.

The computer simulation methods and results are omitted from this note due to the space limitation, but they are available upon request.

A Robust Hybrid Stabilization Strategy for Equilibria

John Guckenheimer

Abstract—For an equilibrium of a general dynamical system, the domain of stability of a linear feedback controller is enlarged by the use of a general “hybrid” or “switching” strategy. The strategy is illustrated for numerical simulations of an inverted double pendulum on a cart.

I. INTRODUCTION

Linear control strategies provide a means for the stabilization of equilibria under general hypotheses. When applied to nonlinear systems, the effectiveness of these strategies depends upon the size of the domain of stability that is produced for the stabilized equilibrium. If this domain is small compared to the accuracy of the measurements or the size of disturbances within the system, then the linear controller is likely to fail within a short period. Failure of the system can be catastrophic, with the system wandering far from the desired equilibrium. We present here a general procedure to recapture stability of a linear controller when a trajectory leaves its region of stability. By using a hybrid strategy based upon discrete switching events within the state space of the plant, the system returns to the region of stability for the linear controller from a much larger domain. The control procedure is robust and remains effective under large classes of perturbations of the underlying system. We illustrate the effectiveness of our technique by applying it to the control of an inverted double pendulum.

The stabilization of unstable equilibria is a fundamental problem for the control of engineering systems. A sufficient condition for stability of an equilibrium point of a smooth dynamical system is that the eigenvalues of its linearization lie in the left-half plane. This is easily proved by several means, for example, by defining a quadratic Lyapunov function in a neighborhood of the equilibrium. Control theory addresses the questions of when stabilization is possible with the modifications (controller) that can be built into the underlying system (plant). Over the past 50 years, an extensive theory of “linear control” has developed comprehensive procedures for determining when the stabilization problem is solvable and for the design of controllers that implement stabilization. This theory is widely employed in engineering for the design of controllers in communication systems, chemical process control, avionics, etc. However, linear feedback control is not a complete panacea for all control problems, even ones of stabilizing equilibria when complete state-space information is available at all times. One difficulty that is encountered in some applications is that the domain of attraction of a controlled equilibrium may be small. This leads to unacceptable constraints on system performance. Small random disturbances in the environment or the inability of the actual physical system to implement its model idealization lead to failures of the controller. The results of the failure can be catastrophic in terms of the design objectives. For example, in the double pendulum example we describe below, the failure of a linear controller leads to large motions of the

pendulum, and in the presence of damping, the pendulum eventually falls to rest at its naturally stable hanging position.

The goal of this work is to provide a simple, effective means of recovery from the failure of a linear controller. We want to design a “safety net” around the (small) domain of attraction of a linear controller, so that if a disturbance moves a system outside this domain of attraction, it will be guided back into the domain by the application of a different control strategy. The strategy that we describe is very general. It can be applied to any system that meets conditions of controllability and accessibility. Moreover, the computations that are required for the design of a controller are based on the linearization of the system at its equilibrium, just as with linear controllers. Verification of the effectiveness of a particular design requires more extensive simulation, but the design guidelines are based upon accessible information.

The framework in which our control strategy is implemented has precursors in the literature [2], [3], [11], [12], [15]. The terms “switching” system, “variable structure” system, and “hybrid” system have all been used to describe piecewise smooth vector fields in the context of control, but there does not yet seem to be an effective, systematic theory of such systems. We shall use the terms switching system and hybrid system interchangeably. One of the essential aspects of our work is the presence of “hysteresis” in a piecewise smooth system: there is a discrete component of the state of the system used by the controller in addition to its location in the underlying state space of the physical system. We recall the description of hybrid systems that we have used previously [1] and adopt here.

The problem domain is a disjoint union of open, connected subsets of R^n , called charts. Each chart has associated with it a vector field. Inside each chart is a patch—an open subset with closure contained inside the patch. The patch boundaries are assumed piecewise smooth. The evolution of the system is implemented as a sequence of trajectory segments where the endpoint of one segment is connected to the initial point of the next by a transformation, although the transformations are trivial in the examples studied in this note. However, states of a system have both a continuous and discrete part, and switches that change the discrete part of the system state do occur. Time is divided into contiguous periods separated by instances where a state transformation is applied at times referred to as events.

We end this section with a few “philosophical” comments underlying our approach to nonlinear control. Structural stability is a useful concept for dynamical systems, stating that perturbations of a system remain equivalent to the reference system by continuous changes of coordinates. In implementing hybrid control for stabilizing equilibria, we have sought to maintain this type of robustness to perturbations of the system itself. Nothing in the controller should be subject to the choice of exact values of any parameters. In particular, we have avoided the use of sliding modes or switches that must be implemented exactly to be effective. To a large extent, this strategy involves trade-offs to attempts to achieve optimization of some cost function in the control because that is likely to push one to select parameter values in a system that are borderline for a property. If the property is one that involves the stability of the system, then small perturbations cannot be relied upon to maintain the efficacy of the controller. Here the emphasis is squarely upon reliability rather than efficiency. It is quite possible that modifications of the strategy described here will lead to improved performance by returning a system to the stability region of a linear controller more quickly.

II. BARRIERS TO UNBOUNDED MOTION

This section discusses a strategy for maintaining the motion of a trajectory in a bounded region of an unstable equilibrium point with a piecewise constant control. Consider the following linear system as a model example:

$$\begin{aligned}\dot{x}_1 &= \lambda_1(x_1 - c) \\ \dot{x}_2 &= \lambda_2(x_2 - c).\end{aligned}\quad (1)$$

In (1), c represents a "control" that moves the equilibrium point of the systems along a line. While we have chosen a particular form for this system, most planar vector fields with real eigenvalues can be transformed to this representation by a linear change of coordinates. Such a transformation to a "normal form" exists if the system is controllable. Necessary and sufficient conditions for this are that 1) the eigenvalues are distinct and 2) the control moves the equilibrium along a line that is not an eigendirection. We assume that $\lambda_1 > \lambda_2 > 0$, so that equilibrium point is a source.

The goal is to define a feedback control $c(x)$ so that the motion of the system remains within a moderate-sized bounded neighborhood of the origin. We approach this by defining a hybrid system with two patches that are half-planes H_+ and H_- defined by $y > x - c$, $y < x + c$, respectively. The boundaries of H_+ and H_- are the lines L_{\pm} defined by $y = x \mp c$. These lines are parallel to the control line. In each of the two patches, the control $c(x)$ takes a constant value c_{\pm} . The values of c are chosen with the object of making trajectories in the overlap strip $H_+ \cap H_-$ stay in a bounded region of the origin. This defines a hybrid system with parameters c_+ and c_- . The goal is now clear: to choose values of these parameters to create a trapping region surrounding the origin.

We can compute readily that the trajectories of the system (1) are defined by

$$\begin{aligned}x_1(t) &= c + \exp(t\lambda_1)(x_1(0) - c) \\ x_2(t) &= c + \exp(t\lambda_2)(x_2(0) - c).\end{aligned}$$

Given c , we would like to find c_{\pm} that creates a trapping region around the origin in the strip $-c \leq x_2 - x_1 < c$. Along a segment of the right boundary L_+ of the strip, we would like the vector field associated with H_+ to point to the left, toward the interior of the strip. Similarly, we would like the vector field associated with H_- to point to the right on a segment of the left boundary L_- of H_- . These segments are to be chosen so that the flow carries one into the other. See Fig. 1. To choose c_{\pm} with the desired properties, we argue as follows. For simplicity, we shall assume that $c_+ = -c_-$ so that the system has a symmetry. The symmetry streamlines the analysis, but is not essential to the argument that we give.

Regard the value of c as fixed for the moment. We shall determine the conditions we would like it to satisfy. Along L_+ , define the point p_+ to be the point where the vector field has slope 1. The point p_+ is obtained by solving the equations

$$\begin{aligned}x_2 &= x_1 - c \\ \lambda_1(x_1 - c) &= \lambda_2(x_2 - c)\end{aligned}$$

whose solution is

$$(x_1, x_2) = \left(c - \frac{\lambda_2}{\lambda_1 - \lambda_2}c, c - \frac{\lambda_1}{\lambda_1 - \lambda_2}c \right).$$

Above p_+ on L_+ , the vector field points to the right of L_+ . Below p_+ on L_+ , the vector field points to the left of L_+ . The trajectory starting at p_+ should lie above the trapping region in the strip. For example, we might want the intersection of the $x_2 - x_1$ axis with the strip to lie in the trapping region. For this to occur, it suffices that the trajectory with initial condition p_+ intersect the strip at a point

Fig. 1. The barriers L_{\pm} and region in which trajectories switch back and forth between the boundaries. The curves segments show trajectories, with arrows located where they encounter a patch boundary

TABLE 1

with a nonnegative value of x_1 . A lower bound for c_+ satisfying this criterion is given by the value of c for which the trajectory with initial condition p_+ passes through the point $(0, c)$. This yields an implicit equation for c/e in terms of the ratio $\lambda = \lambda_1/\lambda_2$

$$\frac{\left(\frac{c}{e}\right)^{\lambda_1}}{\left(\frac{c-c}{e}\right)^{\lambda_2}} = \frac{(\lambda_1 - \lambda_2)^{(\lambda_1 - \lambda_2)}(\lambda_2)^{\lambda_2}}{\lambda_1^{\lambda_1}}.$$

Representative values of the solution of this equation are given in Table I to three-digit accuracy. This discussion leads to the following theorem.

Theorem 2.1 Let c_+/c be larger than the solution of the equation

$$\frac{\left(\frac{c}{e}\right)^{\lambda_1}}{\left(\frac{c-c}{e}\right)^{\lambda_2}} = \frac{(\lambda_1 - \lambda_2)^{(\lambda_1 - \lambda_2)}(\lambda_2)^{\lambda_2}}{\lambda_1^{\lambda_1}}$$

and set $c_- = -c_+$. Denote by W_{\pm} the trajectories of the vector fields X_{\pm} defined by

$$\begin{aligned}\dot{x}_1 &= \lambda_1(x_1 - c_{\pm}) \\ \dot{x}_2 &= \lambda_2(x_2 - c_{\pm})\end{aligned}$$

passing through the points $(0, \pm c)$. Assume $\lambda_2 < \lambda_1$. On the lines l_{\pm} defined by $x_2 = x_1 \mp c$, consider the segment s_{\pm} with endpoints at $(0, \mp c)$ and the intersections of W_{\pm} with l_{\pm} . Then trajectories of X_+ with initial conditions on l_+ intersect l_- , and trajectories of X_- with initial conditions on l_- intersect l_+ .

To prove this theorem, we still need to verify that the trajectory of X_- with initial condition at $(0, c)$ intersects the segment s_+ . From X_- , we obtain the equation

$$\frac{dx_2}{dx_1} = \frac{\lambda_2(x_2 + c)}{\lambda_1(x_1 + c)} \quad (2)$$

Equation (2) gives the trajectory of X_- with initial condition $(0, c)$ in a form parameterized by x_1 :

$$\left(x_1, -c + (c + \epsilon)\left(1 + \frac{x_1}{c}\right)^\lambda\right)$$

with $\lambda = \lambda_2/\lambda_1$. Similarly, the trajectory of X_+ with initial condition $(0, c)$ is given by

$$\left(x_1, c + (c - \epsilon)\left(1 - \frac{x_1}{c}\right)^\lambda\right).$$

These two trajectories intersect at one point in the right-half plane if the trajectory of X_- passes below the point (c, c) . Setting $u = x_1/c$ and $b = c/\epsilon$, we want to determine when

$$-1 + (1 + b)(1 + u)^\lambda = 1 - (1 - b)(1 - u)^\lambda.$$

This equation is readily solved for b in terms of u

$$b = \frac{2 - (1 - u)^\lambda - (1 + u)^\lambda}{(1 + u)^\lambda - (1 - u)^\lambda}.$$

At the solution to this equation, we want to have $-1 + (1 + b)(1 + u)^\lambda - u + b > 0$, so that the intersection point of the two trajectories lies above the line l_+ . This yields the requirement that

$$b > \frac{(1 + u) - (1 + u)^\lambda}{(1 + u) - (1 + u)^\lambda}.$$

Substituting the value for b at the intersection point into this inequality and simplifying leads to the requirement that

$$2 - u(1 + u)^\lambda + u(1 - u)^\lambda - 2(1 - u^2) > 0.$$

This inequality holds throughout the unit square in the (u, l) plane, which is the domain of interest. We conclude that the intersection of the trajectories of X_+ and X_- with common initial point $(0, c)$ lies above the line l_+ since we assumed $\lambda < 1$.

Recall that our hybrid system X applies a mode switch from X_- to X_+ when a trajectory hits l_+ from the left and, similarly, a mode switch from X_+ to X_- when a trajectory hits l_- from the right. The theorem implies the following corollary.

Corollary 2.1: With the notations introduced above, define R to be the region bounded by W_\pm , the trajectories of X_\pm with initial conditions at $(0, \mp c)$ and s_\pm . Then trajectories with initial conditions in R remain in R for all forward time.

Less formally, we say that R is a trapping region for the hybrid system X . We can say more still about the dynamics of X in R . There are passage maps θ_+ that map trajectories with initial conditions on s_\pm to their intersections with s_+ . The maps θ_\pm are monotone, so the composition $\theta_- \circ \theta_+$ is a monotone map of the interval s_+ into itself. It follows that this return map has a stable fixed point, representing a stable periodic orbit for the hybrid system. Additional computations lead to the conclusion that the return map is a contraction and has only a single fixed point. To carry forward these computations, we use the coordinates which scale c to 1, writing $u = x_1/c$ and $b = c/\epsilon$ as in the proof of the theorem. The trajectory starting on the line l_- with initial value $u = u_0$ is given by

$$\left(u_0, -1 + (1 + b + u_0)\left(\frac{1 + u}{1 + u_0}\right)^\lambda\right).$$

The intersection of the trajectory occurs at a value of $u = u_1$ satisfying

$$-1 + (1 + b + u_0)\left(\frac{1 + u}{1 + u_0}\right)^\lambda - u_1 + b = 0.$$

We want to estimate du_1/du_0 from this equation. From the equation

$$\frac{(1 + u_0)^\lambda}{1 + u_0 + b} = \frac{(1 + u_1)^\lambda}{1 + u_1 - b}$$

we deduce that $du_1/du_0 < 1$. The right-hand side of the last equation defines a function of u_1 which intersects the function of u_0 on the left-hand side crossing from above to below while decreasing. Therefore implicitly differentiating the last equation gives $du_1/du_0 < 1$. From this, we conclude that the return map of our hybrid system has derivative smaller than 1 and is a contraction.

Theorem 2.2: With the same hypotheses of the previous theorem and corollary, there is a stable limit cycle for the hybrid system that is globally attracting for all initial conditions in the trapping region R .

Remarks:

1) Due to the symmetry of the hybrid system, the stable limit cycle is symmetric with respect to the origin.

2) In systems with equilibria that are saddle points with two-dimensional unstable manifolds, the procedure described above can be applied with switching surfaces that are hyperplanes tangent to the directions spanned by the stable manifold of the equilibrium and the tangent to the control curve. We have not investigated systems with unstable manifolds of dimension larger than two, but the strategy might work there as well. In that case, one can try to use switching surfaces that are tangent to the directions spanned by the tangent to the control curve and all but the largest two eigendirections.

III. MULTIPLE BARRIERS

The results of the previous section can be extended and improved in a number of ways. We describe two.

The barriers described in the previous section can be combined with linear controllers. If one knows a region around the equilibrium that lies in the domain for a linear controller, then one can define a hybrid system with three patches: the system described in the previous section, and a domain cut from these two patches in which the linear controller will be applied. If the stable limit cycle of the switching system intersects the domain in which the linear controller is applied, then the barriers and switching system serve to guide the system to the domain of the linear controller from initial conditions between the two barriers. To prevent the system from exiting the domain of the linear controller, distinct boundaries can be defined to switch the linear controller on and off.

The second extension of the controller described in the previous section is to place multiple barriers in the system parallel to one another. Consider, for example, a planar system with six barriers that are parallel lines l_i , $i = 1, \dots, 6$. The lines l_i divide the plane into seven closed "strips" S_i , $i = 1, \dots, 7$. S_1 and S_7 are half-planes. From the S_i , we form six overlapping patches $D_i = S_i \cup S_{i+1}$. In each of these patches, define a constant control that increases in magnitude as one moves away from the control line. The transition conditions are defined so that if one crosses a patch boundary moving away from the control line, then the control setting of larger magnitude is applied. If one crosses a patch boundary moving toward the control line, then the control value changes to one of smaller magnitude. The effect of these barriers is to guide a trajectory back toward the origin from farther away from the origin, while at the same time decreasing the amplitude of the control when feasible. Combining these multiple barriers with a linear controller in a neighborhood of the origin allows one to recover from disturbances of large size that move the system outside the region of stability for the linear controller. See Fig. 2 for an illustration of the patches

Fig. 2. The geometry of the state space for the system with three sets of barriers and a region in which linear feedback control is used.

associated with a system that has three pairs of barriers and a domain where the linear controller will be applied.

IV. AN EXAMPLE: THE DOUBLE PENDULUM ON A CART

We describe an example—a frictionless double pendulum on a zero mass cart whose acceleration along a track can be controlled. The object is to keep the pendulum in the fully upright position. The control of a pendulum on a cart has been a frequently studied problem [4]–[10], [13], [14]. This example provides a good illustration of the effectiveness of our stabilization strategy on a nonlinear system.

The double pendulum consists of two point masses m_1 and m_2 with body 1 attached to a fulcrum and body 1 attached to body 2 by massless rigid rods of lengths l_1 and l_2 . We want to include within the system of equations the additional effect of applying a horizontal acceleration. See Fig. 3. Choose units for which the acceleration of gravity is 1, let the magnitude of the acceleration be α , and set $\mu = 1 + m_1/m_2$. Then the equations of motion are given by the following vector field X as shown in the equation at the bottom of the page. Here, q_1, q_2 are angular coordinates and p_1, p_2 are the conjugate momenta. The angles q_1, q_2 are measured with respect to vertical rays pointing down, so the stable equilibrium with the pendulum hanging down is given by $q_1 = q_2 = p_1 = p_2 = 0$. The vertically upright position that we want to stabilize is given by $q_1 = q_2 = \pi$ and $p_1 = p_2 = 0$.

Fig. 3. A double pendulum on a cart.

The vertically upright position is an equilibrium of the pendulum equations (without horizontal acceleration) that has a two-dimensional stable manifold and a two-dimensional unstable manifold. Therefore, we are in a situation for which the theory described earlier can be applied. To do so, we need to construct a linear controller, a region in which the linear controller will be applied, barriers parallel to the hyperplanes spanned by the control line and the stable manifold at the vertical equilibrium, and control values for each of the patches to be used by the controller outside the patch of the linear controller.

The linear controller is defined by making the acceleration of the pendulum fulcrum a linear function of the location of the pendulum in phase space. For convenience, we shall use coordinates $(-\sin(q_1), -\sin(q_2), p_1, p_2)$ near the upright equilibrium. We seek a vector $\gamma = (g_1, g_2, q_1, q_2)$ so that setting $\alpha = g_1 q_1 + g_2 q_2 + g_1 p_1 + g_2 p_2$ makes the upright equilibrium stable. Controllability of the system linearized at the upright equilibrium implies that we can find γ to place the eigenvalues of the linearly controlled system anywhere in the complex plane. We describe one approach to solving this problem. Treating the eigenvalues of the linearization as functions of the control coefficients g_i gives a system of equations that can be solved for the g_i . Let $\lambda_i, i = 1 \dots 4$ be the desired eigenvalues for the controlled system. Denoting the Jacobian matrix of the vector field by A and $v = \partial A / \partial \alpha$, we seek vectors $u_i \neq 0$ and γ so that

$$(A + \gamma \cdot v^T)u_i = \lambda_i u_i.$$

If $A + \lambda_i I$ is invertible, rewrite this equation as

$$-\gamma(u_i)(A - \lambda_i I)^{-1}v = u_i.$$

It follows that u_i is a multiple of $(A - \lambda_i I)^{-1}v$ and

$$\gamma((A - \lambda_i I)^{-1}v) = -1.$$

As i varies in $\{1, 2, 3, 4\}$, this yields a system of linear equations for γ . If the system is nonsingular, then it uniquely determines γ in terms of the eigenvalues λ_i .

We have investigated a numerical example with parameters $l_1 = 1/2, l_2 = 3/4, m_1 = 2, m_2 = 1$, and

$$\begin{aligned} \dot{q}_1 &= p_1 \\ \dot{q}_2 &= p_2 \\ \dot{p}_1 &= \frac{\sin(q_2) \cos(q_1 - q_2) - \mu \sin(q_1) - (l_2 p_2^2 + l_1 p_1^2 \cos(q_1 - q_2)) \sin(q_1 - q_2)}{l_1(\mu - \cos^2(q_1 - q_2))} \\ &\quad + \frac{\alpha(-\mu \cos(q_1) + \cos(q_2) \cos(q_1 - q_2))}{l_1(\mu - \cos^2(q_1 - q_2))} \\ \dot{p}_2 &= \frac{\mu(\sin(q_1) \cos(q_1 - q_2) - \sin(q_2)) + (\mu l_1 p_1^2 + l_2 p_2^2 \cos(q_1 - q_2)) \sin(q_1 - q_2)}{l_2(\mu - \cos^2(q_1 - q_2))} \\ &\quad + \frac{\alpha(-\mu \cos(q_2) + \mu \cos(q_1) \cos(q_1 - q_2))}{l_2(\mu - \cos^2(q_1 - q_2))}. \end{aligned}$$

Fig 4 Continued

Fig 4 A typical hybrid trajectory converging to the upright position with magnifications showing increasing detail near the equilibrium position. The initial point of the trajectory is (2.5 3.6) near the left side of (a).

$\{\lambda_1 \lambda_2 \lambda_3 \lambda_4\} = \{-0.1 -0.5 -0.6 -0.7\}$ This gives (exactly) $\gamma = (-3.395 \ 2.416 \ -1.1 \ 1.2595)$. Using these parameter values, we investigated numerically a model of the double pendulum with the hybrid switching control strategy described in the last section. The only modification of the strategy was to define two neighborhoods of the vertical pendulum on which switches to and from the linear controller were applied. This was done because many of the linearly controlled trajectories do not approach the equilibrium with monotonically decreasing distance.

To test the effectiveness of this controller, trajectories were computed on a grid of initial conditions in the plane $p_1 = p_2 = 0$. The domain of stability of the linear controller in this plane contains

a small elongated region around the equilibrium diagonal $q_1 = q_2$ whose length along the diagonal is approximately 0.5 and whose width is approximately 0.07. For the switching system we used level sets of the function $h = (q_1 - \pi)/4 - (q_2 - \pi)/4 + p_1/12 - p_2/6$ as the switching surfaces. The function h was computed so that it is parallel to the hyperplane spanned by the control direction $(0 \ 0 \ 2 \ 0)$ and the stable eigenvalue at the fully upright equilibrium. With switching surfaces given by $h = -0.5$, $h = -0.3$, $h = -0.1$, $h = 0.1$, $h = 0.3$ and $h = 0.5$ with corresponding values for α of $0.3 \ 1 \ -1 \ 3 \ 0$ there is a much larger domain of attraction for the upright pendulum. In the plane $p_1 = p_2 = 0$ it appears that the square with vertices at the points $(q_1 \ q_2) = (2 \ 2.5)$ and $(q_1 \ q_2) = (3.7 \ 3.7)$ is completely contained in the domain of attraction for the upright pendulum. See Fig 4(a) for a projection of a typically trajectory into the plane $p_1 = p_2 = 0$. Fig 4(b) and (c) shows magnifications of this trajectory close to the upright equilibrium. The width of this square is an order of magnitude larger than the width of the domain of stability for the linear controller in the plane $p_1 = p_2 = 0$. If the linear controller is not used then the asymptotic state is the limit cycle described in the first section. Switching to and from the linear controller when the square of the distance to the upright equilibrium is 0.002 and 0.005 respectively appears to robustly stabilize the pendulum at the precise upright state. Note that $0.005 \approx (0.07)^2$ so that the disk for switching the linear controller off could not be chosen smaller and still remain in the basin of attraction of the vertical equilibrium for the linear controller. Addition of stochastic perturbations to the vector field does not appear to significantly diminish the size of the domain of attraction for the upright equilibrium.

As illustrated by this example the hybrid or switching strategy that we have presented for the stabilization of equilibria appears to be robust. All aspects of the strategy seem to be structurally stable and persistent with respect to very general types of perturbations. It augments linear control for stabilizing equilibria by guiding a trajectory back into the domain of attraction for a linear controller from a much larger region.

ACKNOWLEDGMENT

A. Back has helped with the computing and has invested long hours in developing the "hybrid" version of the program DsTool that was used in our numerical investigations. I would like to thank D. Koditschek for bringing to my attention both the need for universal "nonlinear" control strategies and the apparent effectiveness of strategies based upon discrete events. D. Delchamps has been patient and persistent in guiding me toward control theory literature that bears upon the techniques described in this note. S. Johnson has made helpful comments.

Adaptive Control of Systems with Unknown Output Backlash

Gang Tao and Petar V. Kokotović

Abstract—Adaptive control schemes for systems with unknown backlash at the plant output are developed. In the case of known backlash, a backlash inverse controller guarantees exact output tracking. When the backlash characteristics are unknown, adaptive laws are designed to update the controller parameters and to guarantee bounded input-output stability. Simulations show significant improvements of the system performance achieved by such adaptive backlash inverse controllers.

I. INTRODUCTION

Backlash is common in many components of control systems, such as actuators, sensors, and mechanical connections. A typical backlash example is the mechanical motion due to the imperfect contact of two gears. From the early days of classical control theory, the backlash nonlinearity has been recognized as one of the factors severely limiting the performance of feedback systems by causing delays, oscillations, and inaccuracy.

The backlash characteristic is a nondifferentiable nonlinearity which is often poorly known. Therefore, the control of systems with unknown backlash is an open theoretical problem of major relevance to applications. In [1] and [2], we proposed an adaptive control scheme for systems with unknown backlash at input of the plant, that is, in the actuator. In this note, we address the problem with unknown backlash at the plant output, that is, in the sensor, as shown in Fig. 1. Perhaps the most common example is a position servo: the block $G(D)$ represents the power amplifier motor, and the backlash is in the position sensor such as a potentiometer connected to the motor shaft through a gear box.

A contribution of this note is the construction of new adaptive controller structures for the output backlash problem which is essentially different from the actuator backlash problem. Our new controller structures can be initialized to achieve exact output matching when the plant is known. They lead to a linear parameterization of the closed-loop plant when the backlash is unknown. Such a linear parameterization is crucial for the development of an adaptive scheme to deal with the unknown backlash. Our approach is to develop an adaptive backlash inverse to cancel the unknown backlash effect. A feedback-feedforward controller structure is then combined with such an adaptive backlash inverse to achieve the desired tracking performance.

The note is organized as follows. In Section II, we present the model of the backlash at the output of a linear part and formulate the control problem. In Section III, assuming that the backlash is known, we present a backlash inverse and introduce the idea of backlash inverse control. In Section IV, we develop two adaptive backlash inverse controller structures when the backlash is unknown: one for the linear part known, and the other for the linear part unknown.

Fig. 1. Plant with output backlash.

We design adaptive laws to update the controller parameters, which ensure closed-loop signal boundedness. In Section V, we present two design examples and use simulation results to show major performance improvements achieved with our adaptive backlash inverse controllers.

II. PROBLEM STATEMENT

Let us consider the following discrete-time plant with a linear part $G(D)$ and a backlash nonlinearity $B(\cdot)$ at its output, as shown in Fig. 1:

$$y(t) = B(z(t)), \quad z(t) = G(D)[u](t) \quad (2.1)$$

where $u(t)$ is the control input, $y(t)$ is the measured output, $G(D) = k_p \frac{Z(D)}{P(D)}$, k_p is a constant, $Z(D)$ and $P(D)$ are monic polynomials, and the symbol D is used to denote, as the case may be, the z -transform variable or the advance operator: $D[x](t) = x(t+1)$.

The backlash characteristic $B(\cdot)$ with input $z(t)$ and output $y(t)$ is described by

$$y(t) = \begin{cases} m(z(t) - c_l) & \text{for } z(t) \leq z_l \\ m(z(t) - c_r) & \text{for } z(t) \geq z_r \\ y(t-1) & \text{for } z_l < z(t) < z_r \end{cases} \quad (2.2)$$

where $m > 0$, c_r, c_l are constant and $z_l = \frac{y(t-1)}{m} + c_l$, $z_r = \frac{y(t-1)}{m} + c_r$ are the z -axis values of the intersections of the two parallel lines of slope m with the horizontal inner segment containing $y(t-1)$. This backlash model is the discrete-time counterpart of the continuous-time backlash characteristic modeled in [1] and [2].

In our control problems, the backlash parameters m, c_r, c_l are unknown, and the internal signal $z(t)$ is not available for measurement. The control objective is to design a feedback control for the plant (2.1), which stabilizes the closed-loop system and makes the plant output $y(t)$ track a given bounded reference signal $y_m(t)$.

We will consider two designs: one for the plant with a known linear part $G(D)$ and the other for an unknown $G(D)$. We will use the model reference control strategy and therefore make the following assumptions: 1) $G(D)$ is minimum phase; 2) the relative degree n^* of $G(D)$ is known; 3) the degree n of $P(D)$ is known; 4) the sign of k_p is known; 5) $\frac{1}{m} \geq m_0$ for some known constant $m_0 \geq 0$, $c_r \geq 0$, $c_l \leq 0$. Assumption 5) will be used to project the estimate of $\frac{1}{m}$ away from zero. Without loss of generality, in view of 4) and 5), we further assume that $k_p = 1$.

Our approach will be to estimate the backlash parameters m, c_r, c_l so that an adaptive backlash inverse can be implemented to cancel the backlash effects. With such an adaptive backlash inverse, a linear controller structure will be designed to generate the control signal $u(t)$ to achieve the control objective.

III. NONADAPTIVE BACKLASH INVERSE CONTROLLERS

In this section, we introduce the idea of backlash inverse control and develop a backlash inverse control scheme when both the linear part $G(D)$ and the backlash $B(\cdot)$ are known.

Fig. 2. Backlash inverse: (a) block diagram; (b) characteristic

A Backlash Inverse Control

A graphical inverse of the backlash characteristic in Fig. 1 is shown in Fig. 2, which contains vertical jumps. This backlash inverse will be described with the help of the indicator function $\chi[X]$ of the event X :

$$\chi[X] = \begin{cases} 1 & \text{if } X \text{ is true} \\ 0 & \text{otherwise.} \end{cases}$$

To characterize the upward and downward changes of the reference signal $y_m(t)$, we define

$$\chi_{im}(t) = \chi[y_m(t) > y_m(t-1)] \quad \text{or } y_m(t) = y_m(t-1), \chi_{im}(t-1) = 1] \quad (3.1)$$

$$\chi_{lm}(t) = \chi[y_m(t) < y_m(t-1)] \quad \text{or } y_m(t) = y_m(t-1), \chi_{lm}(t-1) = 1] \quad (3.2)$$

and require that $\chi_{im}(t)$ and $\chi_{lm}(t)$ be initialized as $\chi_{im}(t_0) + \chi_{lm}(t_0) = 1$, $\chi_{im}(t_0)\chi_{lm}(t_0) = 0$. A consequence of this definition is that $\chi_{im}(t) + \chi_{lm}(t) = 1$ and $\chi_{im}(t)\chi_{lm}(t) = 0$ for any $t \geq t_0$.

The output of the backlash inverse in Fig. 2 is

$$z_m(t) = \frac{y_m(t)}{m} + \chi_{im}(t)c_r + \chi_{lm}(t)c_l. \quad (3.3)$$

The mapping $BI(\cdot): y_m(t) \rightarrow z_m(t)$ defines a backlash inverse [1]

$$B(BI(y_m(\tau))) = y_m(\tau) \Rightarrow B(BI(y_m(t))) = y_m(t), \quad \forall t \geq \tau.$$

To introduce the idea of an output matching control law with a backlash inverse, we first consider the simplest case when $G(D)$ in Fig. 1 is an n^* -step delay, that is, $z(t+n^*) = u(t)$.

Proposition 3.1 [3]: Suppose that $G(D) = D^{-n^*}$. Then the control law $u(t) = z_m(t+n^*)$, $t \geq t_0$, guarantees that $y(t+n^*) = y_m(t+n^*)$ for any $t \geq t_0$, provided that $y_m(t_0+n^*) = y(t_0+n^*)$.

In this proposition, the condition that $y_m(t_0+n^*) = y(t_0+n^*)$ is used to initialize the backlash inverse controller for output matching, which can be practically achieved by redefining the initial value of $y_m(t)$. For this simple $G(D)$ and with the backlash characteristic known, the measurement of $z(t)$ is not required.

Next we consider $G(D)$ of a general form with known backlash $B(\cdot)$, but we now assume that the signal $z(t)$ is available for measurement. This unrealistic assumption is made only to help us introduce a nonadaptive controller whose structure will be of interest in our adaptive designs in which this assumption will be dropped.

Using the notation

$$\omega_a(t) = a(D)[u](t), \quad a(D) = (D^{-n^*+1}, \dots, D^{-1})^T$$

$$\omega_b(t) = b(D)[z](t), \quad b(D) = (D^{-n^*+1}, \dots, D^{-1}, 1)^T$$

we choose the parameters $\theta_u^* \in R^{n-1}$ and $\theta_z^* \in R^n$ to satisfy the matching equation

$$\theta_u^{*T} a(D)P(D) + \theta_z^{*T} b(D)Z(D) = P(D) - Z(D)D^{n^*} \quad (3.4)$$

and define our nonadaptive controller as

$$u(t) = \theta_u^{*T} \omega_u(t) + \theta_z^{*T} \omega_z(t) + z_m(t + n^*), \quad t \geq t_0. \quad (3.5)$$

Proposition 3.2 [3]: The control law (3.5) guarantees that $z(t + n^*) = z_m(t + n^*)$ for any $t \geq t_0$. Moreover, $y(t + n^*) = y_m(t + n^*)$ for any $t > t_0$, provided that $y_m(t_0 + n^*) = y(t_0 + n^*)$.

Our designs in subsequent sections will avoid the unrealistic assumption that the signal $z(t)$ is available for measurement by replacing the term $\theta_z^{*T} \omega_z(t)$ in (3.5) with terms implementable without the knowledge of $z(t)$.

B. A Backlash Inverse Controller for $G(D)$ and $B(\cdot)$ Known

To develop a controller structure which uses only the measured plant output $y(t)$, we define

$$\lambda_+(t) = \lambda[y(t) > y(t-1) \text{ or } y(t) = y(t-1), \lambda_+(t-1) = 1] \quad (3.6)$$

$$\lambda_-(t) = \lambda[y(t) < y(t-1) \text{ or } y(t) = y(t-1), \lambda_-(t-1) = 1] \quad (3.7)$$

$$\lambda_0(t) = \lambda[y(t) = y(t-1)]. \quad (3.8)$$

Similarly, in (3.6) and (3.7), $\lambda_+(t)$ and $\lambda_-(t)$ are initialized as $\lambda_+(t_0) + \lambda_-(t_0) = 1$, $\lambda_+(t_0)\lambda_-(t_0) = 0$ so that $\lambda_+(t) + \lambda_-(t) = 1$ and $\lambda_+(t)\lambda_-(t) = 0$ for any $t \geq t_0$.

Using (2.2), (3.6)–(3.8), we then express the internal signal $z(t)$ as

$$z(t) = \frac{y(t)}{m} + \lambda_+(t)c_+ + \lambda_-(t)c_- + \lambda_0(t)d_0(t) \quad (3.9)$$

where $d_0(t) \in [c_+, c_-]$ is bounded. The term $\lambda_0(t)d_0(t)$ is the part of the signal $z(t)$ which, due to the backlash characteristic, is unobservable from the output $y(t)$. In general, $\lambda_0(t)d_0(t)$ may be nonzero even if the backlash $B(\cdot)$ is known.

Since $z(t)$ is not available, we choose its estimate to be

$$\hat{z}(t) = \frac{y(t)}{m} + \lambda_+(t)c_+ + \lambda_-(t)c_- \quad (3.10)$$

so that the estimation error is $z(t) - \hat{z}(t) = \lambda_0(t)d_0(t)$.

Hence, when the linear part $G(D)$ and the backlash $B(\cdot)$ are known, but the signal $z(t)$ is not available for measurement, the controller (3.5) is modified as

$$u(t) = \theta_u^{*T} \omega_u(t) + \theta_z^{*T} \omega_z(t) + z_m(t + n^*), \quad t \geq t_0 \quad (3.11)$$

where $\omega_z(t) = b(D)[\hat{z}](t)$. Now, despite the estimation error $z(t) - \hat{z}(t) = \lambda_0(t)d_0(t)$, this controller can ensure the exact tracking $e(t) = y(t) - y_m(t) = 0$.

Lemma 3.1 [3]: The controller (3.11) achieves the exact tracking, that is, $y(t + n^*) = y_m(t + n^*)$, for any $t > t_0$, provided that $\hat{z}(\tau) = z(\tau)$ for $\tau = t_0 - n + 1, t_0 - n + 2, \dots, t_0 - 1, t_0, t_0 + 1, \dots, t_0 + n^* - 1, t_0 + n^*$, and $y_m(t_0 + n^*) = y(t_0 + n^*)$.

For the controller (3.11), the initialization for output matching is achieved through the condition: $\hat{z}(\tau) = z(\tau)$ for $\tau = t_0 - n + 1, \dots, t_0 + n^*$, and $y_m(t_0 + n^*) = y(t_0 + n^*)$, where $\hat{z}(t_0 + n^*) = z(t_0 + n^*)$ initializes the backlash inverse mapping: $y(t) \rightarrow \hat{z}(t)$. The condition $\hat{z}(\tau) = z(\tau)$ is satisfied if the motion of $z(\tau)$ does not stay inside the backlash. Since the backlash region characterized by c_+ and c_- is finite, a proper initial excitation of the system can always keep $z(\tau)$ outside of the backlash region.

IV. ADAPTIVE CONTROL FOR UNKNOWN BACKLASH

In this section we propose two adaptive backlash inverse controllers: one for the design with $G(D)$ known, and the other for the design with $G(D)$ unknown. In both designs, the backlash $B(\cdot)$ is unknown and the signal $z(t)$ is not available for measurement.

A. Design for $B(\cdot)$ Unknown and $G(D)$ Known

With $z_m(t)$, $\hat{z}(t)$ defined in (3.3), (3.10), introducing $\theta_m^* = \frac{1}{m}$, $\theta_{c_+}^* = c_+$, $\theta_{c_-}^* = c_-$ and $\omega_y(t) = b(D)[y](t)$, $\omega_+(t) = b(D)[\lambda_+](t)$, $\omega_-(t) = b(D)[\lambda_-](t)$, $\omega_m(t) = \theta_m^{*T} \omega_y(t) + y_m(t + n^*)$, $\omega_{+,m}(t) = \theta_{c_+}^{*T} \omega_+(t) + \lambda_{+,m}(t + n^*)$, $\omega_{-,m}(t) = \theta_{c_-}^{*T} \omega_-(t) + \lambda_{-,m}(t + n^*)$, we express the controller (3.11) as

$$u(t) = \theta_u^{*T} \omega_u(t) + \theta_m^* \omega_m(t) + \theta_{+,m}^* \omega_{+,m}(t) + \theta_{-,m}^* \omega_{-,m}(t). \quad (4.1)$$

We then proceed to use the adaptive version of (4.1) for θ_m^* , $\theta_{c_+}^*$, $\theta_{c_-}^*$ unknown:

$$\hat{u}(t) = \hat{\theta}_u^{*T} \omega_u(t) + \hat{\theta}_m^* \omega_m(t) + \hat{\theta}_{+,m}^* \omega_{+,m}(t) + \hat{\theta}_{-,m}^* \omega_{-,m}(t) \quad (4.2)$$

in which only the estimates $\hat{\theta}_m(t)$, $\hat{\theta}_{c_+}(t)$, $\hat{\theta}_{c_-}(t)$ of θ_m^* , $\theta_{c_+}^*$, $\theta_{c_-}^*$ are updated, because, with $G(D)$ known, we can solve θ_u^* and θ_z^* from (3.4).

To develop an adaptive law for updating the estimates $\hat{\theta}_m(t)$, $\hat{\theta}_{c_+}(t)$, $\hat{\theta}_{c_-}(t)$, dividing both sides of (3.4) by $P(D)$ and operating the resulting identity on $u(t)$, we obtain

$$u(t) = \theta_u^{*T} \omega_u(t) + \theta_z^{*T} \omega_z(t) + z(t + n^*). \quad (4.3)$$

Defining the parameter and regressor vectors as $\theta_b^* = (\theta_m^*, \theta_{c_+}^*, \theta_{c_-}^*)^T$, $\omega_b(t) = (\theta^{*T} \omega_y(t) + y(t + n^*), \theta_{c_+}^{*T} \omega_+(t) + \lambda_{+,m}(t + n^*), \theta_{c_-}^{*T} \omega_-(t) + \lambda_{-,m}(t + n^*))^T$, and using (3.9), we express $u(t)$ in (4.3) as

$$u(t) = \theta_b^{*T} \omega_b(t) + d_1(t + n^*) \quad (4.4)$$

where θ_b^* is the unknown parameter vector, and $d_1(t + n^*) = d_0(t + n^*)\lambda_0(t + n^*) + \theta_z^{*T} b(D)[d_0 \lambda_0](t)$ is the bounded disturbance representing the unobservable part of the backlash input $z(t)$.

With the estimate $\hat{\theta}_b(t)$ of θ_b^* , we use (4.4) to define the estimation error

$$\epsilon_b(t) = \hat{\theta}_b^{*T} \omega_b(t - n^*) + \hat{\theta}_b^T(t - 1) \omega_b(t - n^*) - u(t - n^*).$$

We then choose the adaptive update law for $\hat{\theta}_b(t)$

$$\hat{\theta}_b(t) = \hat{\theta}_b(t - 1) - \frac{\gamma_b \omega_b(t - n^*) \epsilon_b(t)}{1 + \omega_b^T(t - n^*) \omega_b(t - n^*) + \delta^2(t)} + f_b(t) \quad (4.5)$$

where $0 < \gamma_b < 1$, $\delta(t) = (\hat{\theta}_b(t - 1) - \hat{\theta}_b(t - n^*))^T \omega_b(t - n^*)$. To achieve robustness of the parameter adaptation with respect to the bounded disturbance $d_1(t)$, the design signal $f_b(t)$ is to be chosen as one of the existing robustifying modifications [4]–[6]. For example, the switching σ -modification of [5] generates $f_b(t)$ as $f_b(t) = -\sigma(\hat{\theta}_b(t - 1), \sigma_0, M_b) \hat{\theta}_b(t - 1)$, where

$$\sigma(\hat{\theta}_b(t - 1), \sigma_0, M_b) = \begin{cases} \sigma_0 & \text{for } \|\hat{\theta}_b(t - 1)\|_2 > 2M_b \\ 0 & \text{otherwise} \end{cases}$$

with $0 < \sigma_0 < \frac{1-\gamma_b}{2}$. Although not shown in (4.5), with the assumption 5) we use projection to ensure that $\hat{\theta}_m(t) \geq m_0$, $\hat{\theta}_{c_+}(t) \geq 0$ and $\hat{\theta}_{c_-}(t) \leq 0$.

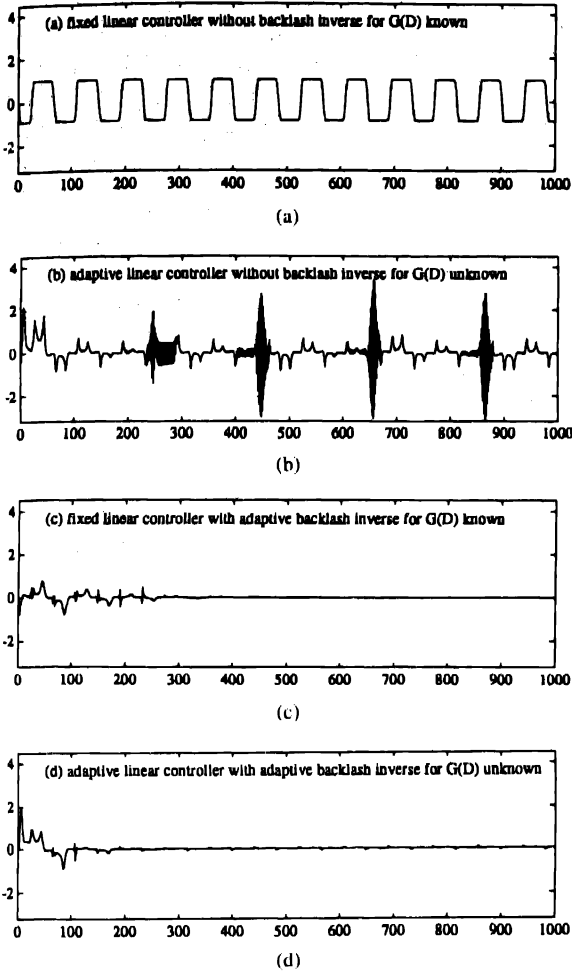

Fig. 3. Tracking errors with different control schemes.

B. Design for $B(\cdot)$ and $G(D)$ Unknown

To develop an adaptive controller structure when both the linear part $G(D)$ and the backlash $B(\cdot)$ are unknown, we define $\theta_y^* = \frac{1}{m}\theta_z^*$, $\theta_r^* = c_r\theta_z^*$, $\theta_l^* = c_l\theta_z^*$, and express (3.11) as

$$u(t) = \theta_u^{*T} \omega_u(t) + \theta_y^{*T} \omega_y(t) + \theta_r^{*T} \omega_r(t) + \theta_l^{*T} \omega_l(t) + \theta_m^* y_m(t+n^*) + \theta_{cr}^* \chi_{rm}(t+n^*) + \theta_{cl}^* \chi_{lm}(t+n^*). \quad (4.6)$$

Since the parameters θ_u^* , θ_y^* , θ_r^* , θ_l^* , θ_m^* , θ_{cr}^* , θ_{cl}^* are unknown, we use their estimates $\theta_u(t)$, $\theta_y(t)$, $\theta_r(t)$, $\theta_l(t)$, $\theta_m(t)$, $\theta_{cr}(t)$, $\theta_{cl}(t)$ to implement the adaptive version of (4.6):

$$u(t) = \theta_u^T(t) \omega_u(t) + \theta_y^T(t) \omega_y(t) + \theta_r^T(t) \omega_r(t) + \theta_l^T(t) \omega_l(t) + \theta_m(t) y_m(t+n^*) + \theta_{cr}(t) \chi_{rm}(t+n^*) + \theta_{cl}(t) \chi_{lm}(t+n^*). \quad (4.7)$$

In this case, we need to update not only the adaptive backlash but also the feedforward and feedback parts of the controller structure (4.7). To develop such an adaptive update law, we introduce $\theta^* = (\theta_u^{*T}, \theta_y^{*T}, \theta_r^{*T}, \theta_l^{*T}, \theta_m^*, \theta_{cr}^*, \theta_{cl}^*)^T$, $\omega(t) = (\omega_u^T(t), \omega_y^T(t), \omega_r^T(t), \omega_l^T(t), y(t+n^*), \chi_{rm}(t+n^*), \chi_{lm}(t+n^*))^T$, and express $u(t)$ in (4.3) as

$$u(t) = \theta^{*T} \omega(t) + d_1(t+n^*). \quad (4.8)$$

With the estimate $\theta(t)$ of θ^* , we use (4.8) to define the estimation error

$$e(t) = \theta^T(t-1) \omega(t-n^*) - u(t-n^*)$$

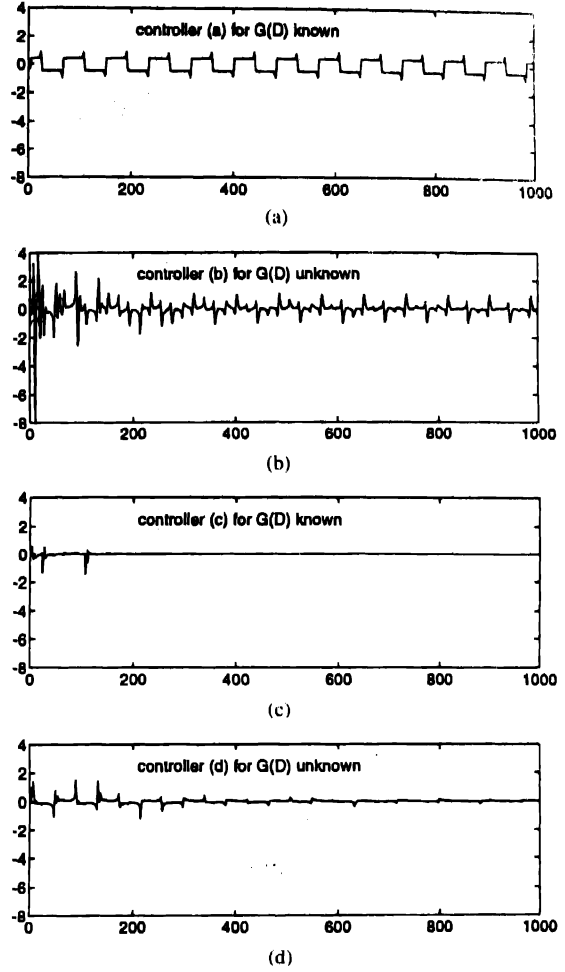

Fig. 4. Tracking errors of the second-order plant.

and use it to construct the update law for $\theta(t)$

$$\theta(t) = \theta(t-1) - \frac{\gamma \omega(t-n^*) e(t)}{1 + \omega^T(t-n^*) \omega(t-n^*)} + f(t) \quad (4.9)$$

where $0 < \gamma < 1$, and $f(t)$ is a design signal for robustness, e.g., $f(t) = -\sigma(\theta(t-1), \sigma_0) M \theta(t-1)$ with $0 < \sigma_0 < \frac{1-\gamma}{2}$. We also use projection to ensure that $\theta_m(t) \geq m_0$, $\theta_{cr}(t) \geq 0$, $\theta_{cl}(t) \leq 0$.

Our adaptive control schemes ensure the bounded-input bounded-output stability, as follows.

Theorem 4.1 [3]: All signals in the closed-loop system consisting of the plant (2.1), the controller (4.2) [or (4.7)], and the update law (4.5) [or (4.9)] are bounded.

Since we have not yet shown that the tracking error $e(t) = y(t) - y_m(t)$ converges to zero, the tracking performance of the adaptive systems will be illustrated by simulation results.

V. EXAMPLES

We now use examples to illustrate our adaptive designs and present simulation results which show that our adaptive control schemes lead to significant improvements of tracking performance.

Example 5.1: We consider $G(D) = \frac{1}{D+a_1}$ where $a_1 = 1.83$. The backlash $B(\cdot)$ with $m = 0.014$, $c_r = 22.5$, and $c_l = -24.7$ is unknown to the following controllers.

a) Fixed linear controller with no backlash inverse for $G(D)$ known:

$$u(t) = \theta_m^* \theta_z^* y(t) + \theta_m^* y_m(t+1), \quad \theta_m^* = \frac{500}{7}.$$

b) Adaptive linear controller with no backlash inverse for $G(D)$ unknown:

$$u(t) = \theta_y(t)y(t) + \theta_m(t)y_m(t+1).$$

c) Fixed linear controller with an adaptive backlash inverse (see Section IV-A):

$$u(t) = \theta_m(t)(\theta_y^* y(t) + y_m(t+1)) + \theta_{i,1}(t)(\theta_{i,1}^* \lambda_1(t) + \lambda_{1,m}(t+1)) + \theta_{i,2}(t)(\theta_{i,2}^* \lambda_2(t) + \lambda_{2,m}(t+1)).$$

d) Adaptive linear controller with an adaptive backlash inverse (see Section IV-B):

$$u(t) = \theta_y(t)y(t) + \theta_{i,1}(t)\lambda_1(t) + \theta_{i,2}(t)\lambda_2(t) + \theta_m(t)y_m(t+1) + \theta_{i,1}(t)\lambda_{1,m}(t+1) + \theta_{i,2}(t)\lambda_{2,m}(t+1).$$

The initial parameter estimates are $\theta_y(0) = \theta(0)\theta_m(0)$, $\theta_{i,1}(0) = \theta_{i,1}(0)$, $\theta_{i,2}(0) = \theta_{i,2}(0)$, $\theta(0) = 2.5$, $(\theta_m(0), \theta_{i,1}(0), \theta_{i,2}(0))^T = (70, 10, -10)^T$. Their matching values are $\theta_y^* = \theta^*\theta_m^*$, $\theta_{i,1}^* = \theta^*\theta_{i,1}^*$, $\theta_{i,2}^* = \theta^*\theta_{i,2}^*$, $\theta^* = 1.83$, $(\theta_m^*, \theta_{i,1}^*, \theta_{i,2}^*)^T = (\frac{500}{7}, 22.5, -24.7)^T$.

Example 5.2 We now consider the second-order $G(D) = \frac{1}{D^2 + a_2 D + a_1}$ with $a_2 = -1.3$, $a_1 = -0.3$. The backlash $B(\cdot)$ is the same as in Simulation 1. For this $G(D)$, we have the following.

Controller a):

$$u(t) = \theta_u^* u(t-1) + \theta_m^* \theta_{i,1}^{*-1} (y(t-1), y(t))^T + \theta_m^* y_m(t+2).$$

Controller b):

$$u(t) = \theta_u(t)u(t-1) + \theta_y^T(t)(y(t-1), y(t))^T + \theta_m(t)y_m(t+2).$$

Controller c):

$$u(t) = \theta_u^* u(t-1) + \theta_m(t)(\theta^{*-1} (y(t-1), y(t))^T + y_m(t+2)) + \theta_{i,1}(t)(\theta^{*-1} (\lambda_1(t-1), \lambda_1(t))^T + \lambda_{1,m}(t+2)) + \theta_{i,2}(t)(\theta^{*-1} (\lambda_2(t-1), \lambda_2(t))^T + \lambda_{2,m}(t+2)).$$

Controller d):

$$u(t) = \theta_u(t)u(t-1) + \theta_y^T(t)(y(t-1), y(t))^T + \theta_{i,1}^T(t)(\lambda_1(t-1), \lambda_1(t))^T + \theta_{i,2}^T(t)(\lambda_2(t-1), \lambda_2(t))^T + \theta_m(t)y_m(t+2) + \theta_{i,1}(t)\lambda_{1,m}(t+2) + \theta_{i,2}(t)\lambda_{2,m}(t+2).$$

The initial parameters are: $(\theta_u(0), \theta_y^T(0), \theta_m(0)) = (\theta_u^*, \theta^{*-1} \theta_m^*, \theta_m^*)$ for b); $(\theta_m(0), \theta_{i,1}(0), \theta_{i,2}(0)) = (80.5, 21, -21)$ for c); and $\theta_u(0) = -1.2$, $\theta_y(0) = 80.5\theta(0)$, $\theta_{i,1}(0) = 24.9\theta(0)$, $\theta_{i,2}(0) = -25.3\theta(0)$, $\theta(0) = (-0.3, -1.5)$, $(\theta_m(0), \theta_{i,1}(0), \theta_{i,2}(0)) = (80.5, 24.9, -25.3)$ for d). Their matching values are $\theta_u^* = -1.3$, $\theta^* = (-0.39, -1.99)^T$, $(\theta_m^*, \theta_{i,1}^*, \theta_{i,2}^*)^T = (\frac{500}{7}, 22.5, -24.7)^T$.

Typical responses of these control schemes to $y_m(t) = 15 \sin(0.0754t)$, $\gamma = 0.1$ and $\sigma_0 = 0.02$ are given in Fig. 3 for Example 5.1, and in Fig. 4 for Example 5.2. The simulation results show that the control schemes a) and b) which ignore backlash lead to large tracking errors $e(t) = y(t) - y_m(t)$. Our adaptive backlash inverse control schemes c) and d), which take into account the effects of the unknown backlash, lead to very small tracking errors.

VI. CONCLUSIONS

In this note we have developed two adaptive control schemes for systems with a backlash characteristic at the output. The first scheme is for systems with a known linear part and an unknown backlash. The second scheme is for a plant with both the linear part and backlash unknown. Our adaptive controller structures consist of a linear feedforward part and a linear-like feedback part which incorporates an adaptive backlash inverse. These controller structures result in linear parameterizations from which adaptive laws can be designed to update the controller parameters to ensure the closed-loop signal boundedness. Simulations results show that significantly improved system performance can be achieved by our adaptive control schemes.

Reciprocal Processes on a Tree—Modeling and Estimation Issues

Robert W. Dijkerman, Ravi R. Mazumdar, and Arunabha Bagchi

Abstract—Motivated by multiresolution decomposition methods such as the discrete wavelet transformation, we introduce reciprocal processes on truncated N -ary trees. We discuss the relationship between such processes and nearest neighbor models. We show that we can derive a recursive description of the process, and that all reciprocal processes on N -ary trees reduce to autoregressive processes in the case of zero-valued boundary values at the bottom of the tree, corresponding to truncation of the tree. We then study the smoothing equations associated with such models.

1 INTRODUCTION

Many multiresolution signals can be described on truncated λ -ary trees. For instance, the discrete wavelet coefficients of an n -dimensional signal can be identified with the nodes on a truncated 2-ary tree. We show an example of such an λ -ary tree in Fig. 1 for $\lambda = 2$. Each node on the tree, except for the sets of initial nodes in the top and the final nodes at the bottom of the tree, has one 'parent' node and λ 'offspring' nodes. Note that the simplest tree, where $\lambda = 1$, can be identified with an interval $[Z_1, Z_2]$ on the set of integers.

In [4], Dijkerman and Mazumdar showed that for a wide class of second-order processes, there is nonzero correlation between wavelet coefficients at all scales with strong decay in the correlation when coefficients are located further away from each other in the wavelet domain. We are therefore interested in the class of stochastic processes on truncated λ -ary trees, having a so-called reciprocal property. That is, the conditional probability of the value of a node on the tree, given the values of all other nodes in the tree, is only dependent on the values of the parent node and the offspring nodes. Basseville *et al.* [1] introduced autoregressive processes on λ -ary trees, where a node is conditionally dependent only on its parent node. Although causality is very well motivated in time, this is not really the case in the time-frequency domain. The conditional dependence of a time-frequency coefficient on the scale above it is not obvious.

Discrete time reciprocal processes on an interval were studied in detail by Levy *et al.* [8]. In this note, we closely follow their approach and extend their results for the case $\lambda > 1$. We like to mention as well the work by Greenc and Levy [5], who studied in detail several different solution procedures of the smoother problem for discrete time reciprocal processes, and the work by Levy, Fabre, and Benveniste [7], who studied independently a class of Markov random fields on trees. Their tree structure is slightly more complicated, but techniques and derivations similar to the work in this note are reported. They study a smoothing problem and discuss several iterative solution techniques. We refer to [3] for a more detailed version of this note.

II RECIPROCAL PROCESSES AND NEAREST NEIGHBOR MODELS ON TREES

In this section, we define the notion of reciprocity of processes on trees and establish the relation between such processes and so-called nearest neighbor models.

Let us denote by $t, t_{-1}, \dots, t_{-\lambda}$, respectively, the parent and the λ offspring nodes of the node t in the truncated tree T , where t does not belong to I , the set of root nodes, and I_f , the set of final nodes of T . For simplicity of notation, we now consider processes on binary trees only, although the case where $\lambda > 2$ is a straightforward extension of $\lambda = 2$. We shall say that a stochastic process $S(\cdot)$, defined on a truncated binary tree T , taking values in R^n , is reciprocal

if and only if

$$P[S(t) \leq s(t) | S(s) = s(s), \quad s \in T \setminus \{t\}] \\ = P[S(t) \leq s(t) | S(t) = s(t), S(t_{-1}) = s(t_{-1}), \dots, S(t_{-\lambda}) = s(t_{-\lambda})] \quad (1)$$

for $t \in \text{int}(I)$ (i.e., $t \in I, t \neq \{T, T_f\}$), where $P(\cdot)$ denotes the probability.

Assume we have a zero mean Gaussian reciprocal process $S(\cdot)$. We project $S(t), t \in \text{int}(T)$, on all other stochastic variables on the tree:

$$L[S(t) | S(s), \quad s \in T \setminus \{t\}] \\ = P_{-1}(t)S(t) + P_1(t)S(t_{-1}) + P_{-2}(t)S(t_{-2}) + \dots \quad (2)$$

The projection implies that the so-called residual process

$$d(t) = S(t) - (P_{-1}(t)S(t) + P_1(t)S(t_{-1}) + P_{-2}(t)S(t_{-2}) + \dots) \quad (3)$$

is orthogonal to $S(s), t \neq s$.

The relation (3) specifies a Nearest Neighbor Model (NNM) for $S(\cdot)$, where the driving noise is the residual process $d(\cdot)$, having the following correlation structure:

$$\begin{cases} D(t) - \Gamma[d(t)d(t)^T] = \sigma_{d(t)} \\ \Gamma[d(t)d(t_{-1})^T] = -\sigma_{d(t)}^T P_{-1}^T(t) - P_{-1}(t)\sigma_{d(t_{-1})} \\ L[d(t)d(s)^T] = 0, \quad s \neq t, t_{-1}, \dots, t_{-\lambda} \end{cases} \quad (4)$$

where $\sigma_{d(t)}$ is the covariance matrix of the random vector $d(t)$. The correlation structure of $d(t)$ tells us that it is a moving average process (defined on T). We shall discuss this later in detail. Property (4) shows that the projection matrices P_{-1}, \dots , and the noise variance $D(\cdot)$ cannot be specified independently of each other. Standard Gaussian estimation theory implies that the existence and unicity of P_{-1}, \dots is guaranteed if the covariance matrix of the vector $[S(t)S(t_{-1})S(t_{-2})]$ is positive definite for all $t \in \text{int}(T)$. The model described by (3) specifies the process $S(\cdot)$ on $\text{int}(I)$. The residual process $d(t), t \in \text{int}(I)$, is uncorrelated with all $S(s), s \in \{T, I_f\}$. Therefore, we choose independently of the residual process, a vector b of Dirichlet boundary values (corresponding to all boundary nodes) having an arbitrary covariance matrix, which we shall denote B .

The truncation of a tree implicitly implies that the values of the nodes lower in the tree are zero or independent of the truncated tree. Therefore, as an extra assumption, we could demand the following autoregressive property to hold for $t \in I_f$:

$$d(t) = S(t) - P_{-1}(t)S(t_{-1}) \quad (5)$$

with $d(t)$ orthogonal to $S(s)$ for $t \neq s$. That is, the final nodes have an autoregressive property. This is equivalent to the assumption of a reciprocal process on an extended tree T having a layer of zero-valued final nodes.

It can be verified following [8] that the model (3) with the specified noise structure and the Dirichlet boundary conditions is well defined. There is a unique solution if the covariance matrix R of the vector of interior nodes values is positive definite.

We show now that an NNM, as in (3), with noise structure as in (4) and the Dirichlet boundary conditions implies necessary reciprocity. Let us assume we have the following Nearest Neighbor Model for $t \in \text{int}(T)$:

$$M_0(t)S(t) - M_{-1}(t)S(t_{-1}) - M_1(t)S(t_{-2}) - \dots = \epsilon(t) \quad (6)$$

such that $M_{-i}(t)^T = M_i(t)$ for $i = 1, 2, \dots$, being square matrices of size n . We assume a Gaussian distributed vector of root and final nodes values b having covariance matrix B . The input noise $\epsilon(t)$ is

a Gaussian process uncorrelated with the boundary process b and has the following correlation structure:

$$\begin{cases} E[e(t)e(t)'] = M_0(t) \\ E[e(t)e(t_{\gamma_1})'] = -M_1(t) \\ E[e(t)e(s)'] = 0 \quad s \neq t, \hat{t}, t_{\gamma_1}, t_{\gamma_2}. \end{cases} \quad (7)$$

Furthermore, it is assumed that the system is well posed, i.e., it admits a unique solution. The relation between the original NNM and this model is easily established. Assume that $S(\cdot)$ is a reciprocal process with driving noise process $d(\cdot)$, such that $D(t)$ is invertible for all $t \in \text{int}(T)$. The multiplication of (3) by $D(t)^{-1}$ and the definitions $M_0(t) = D(t)^{-1}$, $M_-(t) = D(t)^{-1}P_-(t)$, $M_i(t) = D(t)^{-1}P_i(t)$, and $e(t) = D(t)^{-1}d(t)$ results in (6). We can now easily verify that $M_-(t_{\gamma_1})' = M_1(t)$ and that (7) holds.
